ORGANIZATIONAL COMMITTEE

Nenad Miloradović, PhD Eng, Acting Assistant Minister of Defense for Materiel Resources, ***President of the Organizational Committee***
Major General **Slavko Rakić**, PhD Eng, Head of the Department for Defense Technologies
colonel **Ivan Pokrajac**, PhD Eng, Director of the Military Technical Institute
Brigadier General **Stanisav Mijailović**, Head of the Department for Planning and Development - GS SAF
colonel **Dejan Stojković**, PhD Eng, Head of the Department for Strategic Planning
colonel **Vinko Žnidaršič**, PhD Eng, Department for Strategic Planning
Prof. **Boban Đorović**, PhD Eng, rector of the University of Defense
Major General **Željko Furundžić**, Head of the Military Academy
colonel **Zlatko Bogosavljević**, Head of the Department for International Military Cooperation
colonel **Saša Veselinović**, PhD Eng, Director of the Technical Test Center
colonel **Boriša Jovanović**, PhD Eng, Applied Mathematics and Electronics Center – GS SAF
colonel **Aleksandar Mitić**, BSc Eng, Director (authorized by the Minister of Defense) od the Directorate for Standardization, Codification and Metrology
lt col **Ljubo Kurćubić**, Director of the Military Quality Control
colonel **Saša Bakrač**, Phd Eng, Acting Director of the Military Geographical Institute
Prof. **Dragan Stanar**, PhD Eng., Strategic research Institute - MoD RS
Ana Marinković, Assistant Minister, Sector for Innovations, transfer of Technologies and Technological development, Ministry of Science, Technological Development and Innovations
Vladimir Popović, PhD Eng, Dean of the Faculty of Mechanical Engineering, University of Belgrade
Prof. **Zoran Čiča**, PhD Eng, Acting Dean of the Faculty of Electrical Engineering, University of Belgrade
Prof. **Mirjana Kijevčanin**, PhD Eng, Dean of the Faculty of Technology and Metallurgy, University of Belgrade
Boris Dumnić, PhD Eng, dean of the Faculty of Technical Sciences, University of Novi Sad
Prof. **Slobodan Savić**, PhD Eng, Dean of the Faculty of Engineering Sciences, University of Kragujevac
Prof. **Ivan Milićević**, PhD Eng, Acting Dean of the Faculty of Technical Sciences, Čačak, University of Kragujevac
Prof. **Goran Janevski**, PhD Eng, Dean of the Faculty of Mechanical Engineering, University of Niš
Prof. **Vladimir Ćirić**, PhD Eng, Dean of the Faculty of Electronic Engineering, University of Niš
Vladimir Kostić, BSc Eng, Director, IRITEL, Belgrade
Vladimir Cizelj, PhD Eng., Vlatacom Institute, Belgrade
Nikola Tomašević, PhD Eng., Director, Mihailo Pupin Institute
Jugoslav Petković, Director, "Yugoimport – SDPR", Belgrade
Jovanka Andrić, Director, "Krušik", Valjevo
Zoran Stefanović, Director, "Sloboda", Čačak
Predrag Ilić, Director "Milan Blagojević – namenska A.D.", Lučani
Dobrosav Andrić, Director, "Prvi partizan", Užice
Stanoje Biočanin, Director, "Prva Iskra-namenska", Barič
Saša Milošević, Director, "Zastava oružje", Kragujevac
Andrijana Jovanović, Director, "Prva Petoletka – Namenska", Trstenik
Stefan Đurić, Director, "Zastava TERVO", Kragujevac
Časlav Kljajić, Director, "PPT-TMO A.D.", Trstenik

SCIENTIFIC COMMITTEE

colonel **Aleksandar Kari**, PhD Eng, Military Technical Institute, Belgrade, Serbia, ***President of the Scientific Committee***
Prof. **Ljubica Radović**, PhD Eng, Military

Technical Institute, Belgrade, Serbia
colonel **Bojan Pavković,** PhD Eng, Research Associate, Military Technical Institute, Belgrade, Serbia,
colonel **Dejan Ivković**, PhD Eng, Research Associate, Military Technical Institute, Belgrade, Serbia,
Prof. **Taek Lyul Song**, PhD Eng, Hanyang University, South Korea
Evgeny V. Sudov, PhD Eng, R&D Applied Logistic Centre, Moscow, Russia
Stevan Berber, PhD Eng, Auckland University, New Zealand
Srećko Stopić, PhD Eng, RWTH University, Aachen, Germany
Zbysek Korecki, PhD Eng, University of Defence, Brno, Czech Republic
Radi Ganev, PhD Eng, University "Lyuben Karavelov", Sofia, Bulgaria
Prof. **Constanca Rigueiro**, PhD Eng, Polytechnic Institute Castelo Branco, Portugal
Prof. **Tomaž Vuherer**, PhD Eng, Faculty of Mechanical Engineering, Maribor, Slovenia
Prof. **Biljana Marković**, PhD Eng, Faculty of Mechanical Engineering, East Sarajevo, Republic of Srpska (Bosnia and Herzegovina)
Prof. **Milan Tica**, PhD Eng, Faculty of Mechanical Engineering, University of Banja Luka, Republic of Srpska (Bosnia and Herzegovina)
Prof. **Dženana Gačo**, PhD Eng, University of Bihać, Bosnia and Herzegovina
Prof. **Mersida Manjgo**, PhD Eng, Faculty of Mechanical Engineering Mostar, Bosnia and Herzegovina
Prof. **Kemal Delijić**, PhD Eng, Faculty of Metallurgy and Technology, Podgorica, Montenegro
colonel **Predrag Rakonjac**, PhD Eng, University of Defense, Belgrade, Serbia
colonel Prof. **Dragan Trifković**, PhD Eng, Military Academy, Belgrade, Serbia
colonel Prof. **Slobodan Simić**, PhD Eng, Military Academy, Belgrade, Serbia
colonel Prof. **Damir Jerković**, PhD Eng, Military Academy, Belgrade, Serbia
colonel **Branimir Krstić**, PhD Eng, Military Academy, Belgrade, Serbia
colonel Prof. **Boban Pavlović**, PhD Eng, Military Academy, Belgrade, Serbia
colonel **Boban Bondžulić**, PhD Eng, Military Academy, Belgrade, Serbia
colonel **Milan Mihajlović**, PhD Eng, Military Academy, Belgrade, Serbia
colonel Prof. **Milenko Andrić**, PhD Eng, Military Academy, Belgrade, Serbia
colonel **Dimitrije Bujaković**, PhD Eng, Military Academy, Belgrade, Serbia
colonel Prof. **Zoran Bajić**, PhD Eng, Military Academy, Belgrade, Serbia
colonel Prof **Radovan Karkalić**, PhD Eng, Military Academy, Belgrade, Serbia
lieutenant colonel Prof. **Mihael Bučko**, PhD Eng, Military Academy, Belgrade, Serbia
colonel **Nenad Stefanović**, PhD Eng, Applied Mathematics and Electronics Center - GS SAF, Belgrade, Serbia
colonel **Saša Bakrač**, PhD Eng, Military Geographical Institute, Belgrade, Serbia
Jasmina Stevanović, PhD Eng, Institute of Chemistry, Technology and Metallurgy, Belgrade, Serbia
Srećko Manasijević, PhD Eng, Principal Research Fellow, Lola Institute, Belgrade, Serbia
Dragana Perić, PhD Eng, Vlatacom Institute, Belgrade, Serbia
Srećko Nijemčević, PhD Eng, Vlatacom Institute, Belgrade, Serbia
Ivan Vulić, PhD Eng, Vlatacom Institute, Belgrade, Serbia
Miroslav Sokić, PhD Eng, Principal Research Fellow, Institute for Technology of Nuclear and Other Raw Materials, Belgrade, Serbia
Prof. **Stevica Graovac**, PhD Eng, Mihailo Pupin Institute, Belgrade, Serbia
Nikola Zogović, PhD Eng, Principal Research Fellow**,** Mihailo Pupin Institute, Belgrade, Serbia
Violeta Nikolić, PhD Eng, Senior Research Assistant, Vinča Institute of Nuclear Sciences, Belgrade, Serbia
Ivana Perović, PhD Eng, Senior Research Assistant, Vinča Institute of Nuclear Sciences, Belgrade, Serbia
Nataša Lazarević, PhD Eng, Nuclear Facilities of Serbia, Belgrade, Serbia
Prof. **Vladimir Mladenović**, PhD Eng, Faculty of Engineering Sciences - Čačak, University of Kragujevac, Serbia
Dušan Arsić, PhD Eng, Faculty of Engineering Sciences, University of Kragujevac, Serbia
Prof. **Vladimir Arsoski**, PhD Eng, Faculty of Electrical Engineering, University of Belgrade, Serbia

Prof. **Dragan Milčić**, PhD Eng, Faculty of Mechanical Engineering, University of Niš, Serbia
Prof. **Dragan Šešlija**, PhD Eng, Faculty of Technical Sciences, University of Novi Sad, Serbia
Prof. **Predrag Elek**, PhD Eng, Faculty of Mechanical Engineering, University of Belgrade, Serbia
Prof. **Aleksandar Simonović**, PhD Eng, Faculty of Mechanical Engineering, University of Belgrade, Serbia
Prof. **Jelena Svorcan**, PhD Eng, Faculty of Mechanical Engineering, University of Belgrade, Serbia
Prof. **Ivan Kostić**, PhD Eng, Faculty of Mechanical Engineering, University of Belgrade, Serbia
Prof. **Aleksandar Marinković**, PhD Eng, Faculty of Technology and Metallurgy, University of Belgrade, Serbia
Prof. **Dragomir Glišić**, PhD Eng, Faculty of Technology and Metallurgy, University of Belgrade, Serbia
Marija Samardžić, PhD Eng, Military Technical Institute, Belgrade, Serbia
Jelena Gržetić, PhD Eng, Military Technical Institute, Belgrade, Serbia
Prof. **Maja Vitorović-Todorović**, PhD Eng, Military Technical Institute, Belgrade, Serbia
Miloš Pavić, PhD Eng, Principal Research Fellow, Military Technical Institute, Belgrade, Serbia
lieutenant colonel **Saša Brzić**, PhD Eng, Military Technical Institute, Belgrade, Serbia
Danica Bajić, PhD Eng, Military Technical Institute, Belgrade, Serbia
colonel **Rade Pavlović**, PhD Eng, Military Technical Institute, Belgrade, Serbia
lieutenant colonel **Boban Sazdić-Jotić**, PhD Eng, Principal Research Fellow, Military Technical Institute, Belgrade, Serbia
Miodrag Milenković-Babić, PhD Eng, Principal Research Fellow, Military Technical Institute, Belgrade, Serbia
Srđa Perković, PhD Eng, Principal Research Fellow, Military Technical Institute, Belgrade, Serbia

PREFACE

Military Technical Institute, the first and the largest military scientific-research institution in the Republic of Serbia with over 77 years long tradition, has been traditionally organizing the OTEH scientific conference, devoted to defense technologies. The Conference is supported by the Ministry of Defense and it takes place every second year.

Its aim is to gather scientists and engineers, researchers and designers, manufactures and university professors in order to exchange ideas and to develop new relationships.

The 12th International Scientific Conference OTEH 2026 is scheduled as follows: lecture on the occasion of "Miomir Vukobratović", given by Aleksandar Rodić, PhD Eng, and two plenary lectures: given by representatives of DRS RADA Technologies, and presented by Velibor Ilić, PhD Eng "Artificial Intelligence from Perception to Autonomous Action: Applications, Opportunities and Challenges" .

The papers which will be presented at the Conference have been classified into the following topics:
− Aerodynamics and Flight Dynamics
− Aircraft
− Weapon Systems and Combat Vehicles
− Ammunition and Energetic Materials
− Integrated Sensor Systems and Robotic Systems
− Telecommunication and Information Systems
− Materials and Technologies
− Quality, Standardization, Metrology, Maintenance and Exploitation.

The Proceedings contain 160 reviewed papers which have been submitted by the authors from 13 different countries. I would also like to emphasize that we have 15 papers with authors from abroad. The quality of papers accepted for publication achieved very high standard. I expect stimulated discussion on many topics that will be presented online, during two days of the Conference.

On behalf of the organizer I would like to thank all the authors and participants from abroad, as well as from Serbia, for their contribution and efforts which made this Conference possible and successful.

I would also like to thank the Ministry of Science, Technological Development and Innovations of the Republic of Serbia for its financial support.

Finally, dear guests and participants of the Conference, I would like to wish you a pleasant and successful work during the Conference. I am looking forward to see you again at the Conference. All the best and stay healthy.

Serbia, Tara, October, 2026

Col. Aleksandar Kari PhD Eng
President of the Scientific Committee
OTEH 2026

TABLE OF CONTENTS

1. SECTION : AERODYNAMICS AND FLIGHT DYNAMICS - AFD

2 **COMPARATIVE STUDY OF HYBRID DOLPHIN AND OTHER BIONIC AIRFOILS FOR DEFENSE APPLICATIONS,** Zorana Z. Dančuo, Ivan A. Kostić, Olivera P. Kostić, Aleksandar Č. Bengin, Goran S. Vorotović
10.5937/OTEH26001B

8 **INFLUENCE OF UNDERWING PAYLOAD ON THE FLIGHT PERFORMANCE OF A TACTICAL UAV,** Branislav Ostojić, Miodrag Milenković-Babić, Aljoša Ljuboja, Ognjen Peković
10.5937/OTEH26002O

14 **SYSTEMATIC MODELING AND EXPERIMENTAL EVALUATION OF BLDC MOTOR-PROPELLER SYSTEMS IN MULTICOPTERS,** Aljoša Ljuboja, Milenko Trifković, Branislav Ostojić, Toni Ivanov
10.5937/OTEH26003L

21 **SIMULATING SHOCK-WAVE/BOUNDARY-LAYER INTERACTIONS,** Jelena Svorcan, Dragoljub Tanović, Milica Ivanović
10.5937/OTEH26004S

27 **HIGH-PRESSURE JET SUPPLY SYSTEM FOR POWERED WIND TUNNEL MODELS: CALIBRATION AND PERFORMANCE,** Biljana Ilić, Marija Samardžić, Božidar Simović, Isidora Stanković, Ognjen Babić, Goran Ocokoljić
10.5937/OTEH26005I

33 **COMPARISON OF MISSILE AERODYNAMIC DATA OBTAINED IN WIND TUNNEL TESTS USING TWO INTERNAL STRAIN GAUGE BALANCES,** Marija Samardžić, Biljana Ilić, Isidora Stanković, Božidar Simović, Ognjen Babić, Goran Ocokoljić
10.5937/OTEH26006S

39 **SIDE JET INTERACTION WITH SUBSONIC, TRANSONIC AND SUPERSONIC CROSSFLOW: SURFACE PRESSURE DISTRIBUTION,** Božidar Simović, Biljana Ilić, Marija Samardžić, Isidora Stanković, Ognjen Babić, Goran Ocokoljić
10.5937/OTEH26007S

2. SECTION : AIRCRAFT - A

44 **SM2-M UAV AND Q GROUND CONTROL: SYNERGY OF AUTONOMOUS GUIDANCE AND REAL-TIME MISSION MONITORING IN MODERN MILITARY OPERATIONS,** Miloš Ugrenović
10.5937/OTEH26008U

48 **AIRCRAFT LIFE EXTENSION THROUGH INTEGRATED STRUCTURAL ASSESSMENT AND SYSTEM REVALIDATION,** Marina Ostojić, Tamara Nikolić, Marko Prošić
10.5937/OTEH26009P

54 **DRONE MILITARY TESTING,** Stevan Jovičić, Danilo Vukosavljević, Nikola Zdravković, Jelena Šobot
10.5937/OTEH26010J

59 **CRITICAL LOAD CALCULATION FOR SOME KIND OF NONUNIFORM STRUTS,** Bogdan S. Bogdanović, Tonko A. Mihovilović
10.5937/OTEH26011B

65 **PLATE SPRING-BASED NEGATIVE STIFFNESS ROTARY MECHANISM FOR PASSIVE ENERGY BALANCING OF MORPHING WINGS,** Mašan Vučinić, Toni Ivanov, Jelena Svorcan
10.5937/OTEH26012V

72 **DESIGN AND VALIDATION OF TOPOLOGY-OPTIMIZED 3D-PRINTED QUADCOPTER ARMS,** Milan Z. Rakić, Toni D. Ivanov
10.5937/OTEH26013R

77 **PROPELLER-MOTOR MATCHING FOR MINI-UAV: THRUST AND EFFICIENCY ESTIMATION BY USING THE LY-MICRO-MAX TEST STAND,** Miodrag Milenković-Babić, Branislav Ostojić, Aljoša Ljuboja, Mario Silvagni
10.5937/OTEH26014M

82 **ESSENTIAL TECHNICAL KNOWLEDGE AND SKILLS FOR FUTURE MILITARY AND CIVIL PILOTS IN THE REPUBLIC OF SERBIA,** Slaviša Vlačić, Aleksandar Knežević, Nebojša Radojković
10.5937/OTEH26015V

3. SECTION : WEAPON SYSTEMS AND COMBAT VEHICLES – WSCV

89 **A BALLISTIC MODULE ARCHITECTURE FOR MORTAR FIRE CONTROL SYSTEMS,** Miloš Marković, Andrija Ostojić, Dejan Jevtić
10.5937/OTEH26016M

96 **EXPERIMENTAL STUDY OF FRACTURED PROPELLANT INFLUENCE ON THE IMPULSE ROCKET MOTOR SAFETY,** Katarina Nestorović, Saša Živković, Marina Simović – Pavlović, Veselin Živanović, Jelena Mojsilović, Darko Janković
10.5937/OTEH26017N

101 **INTEGRATED TECHNICAL MODEL OF DETECTION AND RISK MANAGEMENT OF EXPLOSIVE REMNANTS OF WAR - CASE STUDU SMEDEREVO FORTRESS,** Anita Klikovac, Sanela Veljković, Marina Dabetić
10.5937/OTEH26018K

109 **COMPARATIVE ANALYSIS OF THEORETICAL AND EXPERIMENTAL MUZZLE VELOCITIES FOR THE EVALUATION OF POSSIBLE BARREL WEAR FOR THREE 30 mm BARRELS,** Vuk Garčević, Andrija Veljović, Igor Radisavljević
10.5937/OTEH26019G

114 **PERFORMANCE ANALYSIS OF SPECIAL SUBSONIC SMALL CALIBER WEAPONS FOR URBAN CONDITIONS,** Nebojša Hristov, Damir Jerković, Aleksa Aničić, Miljko Pavlović, Igor Epler
10.5937/OTEH26020H

121 **PRACTICAL APPROACHES TO QUALITY TESTING OF PIONEER MACHINES,** Dragan Stojadinović, Aleksandar Đurić, Snežana Jovanović, Miroslav Jovanović, Sreten Perić
10.5937/OTEH26021S

127 **IMPLEMENTATION AND EXPERIMENTAL VERIFICATION OF ENVIRONMENTAL SAFETY SENSOR DEVICE FOR FUZES IN AERIAL BOMBS,** Slobodan Pelemiš, Nikola Latinović, Mladen Veinović
10.5937/OTEH26022P

132 **MONTE CARLO BASED PRECISION ANALYSIS OF A LONG-RANGE ARTILLERY PROJECTILE,** Damir D. Jerković, Nebojša Hristov, Aleksandra Obradović, Nikola Mačar, Branislav Nikolić
10.5937/OTEH26023J

138 **SHEAR STRESS-BASED FORCE MODELING FOR M-84 TRACKED VEHICLE ON DEFORMABLE TERRAIN,** Momir Drakulić, Aleksandar Đurić
10.5937/OTEH26024D

144 **A NEW METHOD FOR INTERPOLATION OF ROCKET MOTOR THRUST - TIME CURVE FOR ARBITRARY PROPELLANT TEMPERATURE,** Miodrag Ćurčin, Goran Marjanović, Srđan Stojković, Bojan Tanaskovski
10.5937/OTEH26025C

152 **ANALYSIS OF RECOIL RESISTANCE FORCE BEHAVIOR AS A FUNCTION OF VARIATIONS IN INFLUENTIAL PARAMETERS,** Milan Simonović, Marko Simonović, Nikola Radovanović, Andrija Veljović, Ana Simonović, Sanja Milinković
10.5937/OTEH26026S

159 **DYNAMIC ANALYSIS OF 30 mm AUTOMATIC CANNON OPERATING MECHANISM,** Nikola Radovanović, Aleksandar Kari, Milan Simonović, Marko Simonović
10.5937/OTEH26027R

165 **INTERNAL BALLISTIC DESIGN OF A 30 x 173 mm AUTOMATIC CANNON USING THE ANALYTIC METHOD,** Marija Milovanović, Nikola Radovanović, Stefan Jovanović
10.5937/OTEH26028M

173 **TOOTH ROOT LOAD-CARRYING CAPACITY OF SPUR GEARS UNDER STANDARD SINGLE AND DOUBLE MESH CONDITIONS,** Vuk Milanović, Predrag Dobratić, Miloš Sedak, Dragan Trifković
10.5937/OTEH26029M

179 **SURROGATE-ASSISTED OPTIMIZATION OF PLANETARY GEARBOXES USING GENETIC ALGORITHM AND DEEP NEURAL NETWORK EFFICIENCY MODELS,** Miloš Sedak, Maja Rosić
10.5937/OTEH26030R

185 **DESIGN, MANUFACTURING AND TESTING OF A FUNCTIONAL MODEL OF A DEVICE WITH A SECURING EXECUTIVE MECHANISM FOR MULTIPLE REMOTE ACTIVATION OF PYROTECHNIC ELEMENTS ON UNMANNED PLATFORMS,** Slobodan Bosiljčić, Miroslav Gluvačević, Goran Marjanović, Jelena Petković Cvetković, Bojan Tanaskovski
10.5937/OTEH26031B

190 **ANALYSIS OF OSCILLATIONS OF A MOBILE PLATFORM UNDER THE ACTION OF FIRING FORCE,** Marko Simonović, Milan Simonović, Pera Srbul, Ana Simonović, Vuk Garčević
10.5937/OTEH26032S

197 **CHALLENGES OF DRONE-DELIVERED EXPLOSIVE ORDNANCE:TECHNICAL, OPERATIONAL, AND LEGAL-ETHICAL CONSIDERATIONS,** Vinko Žnidaršič, Stevan M. Mušicki, Nenad V. Kovačević
10.5937/OTEH26033Z

201 **BIASED PURSUIT GUIDANCE LAW FOR REAR-SECTOR TARGET INTERCEPTION,** Milos Pavić, Saša Antonović, Ivan Marić
10.5937/OTEH26034P

204 **CALIBRATION OF DIAL INDICATORS,** Dragan Lazić, Žaklina Čutović, Miloš Jovanović
10.5937/OTEH26035L

209 **TOTAL QUALITY INTEGRATED IN NEW AMMUNITION PRODUCTS IN AD "PRVI PARTIZAN" (ACCORDING TO ISO/TR 14062 - 2002),** Svetolik Spasenić
10.5937/OTEH26036S

213 **OPTIMIZATION OF CHASSIS GEOMETRY FOR INCREASING THE PRODUCTION CAPACITY OF 4X4 VEHICLE PLATFORM,** Mihajlo Vasiljević, Bogdan Živković, Jovanka Lukić
10.5937/OTEH26037V

220 **INTERNAL BALLISTICS-BASED DESIGN AND STRUCTURAL ANALYSIS OF A 30×165 mm CANNON BARREL,** Mihailo Bojković, Vladimir Dunić, Vladimir Milovanović
10.5937/OTEH26038B

226 **CONCEPTUAL ANALYSIS OF A RADIAL HYDRAULIC MOTOR DRIVE FOR HEAVY DUTY MILITARY VEHICLES,** Mihailo Đuković, Saša Milojević, Slobodan Savić, Milan Bukvić, Horia Abaitancei, Blaža Stojanović
10.5937/OTEH26039D

233 **PREDICTION ALGORITHM FOR THE IMPACT POINT PROJECTILE TRAJECTORY USED FOR DETERMINING CORRECTIVE SHOOTING PROCEDURE ELEMENTS,** Dragoslav R. Petrović
10.5937/OTEH26040P

4. SECTION : AMMUNITION AND ENERGETIC MATERIALS - AEM

240 **STABILITY EVALUATION OF MULTI-COMPONENT PBX UNDER VARYING CLIMATIC CONDITIONS,** Mirjana Krstović, Teodora Stančić, Vesna Petrović, Katarina Nestorović, Jelena Šultans, Danica Bajić
10.5937/OTEH26041K

247 **EXPERIMENTAL AND NUMERICAL STUDY OF PRECURSOR SHAPED CHARGE PERFORMANCE,** Predrag Elek, Biljana Jovanović, Dragana Jelić, Danijela Obradović, Danica Jelić, Dušan Blagojević
10.5937/OTEH26042E

254 **ANALYSIS OF ENERGY DISSIPATION DURING THE IMPACT OF AIR WEAPON PROJECTILES INTO GRANULAR MATERIALS – COMPARISON OF ANALYTICAL MODEL AND EXPERIMENTAL RESULTS,** Darko Jankovic, Marina Simovic Pavlovic, Nada Citakovic, Lana Milosavljevic, Ljubisa Tomic, Martin Ocsenhofer, Darko Vasiljevic
10.5937/OTEH26043J

259 **SAPONIFICATION AS AN ENABLING STEP FOR FAST GC DETERMINATION OF STABILIZERS IN SMOKELESS POWDERS,** Teodora Stančić, Nada Marinković, Suzana Kovačević, Mirjana Milekić, Vesna Petrović, Mirjana Krstović
10.5937/OTEH26044S

265 **ANALYTICAL DETERMINATION OF MEAN BALLISTIC PRESSURE FROM THE ENERGY BALANCE OF PROPELLANT COMBUSTION PRODUCTS WITH EXPERIMENTAL VALIDATION,** Slobodan Orašanin, Miodrag Lisov, Aleksa Aničić, Miloš Jončić, Miljko Pavlović
10.5937/OTEH26045O

271 **DEFINITION OF A METHOD FOR VERIFYING THE QUALITATIVE CHARACTERISTICS OF ELECTRIC IGNITER HEADS,** Jelena Petković-Cvetković, Branka Džunić, Slobodan Bosiljčić, Goran Marjanović, Dragan Knežević, Jelena Mojsilović, Marko Radisavljević
10.5937/OTEH26046P

277 **MODIFIED PBXN-5 EXPLOSIVE: EFFECT OF IF-WS2 NANOPARTICLES ON PHLEGMATIZATION OF HMX,** Danica Bajić, Mirjana Krstović, Ivan Dimitrijević, Mladen Timotijević, Ognjen Rajković, Jelena Marinković
10.5937/OTEH26047B

283 **APPLICATION OF A CASCADE OF NEURAL NETWORKS FOR MODELING AND PREDICTING DETONATION CHARACTERISTICS OF HIGH-ENERGY MATERIALS,** V.S. Abrukov, D.A. Anufrieva, S.S. Kuzmin, D.A. Saperov, I.N. Ulyanov
10.5937/OTEH26048A

287 **NUMERICAL–EXPERIMENTAL ANALYSIS OF EXPLOSIVELY FORMED PROJECTILE PENETRATION CHARACTERISTICS,** Andjela Ivković, Sasa Savić, Jelena Marinković, Mladen Timotijević
10.5937/OTEH26049I

292 **DETERMINING LAW COMBUSTION PARAMETERS AND THEIR PRESSURE/COMPOSITION DEPENDENCES FOR HIGH-ENERGY MATERIALS VIA NEURAL NETWORK SEQUENTIAL APPROXIMATIONS,** D.A. Anufrieva, V.S. Abrukov, Vladica Bozic, D.A. Sapyerov, I.N. Ulyanov
10.5937/OTEH26050A

296 **INFLUENCE OF GROOVE GEOMETRY ON THE INTERNAL BALLISTICS OF A MONOLITHIC .308 CALIBER BULLET,** Igor Babić, Mihailo Erčević
10.5937/OTEH26160B

303 **TBX FORMULATIONS WITH ALTERNATIVE METAL FUELS, HIGH EXPLOSIVES AND OXIDIZERS,** Thomas M. Klapötke, Danica Bajić, Stanisław Cudziło, Muhamed Sućeska
10.5937/OTEH26051K

5. SECTION : INTEGRATED SENSOR SYSTEMS AND ROBOTIC SYSTEMS – ISSRS

308 **SIMULATION OF COMPLIANT ROBOTIC SYSTEM WITH A PARALLEL MECHANISM AND SCISSOR LIFT**, Nemanja Tanasković, Damir Krklješ, Mihailo Lazarević
10.5937/OTEH26052T

315 **REAL-TIME THERMAL IMAGE SYNTHESIS IN UNITY 3D VIA EMPIRICAL INFRARED ADAPTATION OF LIGHT SIMULATION MODELS**, Bojan Šmidling, Stefan Stojkov
10.5937/OTEH26053S

321 **IMPROVING DRONE DETECTION USING ACOUSTIC METHODS AND STATISTICAL FILTERING,** Miodrag Vračar, Stevo Vračar, Radiana Brusin
10.5937/OTEH26054V

327 **ADVANCED HYDROGEN DETECTION MATERIALS FOR CBRN APPLICATIONS: FROM METAL–ORGANIC FRAMEWORKS TO REAL-TIME THREAT ASSESSMENT,** Ivana Perović, Snežana Brković, Mina Seović, Stefan Mitrović, Milena Pijović Radovanović, Jelena Georgijević, Petar Laušević
10.5937/OTEH26055P

333 **INTERACTING MULTIPLE MODEL–BASED ESTIMATION OF AIRSPEED AND ALTITUDE FROM PITOT–STATIC MEASUREMENTS,** Vlada Sokolović, Momir Stanković, Goran Marković

10.5937/OTEH26056S

339 **SENSOR FUSION FOR DRONE CLASSIFICATION IN RADIO FREQUENCY DOMAIN,** Darko Mikanović, Boban Sazdić-Jotić, Vasilija Joksimović

10.5937/OTEH26057M

345 **FEDERATED LEARNING FOR AUTONOMOUS DISTRIBUTED GNSS JAMMING SWARMING STATIONS,** Boban Sazdić-Jotić, Dragana Bojić, Radiana Brusin

10.5937/OTEH26058S

352 **A COMPARATIVE EVALUATION OF SPECTROGRAM- AND BISPECTRUM-BASED TRANSFER LEARNING FOR DRONE AUDIO CLASSIFICATION,** Sara Milanović, Miodrag Vračar, Ivan Pokrajac

10.5937/OTEH26059M

358 **IMPACT OF JPEG COMPRESSION ON YOLO-BASED ROAD SCENE OBJECT DETECTION IN VISIBLE AND THERMAL IMAGES,** Boban Pavlović, Boban Bondžulić, Dimitrije Bujaković, Momir Stanković

10.5937/OTEH26060P

365 **AUTONOMOUS ROBOTIC SYSTEMS FOR 3D MOBILE MAPPING IN UNDERGROUND MINING,** Nenad Vušović, Milica Vlahović

10.5937/OTEH26061V

371 **EDGE AI DRONE CLASSIFICATION IN RADIO FREQUENCY DOMAIN,** Vasilija Joksimović, Darko Mikanović, Radiana Brusin, Dragana Bojić

10.5937/OTEH26062J

Abstract: *This paper presents a comparative study of hybrid dolphin and other bionic airfoils aimed at improving aerodynamic performance through a combined computational and experimental approach. Contemporary designs inspired by avian and marine species employ distinctive geometries and surface textures to enhance lift, reduce drag, and increase the lift-to-drag (L/D) ratio. A systematic comparative analysis of hybrid dolphin airfoils was conducted, evaluating their performance relative to established bionic optimization strategies reported in the literature. Aerodynamic characteristics were assessed using computational optimization techniques, including genetic algorithms and multi-island genetic algorithms, in conjunction with CFD simulations and experimental investigations across a range of Reynolds numbers. The obtained results demonstrate that optimized configurations consistently outperform baseline models, showing notable lift enhancement and drag reduction, leading to significant improvements in L/D ratio. These findings are consistent with literature reports indicating lift increases of up to 28.4%, drag reductions of up to 18.09%, and L/D enhancements of up to 323% under specific flow conditions. Such dramatic L/D improvements are associated with shark denticle-inspired surface structures at low angles of attack (below 4°) and Reynolds numbers of the order of* 4×10^4*. The comparative results confirm that bionic airfoil optimization provides measurable advantages over conventional designs, particularly within targeted operational regimes.*

Keywords: *optimisation, bionic airfoils, comparative analysis, aerodynamic efficiency, defense applications.*

1. INTRODUCTION

The continuous pursuit of improved aerodynamic efficiency is a key objective in the design of aerospace and defense systems, driven by the need to enhance performance, reduce fuel consumption, and expand operational capabilities. Among various optimization approaches, bio-inspired design has emerged as a promising strategy, drawing inspiration from the highly efficient aerodynamic and hydrodynamic adaptations observed in nature.

Bio-inspired design strategies in aerodynamics are based on the translation of morphological and functional characteristics observed in biological systems into engineering solutions for improved performance. In past decades, avian wing structures, marine animal skins, and aquatic locomotion mechanisms have served as primary sources of inspiration for enhancing aerodynamic efficiency in airfoil design [1, 2].

These strategies typically involve two directions. The first is geometric adaptation, in which the overall shape of the airfoil is modified to mimic profiles, such as those found in bird wings or dolphin-like shapes. The second direction focuses on surface modifications, including the incorporation of riblets, denticle-like textures, and micro coatings inspired by shark skin and other marine organisms, to reduce skin friction and minimize drag [3–7]. Along with morphological adaptations, contemporary and selected bionic optimization increasingly incorporates computational methods. Evolutionary algorithms, such as genetic algorithms and multi-island genetic algorithms, are commonly employed to explore large design spaces and identify configurations that yield optimal aerodynamic performance under given flow conditions [8, 9]. When combined with CFD simulations, these methods enable a detailed evaluation of complex bio-inspired geometries and their aerodynamic behaviour. Such approaches form an optimization framework in which biological principles, as well as numerical and experimental methods, are integrated. Despite significant advances in bio-inspired aerodynamic design, certain

DOI: 10.5937/OTEH26001B

limitations remain in the current literature. Previous studies have demonstrated the potential of genetic algorithms and biomimetic surface structures to improve aerodynamic performance through lift enhancement and drag reduction [1-9]. However, most research focuses on optimization approaches, such as surface-texture adaptations. Furthermore, comparative analyses evaluating different bionic optimization strategies within a unified computational and experimental framework remain limited. In particular, the aerodynamic performance of hybrid dolphin-inspired airfoils has rarely been systematically compared with other bio-inspired optimization concepts under similar operating conditions.

To address this gap, this study provides a comparative assessment of hybrid dolphin airfoils [10-13] and selected bionic optimization strategies reported in the literature, using computational optimization, CFD simulations, and experimental investigations to evaluate their aerodynamic efficiency. The findings aim to support the development of more aerodynamically efficient configurations for aerospace and defense applications.

2. METHODS

2.1 Airfoil Selection

The Dolphin 0006 M4 airfoil (Figure 1) was selected from a seven-member hybrid Dolphin family due to its highest percentage improvement in lift coefficient. The study considers the hybrid Dolphin airfoils developed and analyzed by the authors [10–13], together with selected bio-inspired airfoil optimization concepts reported in the literature for subsequent comparative analysis. The analyzed configurations represent different bionic design approaches, including geometric modifications and biomimetic surface adaptations inspired by marine and/or avian species.

The selected studies were chosen because they reported quantitative aerodynamic improvements and represented distinct categories of bio-inspired aerodynamic optimization, including surface modifications, leading-edge modifications, and geometry-based airfoil designs.

2.2 Comparative Evaluation Procedure

A comparative assessment was performed using the obtained results for the hybrid Dolphin airfoils and the corresponding performance indicators reported in the literature. The analysis focused on lift enhancement, drag reduction, and L/D ratio improvements under the corresponding operating conditions.

2.3 Performance Metrics

The aerodynamic performance of the analyzed airfoils was evaluated using the lift coefficient (CL), drag coefficient (CD), and lift-to-drag ratio (L/D). These parameters were used to compare the effectiveness of different bionic optimization strategies and identify configurations offering improved aerodynamic efficiency.

2.4 Computational Fluid Dynamics Setup

Numerical simulations were performed to evaluate the aerodynamic characteristics of the investigated airfoil configurations under controlled flow conditions. The analysis was carried out using a finite volume-based CFD approach, solving the Reynolds-averaged Navier–Stokes (RANS) equations for incompressible flow. The computational domain was designed to capture wake development downstream of the airfoil accurately. A C-type structured mesh was employed, with local refinement in the vicinity of the airfoil surface and in the boundary layer region to properly resolve near-wall gradients. Special attention was given to mesh density in the leading- and trailing-edge regions, where strong pressure gradients and flow separation may occur [10-13].

Near-wall resolution was adjusted to maintain a dimensionless wall distance (y^+) close to unity, thereby accurately capturing boundary-layer behavior without relying on wall functions. Mesh independence was verified through successive grid refinement, ensuring that variations in lift and drag coefficients remained within acceptable numerical tolerance.

Turbulent effects were modeled using the k–ω SST turbulence model, which provides balanced performance for both near-wall treatment and free-stream flow prediction, particularly in cases involving adverse pressure gradients and potential flow separation [10-13]. Boundary conditions were defined as a pressure far-field inlet with specified Reynolds number values corresponding to the investigated cases, while a pressure outlet condition was applied at the downstream boundary. The airfoil surface was treated as a no-slip wall. Simulations were conducted under steady-state assumptions. Convergence was monitored through residual reduction criteria and stabilization of aerodynamic coefficients (CL and CD). Residuals were set to $10^{-7,}$ and parameters reached convergence. Since experimental validation of the hybrid Dolphin 0006 M4 configuration (Figure 1) is not included in the present study, the reliability of the obtained results is supported through consistency checks with published experimental and numerical data for comparable bio-inspired airfoils. Consequently, the CFD results are interpreted primarily in a comparative sense, focusing on relative performance differences between configurations rather than absolute aerodynamic prediction accuracy.

3. RESULTS

The analysis of selected bio-inspired airfoil optimization strategies indicates consistent improvements in aerodynamic performance across different design approaches. Both geometric modifications and biomimetic surface adaptations contribute to enhanced lift generation, reduced drag, and improved lift-to-drag ratio under specific flow conditions. A review of the literature shows that shark denticle-inspired surface structures can significantly increase aerodynamic efficiency, particularly at low angles of attack (below 4°) and Reynolds numbers on the order of 4×10^4. Reported improvements in lift-to-drag ratio reach up to 323% [15], while lift increases to

28.4% [10-13] and drag reductions of up to 18.09% [14] have also been documented for optimized configurations. The hybrid dolphin airfoils developed by the authors demonstrate improved aerodynamic characteristics compared to their baseline configurations. The results indicate consistent lift enhancement and drag reduction across the investigated operating range. Compared with selected bionic airfoil concepts in the literature, the hybrid dolphin configuration exhibits competitive aerodynamic performance. While certain literature-based optimization approaches show higher localized performance gains under specific conditions, the hybrid dolphin airfoils provide stable and balanced aerodynamic behavior across a broader range of operating regimes relevant to aerospace and defense applications. The Dolphin 0006 M4 airfoil was compared with ten bio-inspired airfoil concepts presented in Table 1. It should be emphasized once again that this comparison is intended only as a general comparison, since airfoils with different thickness ratios (e.g., 6%, 12%, 21%, etc.) cannot be directly compared.

Table 1. Comparative summary of optimized bionic airfoils and their aerodynamic improvements

The results obtained for the hybrid Dolphin airfoils are presented separately from the findings reported in the literature, which are subsequently considered for comparative analysis. Table 1 summarizes the main aerodynamic characteristics and reported performance improvements of the selected bio-inspired airfoil concepts, providing the basis for the comparative assessment of the hybrid Dolphin 0006 M4 against the selected literature-based configurations.

For clarification, the term baseline airfoil used in relation to the Dolphin 0006 M4 in this study refers to airfoil NACA 0006, although there are two baselines involved in this airfoil modification:

1. The original Dolphin airfoil developed by Iosif Taposu, as presented in Refs. [10-13]. The semi-elliptical ("natural") modification method, described in these studies, resulted in performance improvements relative to the original Dolphin configuration.

2. The NACA 0006 geometric counterpart is the primary baseline airfoil in terms of the aerodynamic improvements reported for the Dolphin 0006 M4 in Table 1 (first row). Although the original Dolphin 0006 developed according to Taposu's method (Refs. [10-13]) may also be regarded as the baseline configuration from a design perspective, the corresponding percentage improvements relative to that airfoil are not presented here because its aerodynamic performance is substantially lower than that of the NACA 0006. Consequently, the results in Table 1 quantify the performance gains of the Dolphin 0006 M4 with respect to the NACA 0006, while the modified airfoil itself originates from the original Dolphin 0006 through the semi-elliptic ("natural") modification described in Refs. [10-13].

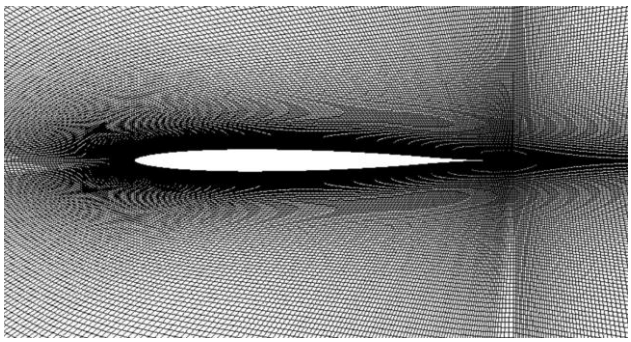

Figure 1. Computational mesh and geometry of the Hybrid Dolphin 006 M4 airfoil

Figure 1 presents the computational mesh and the geometry of the Hybrid Dolphin 0006 M4 airfoil with the corresponding structured C-mesh used for the CFD analysis performed by the authors of this paper. The mesh is refined in the vicinity of the airfoil surface to properly resolve boundary layer effects and ensure accurate prediction of aerodynamic quantities. The Dolphin 0006 M4 was designed using the semi-elliptical, or "natural" optimization method [10-13].

In addition to the quantitative values summarized in Table 1, the comparative analysis reveals distinct performance trends associated with different categories of bio-inspired optimization strategies. Surface-modification techniques, particularly those inspired by shark denticles and micro-groove structures, tend to exhibit pronounced improvements in aerodynamic efficiency at lower Reynolds numbers. These effects are primarily attributed to delayed boundary layer separation and modified near-wall momentum exchange mechanisms, which contribute to significant drag reduction under specific flow conditions.

In contrast, geometry-based modifications, such as leading-edge tubercles and wavy airfoil configurations, demonstrate a more balanced influence on both lift generation and flow stability. These configurations generally provide moderate but consistent improvements across a wider range of angles of attack, suggesting improved robustness rather than isolated peak performance gains.

The hybrid Dolphin 0006 M4 airfoil follows a similar trend to geometry-driven optimization approaches, where performance enhancement is distributed across the operating envelope rather than concentrated at specific flow conditions. The observed increase in lift coefficient and reduction in drag indicate favorable pressure distribution over the airfoil surface, which can be associated with smooth curvature transitions and optimized thickness distribution.

Unlike certain surface-texture-based configurations that exhibit extremely great localized improvements under narrowly defined conditions, the hybrid Dolphin configurations maintain stable aerodynamic behavior across the investigated operating range. This characteristic is particularly relevant for aerospace and defense applications, where operational variability and off-design conditions are critical considerations.

Furthermore, the comparison highlights a clear dependency of aerodynamic enhancement mechanisms on Reynolds number regime. At lower Reynolds numbers, viscous effects dominate, making surface texture modifications more effective. At higher Reynolds numbers, inertial effects become more pronounced, increasing the relative importance of global geometric optimization.

Overall, the results indicate that no single bio-inspired strategy universally outperforms others across all conditions. Instead, each approach demonstrates distinct advantages depending on the flow regime and design objective, with hybrid configurations offering a balanced compromise between performance improvement and operational stability.

4. DISCUSSION

The comparative analysis presented in Table 1 demonstrates that bio-inspired aerodynamic concepts can improve lift generation, reduce drag, and enhance aerodynamic efficiency through different physical mechanisms. However, direct comparison of reported improvements remains challenging because the reviewed studies employ different airfoil geometries, Reynolds number regimes, angles of attack, and evaluation

methodologies.

The Hybrid Dolphin 0006 M4 airfoil achieved a maximum lift increase of 28.4%, a drag reduction of 6.2%, and an L/D improvement of 41.9% at $Re = 6 \times 10^6$ and $\alpha = 10°$ [10–13]. Among the reviewed concepts, these results represent one of the highest simultaneously reported improvements in lift and aerodynamic efficiency under clearly defined operating conditions. However, a limitation of the present assessment is that the reported Dolphin 0006 M4 results are restricted to $Re = 6 \times 10^6$ and $\alpha = 10°$, which limits direct assessment of its performance across a broader range of operating conditions.

Several literature studies reported higher localized performance gains under specific conditions. Shark denticle-inspired surface modifications achieved L/D improvements of up to 323% at $Re \approx 4 \times 10^4$ and $\alpha < 4°$ [15], while shark-inspired micro-groove configurations reduced drag by up to 18.09% [14]. Wavy leading-edge airfoils increased lift by up to 21% [16], whereas leading-edge tubercle configurations reported lift improvements ranging from 4.8% to 28% depending on geometry and operating conditions [17, 20–22].

Nevertheless, many studies provide results only in graphical form or without explicit percentage quantification, which limits direct quantitative comparison [15, 17, 19, 21–23]. Furthermore, substantial differences in Reynolds number and AoA ranges prevent the establishment of a universal ranking among bio-inspired concepts.

The principal contribution of the present study is therefore not the claim of the greatest aerodynamic improvement, but the provision of a systematic and previously validated framework for evaluating a complete Hybrid Dolphin airfoil family. Unlike many studies focused on isolated geometric or surface modifications, the proposed approach enables consistent comparison within a unified design methodology. Such a framework is particularly relevant for aerospace and defense applications, where reproducibility, robustness, and reliable performance assessment are often more important than isolated peak improvements achieved under narrowly defined operating conditions. An important observation from the comparative analysis is the trade-off between peak aerodynamic performance and operational robustness. While some bio-inspired configurations achieve very great localized improvements in lift-to-drag ratio, these gains are often limited to narrow Reynolds number ranges and small angles of attack, which reduces their applicability in variable operating conditions. In contrast, the hybrid Dolphin 0006 M4 airfoil shows more stable aerodynamic behavior across a wider range of conditions. This suggests that its geometry supports smoother pressure distribution and reduced sensitivity to flow variations.

From an application perspective, this distinction is relevant for aerospace and defense systems, where consistency under off-design conditions is often more critical than isolated performance peaks. The results therefore indicate that hybrid bio-inspired designs offer a balanced compromise between efficiency and robustness.

5. CONCLUSION

This study presented a comparative evaluation of the hybrid Dolphin 0006 M4 against selected bio-inspired aerodynamic concepts reported in the literature. The analysis was based on aerodynamic performance indicators including lift coefficient, drag coefficient, and lift-to-drag ratio, obtained from numerical simulations, and experiments obtained from literature-based data.

The results show that the Dolphin 0006 M4 airfoil achieves a maximum lift increase of 28.4%, a drag reduction of 6.2%, and a lift-to-drag ratio improvement of 41.9% relative to its NACA 0006 baseline configuration. While certain bio-inspired surface modification strategies demonstrate higher localized performance gains under specific flow conditions, these improvements are often restricted to narrow operating regimes.

In contrast, the hybrid Dolphin 0006 M4 configuration exhibits stable aerodynamic behavior across a broader range of operating conditions, indicating improved robustness and practical applicability. This balance between performance enhancement and operational stability is particularly relevant for aerospace and defense applications, where reliability under variable flow conditions is essential.

The study confirms that hybrid bio-inspired design approaches, supported by computational optimization techniques, provide a viable framework for achieving consistent aerodynamic improvements. Future work may focus on further refinement of hybrid geometries and multi-objective optimization strategies to enhance performance across extended flight regimes.

Abstract: *This paper presents a performance analysis of a tactical unmanned aerial vehicle (UAV) with and without integrated rocket payload. The study is based on the application of standard flight mechanics methods combined with available experimental flight data for validation purposes. The aerodynamic characteristics of the UAV are evaluated for both configurations, taking into account the increase in mass and additional parasitic and interference drag caused by externally mounted rockets. These changes are incorporated into the equations of motion in order to estimate key performance parameters. The analysis focuses on the determination of maximum flight speed, rate of climb, endurance, and range under different flight conditions. Two calculation methodologies are applied and their results are compared with experimental data obtained during flight testing. The results show a noticeable degradation of flight performance due to rocket integration, with deviations between theoretical predictions and experimental data remaining within acceptable engineering limits. The presented approach provides a reliable basis for performance estimation of UAVs with external payload configurations.*

Keywords: *UAV, rocket payload, flight performance, flight testing.*

1. INTRODUCTION

The development of tactical unmanned aerial vehicles began during the second half of the 20th century, primarily for reconnaissance and intelligence-gathering purposes without risking human crews. During military conflicts worldwide, UAV systems were significantly improved, evolving from simple reconnaissance platforms into complex systems with greater autonomy, reliability, and operational range. At the beginning of the 21st century, intensive technological development in the fields of sensors, communication systems, and precision-guided weaponry enabled the transformation of UAV systems into multifunctional platforms. Modern tactical unmanned aerial vehicles, developed, among others, at the Military Technical Institute, represent the integration of reconnaissance and combat capabilities, offering a high degree of flexibility and relatively low operational costs. Such development further confirms their increasingly important role in modern military operations.

Medium-range unmanned aerial vehicles, such as the system considered in this paper, are designed as platforms capable of performing a wide range of tasks, including surveillance, intelligence gathering, artillery fire correction, and precision strike missions. Their ability to remain in the mission area for extended periods and transmit data in real time significantly enhances situational awareness and command efficiency. The integration of external stores further expands the operational capabilities of these systems; however, it also affects the aircraft's fundamental aerodynamic and mass characteristics. As demonstrated in previous studies, any modification of the configuration requires careful analysis of its impact on the center of gravity position, drag, and overall performance, while achieving a balance between operational efficiency and flight performance [1-3].

The integration of rocket armament enables the execution of direct fire support and reduces reaction time, thereby combining reconnaissance and combat functions within a single platform. However, the presence of external stores leads to an increase in mass and parasite drag, as well as the occurrence of additional interference drag, which directly results in reduced maximum speed, climb rate, endurance, and range. In addition, limitations on the maximum takeoff weight often require a reduction in fuel quantity, while changes in mass distribution may affect the aircraft's stability and controllability. Although aerodynamically unfavorable, such a configuration represents an operationally justified compromise in missions where combat capability takes priority over maximum flight performance.

In this context, there is a need for a reliable assessment of

Corresponding author: B. Ostojić;
E-mail: branislavostojic1994@gmail.com
DOI: 10.5937/OTEH26002O

the influence of external stores on the performance of unmanned aerial vehicles. Although standard analytical methods based on the literature exist [4-6], their application to configurations with external payloads requires additional verification.

The aim of this paper is to provide a quantitative analysis of the impact of rocket armament integration on the performance of an unmanned aerial vehicle through a combination of theoretical calculations and experimental data. The analysis includes the determination of drag, required power, maximum speed, climb rate, endurance, and range, together with a comparison to the results obtained from flight tests conducted in configurations with and without rockets. Special emphasis is placed on evaluating the deviations between theoretical models and actual performance, as well as identifying the dominant factors contributing to performance degradation caused by the integration of external payloads. The obtained results are used to assess the accuracy and limitations of existing UAV performance calculation methods for configurations with external stores (rockets) through comparison with flight test results.

2. FLIGHT PERFORMANCE

The focus of this chapter is the analysis of the UAV flight performance in configurations with and without externally mounted rocket armament, with the aim of assessing the influence of external payloads on the main flight characteristics. The performance analysis was carried out using standard analytical methods for determining drag, required power, maximum speed, climb rate, range, and endurance. The obtained results will be compared with experimental data from flight tests in order to evaluate the accuracy of the applied methods and identify the dominant factors influencing UAV flight performance.

Table 1 presents some of the basic characteristics of the considered unmanned aerial vehicle shown in Figure 1.

Table 1. Key Parameters of the UAV Configuration

Internal combustion engine power [7]	38.8 kW
Propeller diameter	0.86 m
Maximal mass of UAV	265 kg
Maximal mass of usable fuel	70 kg
Wing area	4.33 m^2
Mean aerodynamic chord	0.736 m

Figure 1 Tactical UAV with rockets

The propulsion system must be properly sized to ensure the overcoming of aerodynamic drag and supplying power to all onboard systems. In this regard, it is necessary to take into account that different engines have specific optimal operating RPM ranges. The efficiency of the propeller, as an integral part of the propulsion system, depends on propeller advance ratio, which is determined using the following expression:

$$J = \frac{V}{ND} \tag{1}$$

In Equation (1), the parameter J represents the propeller advance ratio, V the flight speed, N the propeller rotational speed, and D the propeller diameter. Maximum propeller efficiency is achieved when the propeller advance ratio is within the range of 0.5 to 0.6, as illustrated in Figure 2.

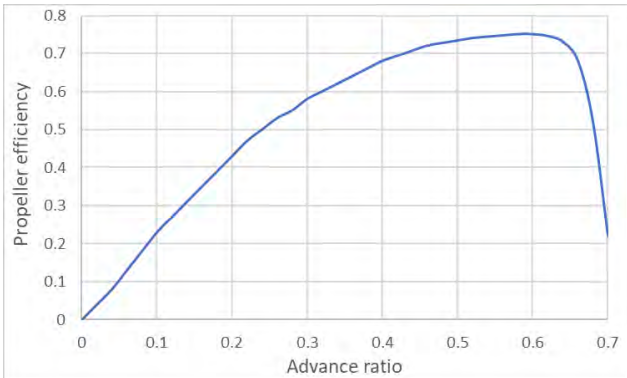

Figure 2. Propeller efficiency

For the flight speed to be optimal, it is necessary to satisfy several interrelated conditions. Depending on the mission type, the UAV must achieve an appropriate flight speed at the designated altitude in order to ensure efficient terrain surveillance, tracking of moving and stationary targets, as well as successful rocket launch and target engagement. During different flight regimes, the UAV changes its configuration, including camera deployment and retrieval, as well as variations in the amount of carried armament, which lead to changes in mass and aerodynamic characteristics, and consequently to variations in the required flight power, as shown in Figure 3 and Figure 4.

Figure 3 shows the relationship between the lift coefficient C_L and the drag coefficient C_D for several different configurations (with and without rockets) [8].

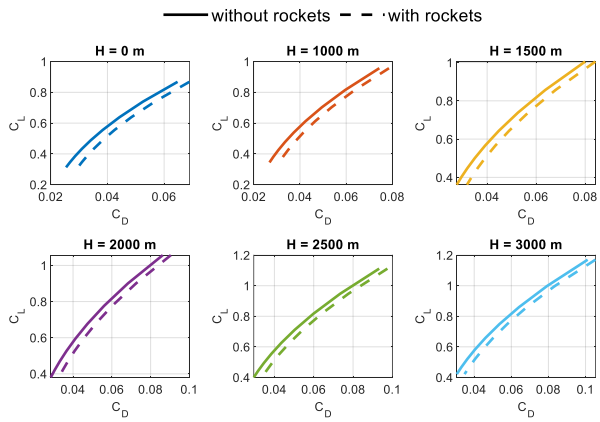

Figure 3. UAV drag polar with and without rockets

Based on the obtained drag coefficient values, the aerodynamic drag force and required flight power can be calculated using the following expressions:

$$D = C_D q S \tag{2}$$

$$P_{req} = DV \tag{3}$$

Figure 4 shows the influence of rocket integration on the required flight power, as well as the variation in available power. Figure 5 presents the maximum flight speeds as a function of altitude for configurations with and without rockets.

It should be emphasized that engine power depends on the rotational speed, throttle setting, flight regime, and atmospheric conditions. With increasing altitude, air pressure, density, and temperature decrease, resulting in reduced engine efficiency. One of the methods used to express the available engine power as a function of altitude is given by:

$$P_{avail} = P_0 \eta_{engine} \eta_{prop} \left(\frac{\rho}{\rho_0}\right)^{1.2} \tag{4}$$

where ρ is the air density at the flight altitude, while ρ_0 is the air density at sea level.

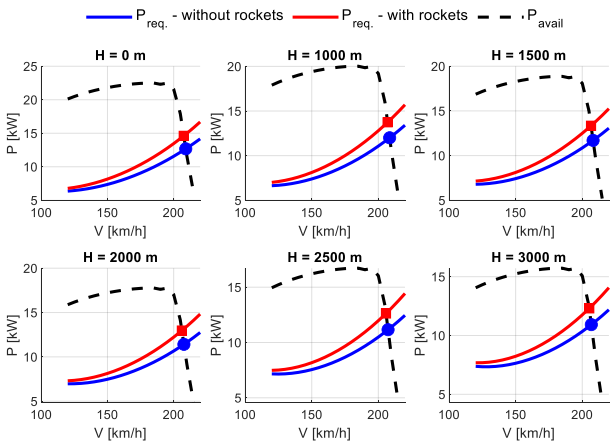

Figure 4. Required and available flight power

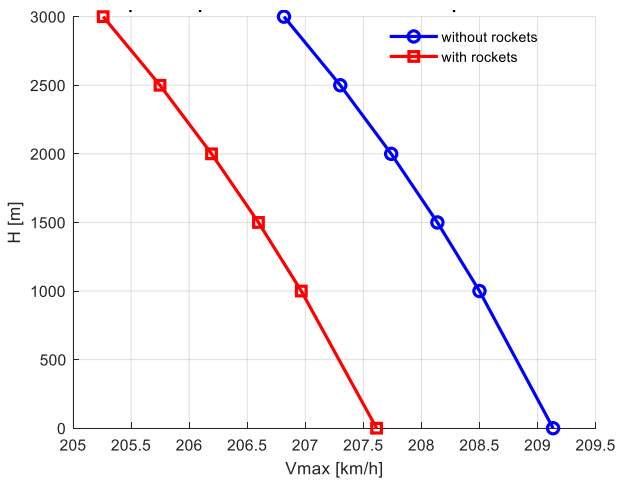

Figure 5. Maximum flight Speed as a Function of Altitude

The vertical rate of climb depends on the difference between the available and required flight power, as well as on the current aircraft weight:

$$w = \frac{P_{avail} - P_{req}}{mg} \tag{5}$$

Figure 6 illustrates the influence of rocket integration on the rate of climb at different flight speeds and altitudes.

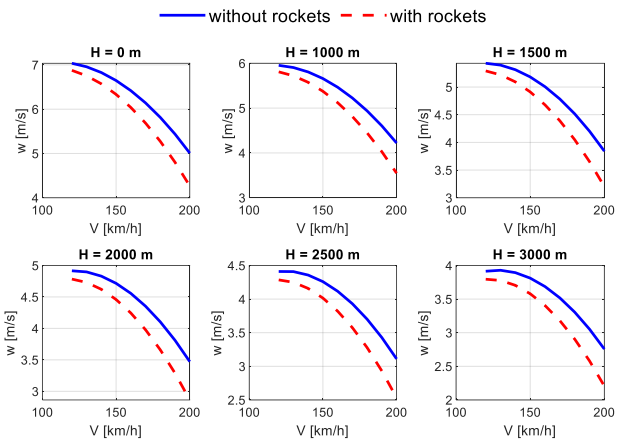

Figure 6. Rate of climb as a function of airspeed and altitude

As shown in Figure 7, with increasing flight altitude, the rate of climb gradually decreases, and for certain flight regimes and airspeeds, the climb rate approaches zero. Such behavior is a consequence of the reduction in available power and thrust with increasing altitude, as well as the increase in the power required to maintain flight under specific aircraft configurations. A similar decrease in climb rate with increasing altitude was also reported in [9] for a propeller-driven UAV operating at altitudes up to 7000 m. Depending on the mission requirements, aerodynamic configuration, and required aircraft performance, the service ceiling may be defined at certain minimum climb rate values, while the theoretical ceiling corresponds to the condition in which the rate of climb reaches 0 m/s.

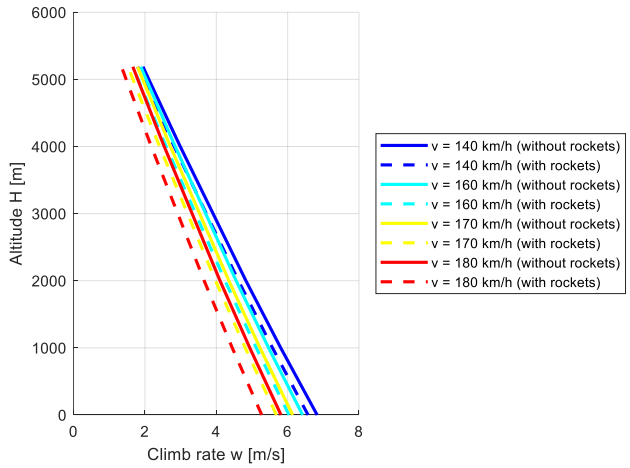

Figure 7. Rate of climb as a function of altitude

When considering flight endurance, the primary objective in the design and analysis of an unmanned aerial vehicle is to ensure the longest possible time aloft without the need for landing and refueling, which requires the optimization of multiple interdependent aerodynamic, propulsion, and mass-related parameters. In this context, one of the key requirements is achieving a high lift-to-drag ratio (L/D),

which directly reduces the power required for sustained level flight, while minimum drag is achieved through optimization of the aircraft configuration and external stores. At the same time, low specific fuel consumption of the propulsion system is of crucial importance, as it enables more efficient utilization of the available energy through the selection of an engine operating within its optimal regime and providing a favorable balance between power output and fuel consumption. The propeller efficiency, as a key element of the propulsion system, must also be maximized in order to convert the largest possible portion of the engine's mechanical power into useful thrust. In addition, the total amount of fuel that the UAV can carry represents a significant factor, although it is constrained by structural and operational requirements such as maximum takeoff weight and load distribution. Therefore, optimal endurance is achieved through a careful balance between aerodynamic efficiency, propulsion system performance, and available energy resources, while taking into account all limitations of the actual operational environment.

Depending on the flight regime, range and endurance can be classified into the following cruise conditions:

- Constant Airspeed/Constant Altitude Cruise.
- Constant Attitude/Constant Altitude Cruise.
- Constant Airspeed/Constant Attitude Cruise.
- Constant Weight Cruise.

This paper presents range and endurance values for steady flight at constant speed and constant altitude, without considering takeoff, climb to cruise altitude, descent, and landing phases. Table 2 presents the corresponding range and endurance expressions, which yield identical results.

Table 2. Analytical expressions for range and endurance

Range [10]	$R = 3600\frac{\eta}{q}\sqrt{\frac{\pi\lambda_e}{C_{Dmin}}}\arctan\frac{m_g}{\frac{\delta V^2}{16}S\sqrt{C_{Dmin}\pi\lambda_e} + \frac{m_o(m_o - m_g)}{\frac{\delta V^2}{16}S\sqrt{C_{Dmin}\pi\lambda_e}}}$
Endurance [10]	$E = \frac{R}{V}$
Range [11]	$R = \frac{V}{c_t\sqrt{kC_{Dmin}}}\left[tan^{-1}\left(\frac{2\sqrt{k}}{\rho V^2 S\sqrt{C_{Dmin}}}W_{ini}\right) - tan^{-1}\left(\frac{2\sqrt{k}}{\rho V^2 S\sqrt{C_{Dmin}}}W_{fin}\right)\right]$
Endurance [11]	$E = \frac{1}{c_t\sqrt{kC_{Dmin}}}\left[tan^{-1}\left(\frac{2\sqrt{k}}{\rho V^2 S\sqrt{C_{Dmin}}}W_{ini}\right) - tan^{-1}\left(\frac{2\sqrt{k}}{\rho V^2 S\sqrt{C_{Dmin}}}W_{fin}\right)\right]$

Figure 8 and Figure 9 present the range and endurance of the analyzed UAV for different flight regimes in configurations with and without rockets. The results show that the UAV configuration with rockets has lower range and endurance compared with the configuration without rockets. This reduction is mainly attributed to the decrease in available fuel capacity caused by rocket instalation, which limits both the total flight time and the achievable range.

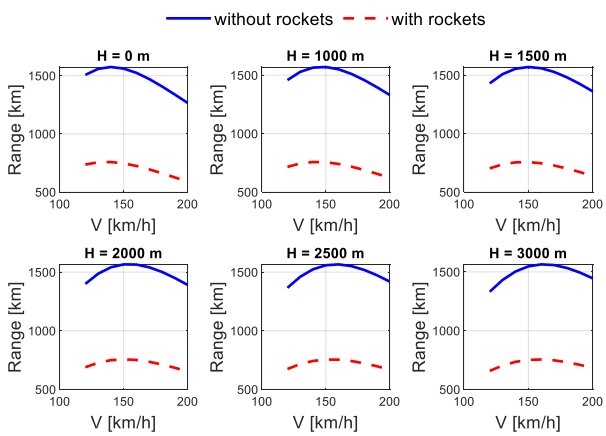

Figure 8. Range as a function of airspeed

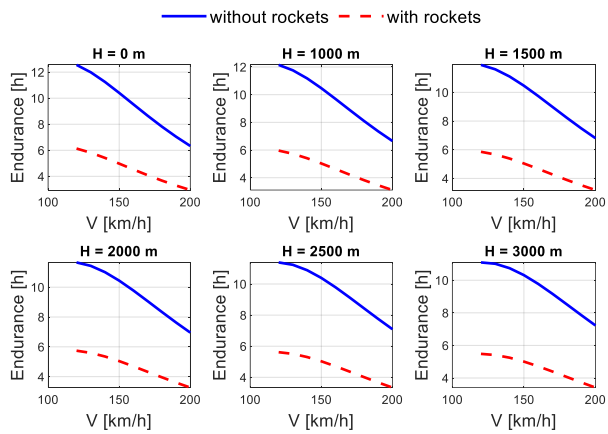

Figure 9. Endurance as a function of airspeed

2.1. Flight test results

The maximum flight speed was evaluated following stabilization at the cruise altitude of 2000 m, where the UAV was operated at a throttle setting of 90% for a duration of three minutes. The UAV was then climbed to an altitude of 3000 m, and the same test procedure was repeated. In order to minimize the influence of wind on the

measurement results, the tests were conducted in both flight directions at each altitude. Table 3 provides a comparison between the calculated performance values and the results obtained during flight testing. It should be noted that the objective of the flight tests was not to determine the maximum attainable flight speed, but rather to verify compliance with the required operational speeds specified in the technical requirements, namely 180 km/h for the configuration without rockets and 160 km/h for the configuration with rockets.

Table 3. Comparison of calculated and measured maximum flight speeds

Without rockets		
H (m)	$V_{calculated}$ (km/h)	V_{test} (km/h)
2000	207.74	190.8
3000	206.82	192.6
With rockets		
H (m)	$V_{calculated}$ (km/h)	V_{test} (km/h)
2000	206.19	186.01
3000	205.26	187.09

Table 4 presents a comparison between the calculated and experimentally measured rates of climb. For the configuration without rockets, the deviations between the calculated and measured values were below 10%, with a maximum difference of 8.1%, indicating good agreement between the analytical model and flight test results. Larger deviations were observed for the configuration with rockets. These discrepancies are attributed to differences in the conditions under which the flight tests were conducted, since the flight tests in the configuration with rockets and the flight tests in the configuration without rockets were performed on different days. As a result, variations in atmospheric conditions, including turbulence encountered during cloudy weather, affected the measured rates of climb.

Table 4. Comparison of maximum rates of climb

Without rockets		
H (m)	$w_{calculated}$ (m/s)	w_{test} (m/s)
1000	5.95	6.33
2400	4.92	4.52
With rockets		
H (m)	$w_{calculated}$ (m/s)	w_{test} (m/s)
1000	5.77	6.62
2200	4.82	6.78

The service ceiling was evaluated by climbing the UAV to an altitude of 5000 m above sea level in the configuration without rockets and to 4000 m in the configuration with rockets, while maintaining a stable flight condition for a duration of three minutes in both cases. The calculated dependence of rate of climb on altitude is presented in Figure 7, while Table 5 presents the corresponding flight test results. It should be noted that the objective of the flight tests was not to determine the maximum attainable altitude, but rather to verify compliance with the required operational ceiling specified in the technical requirements, namely 5000 m for the configuration without rockets and 4000 m for the configuration with rockets. Consequently, the measured values differ from the calculated results, particularly in the configuration with rockets.

Table 5. Service ceiling comparison

H (m)	$w_{cal.}$ (m/s)	w_{test} (m/s)	Rockets
5188	1.95	2	without
4029	2.3	1	with

Endurance was one of the critical requirements that the aircraft had to satisfy during flight testing. Since the UAV successfully met the required flight endurance criteria, maximum range testing was not performed. In order to determine the range and endurance, it is first necessary to evaluate the fuel consumption during ground engine operation, climb, descent, landing, and taxiing. When the required navigation reserve is additionally considered, the remaining available fuel quantity for steady level flight at the prescribed cruise altitude can be determined.

In this study, the endurance values were compared exclusively for the flight segment extending from reaching the target flight altitude to the initiation of descent, with the flight conducted at an average throttle setting of 30%.

During the flight tests conducted in the configuration without rockets, the unmanned aerial vehicle remained airborne for 9.42 hours at an average cruise altitude of 2500 m and an average flight speed of 150 km/h, consuming 46 kg of fuel, as shown in Figure 10. The calculated endurance for the corresponding flight regime was 10.14 hours.

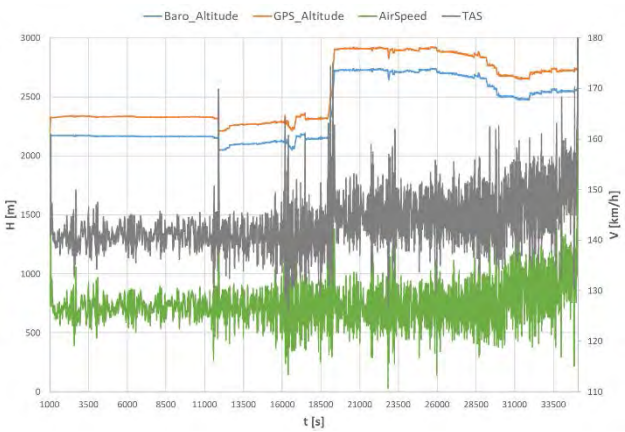

Figure 10. UAV Endurance in the configuration without rockets [12]

During the flight tests conducted in the configuration with rockets, the unmanned aerial vehicle remained airborne for 5.39 hours at an average cruise altitude of 2000 m and an average flight speed of 140 km/h, consuming 26 kg of fuel, as shown in **Figure 11**. The calculated endurance for the corresponding flight regime was 5.35 hours.

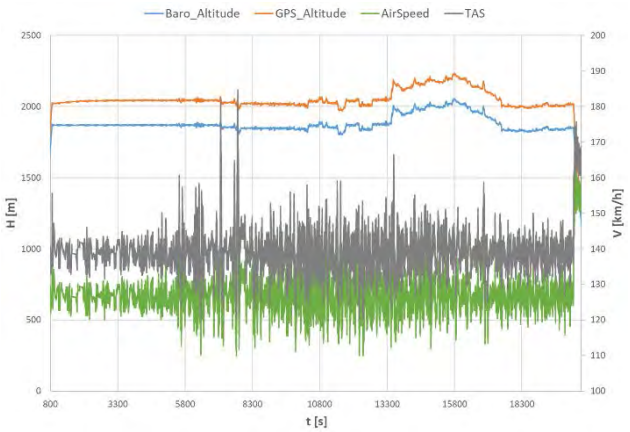

Figure 11. UAV Endurance in the configuration with rockets [12]

3. CONCLUSION

The paper presented a comparative analysis of the flight performance of a tactical unmanned aerial vehicle in configurations with and without external rocket stores. The analysis included the determination of maximum flight speed, rate of climb, endurance, and range through the application of standard analytical flight performance methods, followed by comparison with the results obtained during flight testing.

The obtained results indicate that rocket integration has a relatively small influence on maximum flight speed and rate of climb. Although the presence of external stores leads to an increase in aerodynamic drag and aircraft mass, the corresponding degradation of these performance parameters remained comparatively low under the analyzed flight conditions. In contrast, a significantly greater impact was observed in terms of endurance and range. The primary reason for this reduction was not the increase in aerodynamic drag itself, but rather the decrease in available fuel quantity required to satisfy the maximum takeoff mass limitation in the armed configuration.

A comparison between the calculated and experimentally obtained results showed good agreement across all analyzed cases, confirming that conventional analytical flight performance methods provide sufficiently accurate predictions even for UAV configurations with external stores. This demonstrates that relatively simple analytical approaches can still serve as reliable tools during preliminary design and operational performance assessment.

It should also be noted that flight testing of UAV performance is inherently influenced by atmospheric conditions, which may vary significantly during the execution of the tests. Sudden wind gusts and local atmospheric disturbances can affect the measured flight parameters, potentially contributing to deviations between calculated and experimentally obtained results, even under carefully controlled test conditions.

Future research may include the investigation of advanced endurance enhancement methods for tactical UAVs, such as autonomous soaring, atmospheric energy harvesting, and energy-efficient trajectory optimization techniques presented in recent studies [13].

Finally, despite the reduction in endurance and range, the capability to integrate rocket armament represents a major operational advantage. Modern combat operations increasingly emphasize the importance of unmanned platforms capable of combining reconnaissance and strike functions within a single system, making armed UAV systems an increasingly important component of contemporary military operations.

Abstract: *This paper presents a systematic methodology for assessing the performance of a multicopter propulsion system, focusing on the propeller, brushless direct current (BLDC) motor, electronic speed controller (ESC), and battery system. Addressing the challenge that current literature and datasheets on UAV performances especially concerning electric motors and propellers are usually scattered and poor. This research provides specific motor characteristics that are often difficult to find. By utilizing manufacturer technical specifications, mathematical models are used to evaluate critical metrics, including hover endurance, motor–ESC efficiency across the throttle range, payload capacity and tilt limits, and the optimization of speed and range in forward flight. Central to this research is the comprehensive experimental validation conducted using a motor thrust stand. Detailed experimental measurements of static thrust, torque, propeller RPM, and electricity consumption were performed to validate the numerical models. The results demonstrate a correlation between theoretical predictions and experimental data, confirming that the proposed methodology allows for reliable estimation of flight performance. This integrated approach provides a robust framework for engineers to effectively optimize component selection and accurately predict multicopter behavior.*

Keywords: *Multicopter, Propulsion System, BLDC Motor, Experimental validation.*

1. INTRODUCTION

The quadcopter is the most common multicopter unmanned-aerial-vehicle configuration. Vertical take-off and landing, hovering, low mechanical complexity and precise positioning support reconnaissance, surveillance, relay, logistics and specialized payload missions. In military applications, low observability, short preparation time, and the ability to operate outside the operator's direct line of sight are particularly important [1-3]. At the same time, low available battery energy and limited payload nevertheless remain primary constraints.

Performance depends on matching the propeller, brushless direct-current (BLDC) motor, electronic speed controller (ESC) and battery. Manufacturers do not publish a uniform data set: motor KV, current and resistance may be available, whereas a propeller is often described only by diameter, pitch and blade count. Static thrust and torque coefficients are consequently uncertain, especially at low Reynolds number, while forward flight additionally changes loading through advance ratio and disk incidence [4]. Low-order component models are useful in preliminary design because they connect a small parameter set to hover, endurance and mission estimates [5-7]. For forward flight and maneuvering conditions, where rotors operate under non-uniform and oblique inflow, propeller maps or suitable aerodynamic models are required [8-11]. A calculation based on a zero-advance ratio static test must therefore be reported as a conditional engineering screen rather than as measured flight performance.

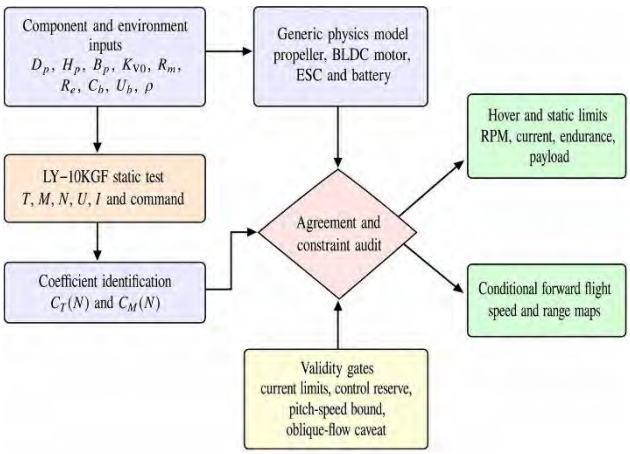

Figure 1. Workflow from confirmed hardware and LY-10KGF data to calibrated coefficients, constraint checks and conditional vehicle-level analysis

The objective is to determine operating points relevant to

DOI: 10.5937/OTEH26003L

hover and high loading, identify ESC and motor constraints, estimate payload, tilt, speed and range, and quantify agreement with a stationary thrust stand experiment. Four experimental measurements of a GEPRC EM3115 900 KV motor, 10x5x3-in propeller and HAKRC 65 A ESC were performed using an LY-10KGF thrust stand. After removing the 90% and 100% regimes, which will be explained later, 32 points remain; 20 points from 40% to 80% are used for coefficient identification. Figure 1 summarizes the traceable workflow.

2. SYSTEM AND METHODS

2.1. Tested configuration

The studied vehicle is m = 5.4 kg quadcopter. Each branch uses a GEPRC EM3115 900 KV motor [12] and a three-blade 10x5x3-in propeller shown in Figure 2. The used electronic speed controller is a HAKRC unit rated at 65 A per branch [13]. The shared source is a 6S, 10 Ah, 30 C LiPo battery. Air density is measured in each experiment and lies between 1.174÷1.175 kg/m³ at 23.2÷23.6 °C. Table 1 lists the model inputs.

Figure 2. Used 10x5x3-in propeller and GEPRC EM3115 900 KV motor

Table 1. Confirmed configuration and test environment

Item	Value
Vehicle	5.4 kg; four rotors
Motor	GEPRC EM3115, 900 KV
Propeller	10x5x3 in; three blades
ESC	HAKRC, 65 A per branch
Battery	6S LiPo; 10 Ah; 30 C;
Atmosphere	23.2÷23.6 °C; ρ=1.174÷1.175 kg m^{-3}

2.2. Analytical and identified static model

At zero advance ratio, thrust T and reaction torque M are expressed by Equations (1a) and (1b), where N is optical speed in RPM, D_p is propeller diameter, ρ is air density, C_T thrust coefficient and C_M is torque coefficient.

$$T = C_T \rho \left(\frac{N}{60}\right)^2 D_p^4 \tag{1a}$$

$$M = C_M \rho \left(\frac{N}{60}\right)^2 D_p^5 \tag{1b}$$

The geometric pitch angle θ_p, which is a function of propeller diameter D_p and propeller pitch H_p, and effective blade angle α_{ab} are defined by Equations (2a) and (2b). The corresponding analytical thrust, blade-drag and torque coefficients follow from Equations (3a) - (3c). Here A is aspect ratio, ε is the downwash correction, λ is the effective blade-area factor, ζ is the mean linear-speed factor, e is the Oswald factor, C_{fd} is the profile-drag coefficient, α_0 is the zero-lift angle and K_0 is the lift-curve slope. Recommendation for the parameter ranges for two blade (B_p = 2) propellers is given in [6].

$$\theta_p = tan^{-1}\left(\frac{H_p}{\pi D_p}\right) \tag{2a}$$

$$\alpha_{AB} = \varepsilon\theta_p - \alpha_0 \tag{2b}$$

$$C_{T,a} = \frac{0.25\pi^3 \lambda \zeta^2 B_p K_0 \alpha_{AB}}{\pi A + K_0} \tag{3a}$$

$$C_d = C_{fd} + \frac{\left(\frac{\pi A K_0^2}{e}\right)\alpha_{AB}^2}{(\pi A + K_0)^2} \tag{3b}$$

$$C_{M,a} = \frac{\pi^2 C_d \zeta^2 \lambda B_p^2}{8A} \tag{3c}$$

For each raw point i, the two regression ordinates are defined by Equations (4a) and (4b). The constant coefficients are then fitted through the physical origin using Equations (5a) and (5b).

$$q_{T,i} = \rho_i \left(\frac{N_i}{60}\right)^2 D_p^4 \tag{4a}$$

$$q_{M,i} = \rho_i \left(\frac{N_i}{60}\right)^2 D_p^5 \tag{4b}$$

$$\hat{C}_T = \frac{\sum q_{T,i} T_i}{\sum q_{T,i}^2} \tag{5a}$$

$$\hat{C}_M = \frac{\sum q_{M,i} M_i}{\sum q_{M,i}^2} \tag{5b}$$

With the parameters recommended from [6] for two bladed propellers: A = 5, ε = 0.85, λ = 0.75, ζ = 0.5, e = 0.83, α_0 = 0°, C_{fd} = 0.015 and K_0 = 6.11 [6]; the obtained values for our case are C_T = 0.1638 and C_M = 0.0174. The experimental fit gives C_T = 0.1506 and C_M = 0.0099. This gives significant deviations between analytical and experimental value of coefficients. Since the parameter B_p affects certain terms in equations (3a) and (3c), it is necessary to determine appropriate values for the other parameters.

Measurable parameters are changed according to case, and others analytical parameters were determined by minimizing the relative-error objective in Equation (6).

The aspect ratio A is fixed at 12.7 and it is based of used 10x5x3-in propeller; ε, λ, ζ, e and α_0 are constrained to the prescribed intervals [6]. Because λ and ζ enter only through $\lambda\zeta^2$, their individual values are not uniquely identified; the feasible pair nearest the centers of the two ranges is retained.

$$J = \left(\frac{C_{T,a}}{\widehat{C_T}} - 1\right)^2 + \left(\frac{C_{M,a}}{\widehat{C_M}} - 1\right)^2 \quad (6)$$

The solution is A = 12.7, ε = 0.918, λ = 0.812, ζ = 0.621, e = 0.80, α_0 = -0.625°, C_{fd} = 0.015 and K_0 = 6.11. It gives, C_d = 0.0363, C_{Ta} = 0.1506 and C_{Ma} = 0.0099. The experimental fit gives C_T = 0.1506 and C_M = 0.0099. Their numerical equality is a result of calibration and is not an independent validation of the geometric model.

2.3. LY-10KGF experiment and data treatment

Testing was performed on a LY-10KGF test stand Figure 3 using MET-V6 acquisition software. For the test, a single battery-ESC-motor-propeller combination was used. Between each of the four experimental measurements, the battery was fully recharged and the motor was allowed to cool to ambient temperature. The test stand specification and vendor software documentation define the measured channels. The LY-10KGF specification gives 10 kgf (98.07 N) thrust range with 0.001 kgf (0.0098 N) resolution and an error expression of 0.1% of reading plus 0.1% full scale. The corresponding torque figures are 5 Nm, 0.001 Nm resolution and 0.2% of reading plus 0.2% full scale [14,15]. Four exports contain command, optical RPM, voltage, DC current, thrust, torque, temperature and environmental data.

Figure 3. LY-10KGF test stand with GEPRC EM3115 and 10x5x3 in three blade propeller

Each of the four experimental sweeps followed a descending command sequence. The command was reduced from 100% to 10% in 10-percentage-point increments, with each level held for 5 s, and was then set to 0% to stop the system. For each sweep and command level, the samples recorded during the corresponding 5-s interval were time-averaged to obtain one representative value for each measured channel.

The original records contain ten nominal command levels, but all 90% and 100% rows are removed before calculation and plotting. These results were not used in analysis because of ESC rating and motor power limitations. At 90%, the mean branch current is 64.27 A, too close to the 65 A rating to provide a useful operating margin; at 100%, every measured branch current exceeds the rating. The retained analysis therefore contains 32 sweep-level points, corresponding to eight command levels from 10% to 80% across four sweeps. The test stand manufacturer recommends testing propulsion units producing more than 1 kgf (9.807 N) [14]. The 10÷30% points are below that level, and the 10% point has 9.7÷19.7% coefficient of variation in principal channels. The coefficient fit is restricted to 20 points from 40% to 80%. For each retained command, the arithmetic mean and sample standard deviation across four measurements are reported. The symbol ± s in the tables and figures is defined by Equation (7). s_x is standard deviation, n = 4 number of repeated measurements, x_i individual value measured during the i-th experimental run, $\bar{x}$ arithmetic mean value of all measurements.

$$s_x = \sqrt{\frac{1}{n-1}\sum(x_i - \bar{x})^2} \quad (7)$$

Agreement is evaluated with the root-mean-square error RMSE and mean absolute percentage error MAPE definitions in Equations (8a) and (8b), where y_i is the experimentally measured thrust or torque value at the i-th data point, and $\hat{y}_i$ is the corresponding thrust or torque value predicted by the model. Leave-one-sweep-out cross-validation was applied. In each of the four iterations, C_T and C_M were identified from the 40÷80% data of three sweeps and evaluated on all retained points of the remaining sweep. This procedure tests whether the identified coefficients are transferable between independent experimental runs and avoids evaluating the model using the same data employed for fitting.

$$RMSE = \sqrt{\frac{1}{n}\sum(y_i - \hat{y}_i)^2} \quad (8a)$$

$$MAPE = \frac{100}{n}\sum\left|\frac{y_i - \hat{y}_i}{y_i}\right| \quad (8b)$$

Piecewise-quadratic curves in Figure 4 are visual guides through the retained command means only. In Figure 5, both analytical curves are direct evaluations of Equations (1a) and (1b). The forward-flight map uses interpolation in measured thrust and remains entirely within the measured 40÷70% interval.

2.4. Electrical and vehicle-level calculations

The analytical motor current model uses the calibrated C_M and the interpolated optical RPM. With nominal no-load motor constant K_{V0} = 900 RPM/V, nominal no-load current I_{m0} = 2 A at nominal no-load voltage U_{m0} = 24 V and motor resistance R_m = 0.041 Ω, motor current follows Equation (9).

$$I_m = \frac{MK_{V0}U_{m0}}{9.55(U_{m0} - I_{m0}R_m)} + I_{m0} \quad (9)$$

Equations (10a) - (10d) close the motor, ESC and battery model. The ESC resistance is R_e = 0.008 Ω, battery resistance is R_b = 0.004 Ω and a conservative battery voltage of U_b = 21 V is adopted for forward-flight performance analysis. The physically admissible smaller root, $0 \le \sigma \le 1$, is used. K_E is back electromotive force constant, and U_{req} is the effective voltage required by the ESC-motor branch to sustain the prescribed rotational speed and torque, including the voltage drop across the ESC resistance.

$$K_E = \frac{U_{m0} - I_{m0}R_m}{K_{V0}U_{m0}} \quad (10a)$$

$$U_m = I_mR_m + K_EN \quad (10b)$$

$$U_{req} = U_m + I_mR_e \quad (10c)$$

$$U_{req} = \sigma[U_b - R_b(4\sigma I_m + I_{other})] \quad (10d)$$

Shaft power P_{shaft} and electrical-to-shaft efficiency η are calculated from synchronized channels by Equations (11a) and (11b). U is the measured DC voltage at the input of the tested ESC-motor branch.

$$P_{shaft} = \frac{2\pi NM}{60} \quad (11a)$$

$$\eta = \frac{P_{shaft}}{UI_e} \quad (11b)$$

For four equal branches and I_{other} = 1 A auxiliary consumption, total current I_b and constant-current endurance in minutes t_{fly} are given by Equations (12a) and (12b). Auxiliary consumption of 1 A is determined from datasheet of other electrical peripherals, and it was confirmed by measuring and rounding up to higher value. Battery capacity is C_b = 10 Ah and usable capacity f_{use}=0.8K_b; 80% of total battery capacity K_b, the constant-current endurance is:

$$I_b = 4I_e + I_{other} \quad (12a)$$

$$t_{fly} = \frac{60f_{use}C_b}{I_b} \quad (12b)$$

The ideal payload and force-balance tilt θ associated with a selected per-rotor thrust limit are given by Equations (13a) and (13b).

$$m_{pay} = \frac{4T_{lim}}{g} - m$$
$$m_{pay} = \frac{4T_{lim}}{g} - m \quad (13a)$$

$$\theta_{max} = arccos\left(\frac{mg}{4T_{lim}}\right) \quad (13b)$$

For conditional forward flight, required thrust per rotor is first evaluated from Equation (14).

$$T_{req}(\theta) = \frac{mg}{4cos\theta} \quad (14)$$

The conditional speed bound combines static drag balance, geometric pitch speed and the stricter minimum in Equations (15a)-(15c). V_D is the static drag-balance speed, V_p is the geometric pitch-speed bound and V_{lim} is their minimum. The projected area varies from 0.028 to 0.035 m² and the assumed drag coefficient from 2.05 to 1.80; these are unmeasured screening inputs based on bluff-body practice [16].

$$V_D = \sqrt{\frac{2mgtan\theta}{\rho S(\theta)C_D(\theta)}} \quad (15a)$$

$$V_p = \frac{NH_p}{60} \quad (15b)$$

$$V_{lim} = min(V_D, V_p) \quad (15c)$$

Finally, Equation (16) converts conditionally limited speed and endurance t_{fly} in minutes into conditional range R in kilometers.

$$R = \frac{V_{lim}t_{fly}60}{1000} \quad (16)$$

3. RESULTS

3.1. Static electrical and mechanical results

Electrical input power U·I exceed shaft power because part of the supplied power is dissipated within the ESC–motor–propeller system. The difference increases with load, primarily due to current-dependent losses and the accompanying reduction in battery voltage. The electrical-to-shaft efficiency increases from 40.2% at 10% command to the highest measured value of 65.5% at 70%, before decreasing to 63.8% at σ = 80%.

Table 2 summarizes the retained pooled measurements. From 10% to 80%, current, thrust, and torque increase monotonically with command. At the highest point the mean branch current is 44.919 A, safely below the 65 A reference line; the excluded 90% regime would leave less than 1 A margin in the highest sweep.

The corresponding current and power trends are shown in Figure 4. Electrical input power U·I exceed shaft power because part of the supplied power is dissipated within the ESC–motor–propeller system. The difference increases

with load, primarily due to current-dependent losses and the accompanying reduction in battery voltage. The electrical-to-shaft efficiency increases from 40.2% at 10% command to the highest measured value of 65.5% at 70%, before decreasing to 63.8% at σ = 80%.

Table 2. LY-10KGF measurements (mean ± sample SD)

σ [%]	N [RPM]	I [A]	T [g]	M [Nm]	η [%]
10	2246±218	0.43±0.08	88±17	0.018±0.003	40.2
20	4833±53	2.81±0.06	446±10	0.080±0.001	58.2
30	6613±49	6.70±0.09	875±15	0.147±0.001	61.8
40	7956±63	11.81±0.07	1285±12	0.213±0.002	61.5
50	9109±67	17.34±0.14	1683±21	0.276±0.003	62.6
60	10128±41	23.71±0.07	2093±9	0.345±0.002	64.1
70	11148±1	31.82±0.59	2587±35	0.425±0.008	65.5
80	12219±97	44.92±0.14	3195±9	0.526±0.003	63.8

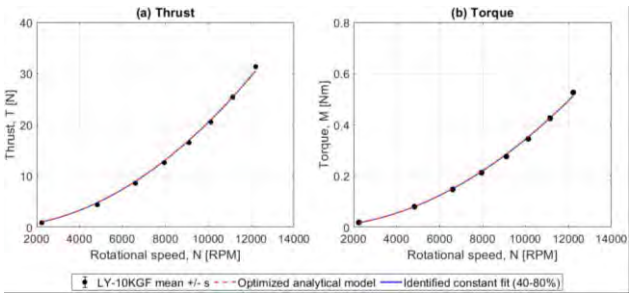

Figure 5. Static thrust (a) and torque (b) versus optical RPM

3.2. Calibrated and identified coefficients

Identification using 20 raw data points from 40% to 80% gives C_T=0.1506 and C_M=0.0099. The constrained geometric optimization produces the same values to plotting precision. **Table 3** reports the agreement metrics, and Figure 5 compares both models with pooled measurements.

Table 3. Agreement in the 40÷80% identification region

Model	C_T	C_M	T MAPE [%]	M MAPE [%]
Analytic geometry	0.1506	0.0099	2.274	2.331
Identified constant	0.1506	0.0099	2.274	2.331

The optimized geometric and identified constant curves overlap because their coefficients are numerically equal.

When evaluated against the same 20 measurements from the 40÷80% command range that were used for coefficient identification, the fitted model gives RMSE 0.5747 N for thrust and 0.00998 Nm for torque; the corresponding centered R^2 values are 0.9924 and 0.9918. Leave-one-sweep-out validation increases MAPE only slightly, from 2.274% to 2.326% for thrust and from 2.331% to 2.419% for torque. This small increase indicates that a single constant pair of C_T and C_M provides a repeatable approximation for the tested 10×5×3 propeller under static conditions within the 40÷80% command range. However, the results do not justify applying the same coefficients outside this operating range or to another propeller.

3.3. Vehicle-level analysis

Per-sweep interpolation to 1350 g per rotor gives hover at 41.65±0.32% command, 8146±91 RPM and 12.715±0.134 A per branch. Equations (12a) and (12b) give 51.86±0.54 A total and t_{fly}=9.26±0.10 min. At 70%, measured branch current is 31.82 A, total current is 128.29 A and t_{fly}=3.74 min. Mean thrust of 2587.3 g per rotor gives necessary vertical trust for steady horizontal flight at 58.55° pitch angle. Table 4 summarizes these results.

Table 4. Conditional vehicle-level results

Quantity	Conditional result
Hover	41.65%; 8146 RPM; 9.26 min
70% point	31.82 A/branch; 3.74 min
Tilt angle at σ = 70%	58.55°
Measured-current max range at θ = 12.34 °	9.363 km; 17.44 m/s; 8.95 min
Analytical-current max range θ = 12.34 °	10.338 km; 17.44 m/s; 9.88 min
Maximum conditional speed bound at σ = 70%	23.6 m/s at 58.55°

The corresponding speed and range maps are presented in Figure 6. In Figure 6a. Up to 12.344°, V_D is active; beyond the crossing, V_p is active. In Figure 6b, the blue curve uses the analytical BLDC/ESC current model with experimentally calibrated propeller loading, whereas the magenta curve directly scales the measured LY-10KGF branch current.

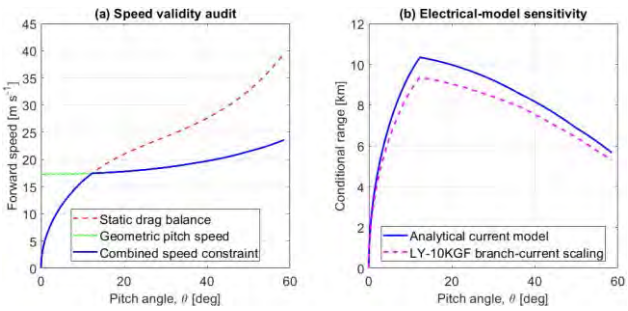

Figure 6. Conditional forward-flight analysis: speed constraints (a) and range sensitivity to the current model (b)

Both range curves peak at $\sigma = 42.5\%$, $\theta = 12.34°$ and $V_{lim} = 17.44$ m/s. When the measured motor current is used, the estimated range is 9.363 km with $t_{fly} = 8.95$ min, while the analytical predicted current model gives 10.348 km of range with $t_{fly} = 9.88$ min, 10.42% higher. The apparent sharp decrease is a slope change at the min (V_D,V_p) constraint switch: thereafter speed grows slowly, while required thrust, current and endurance penalty continue to rise.

4. DISCUSSION

The final analytical and identified coefficients are intentionally equal. The geometric parameters were optimized against the experimental C_T and C_M, so the overlapping curves in Figure 5 demonstrate successful calibration rather than an independent theoretical prediction. The analytical formulation remains useful because it shows how the aspect ratio, blade-area factor, mean-speed factor, downwash correction and drag assumptions influence the coefficients. However, λ and ζ cannot be interpreted separately from this data set because only their product $\lambda\zeta^2$ is observable. The next step is to test other three-bladed propellers with suitable motors in order to validate or refine the selected parameters.

The exclusion of the 90% and 100% command levels is justified on both electrical and methodological grounds. The 90% mean does not exceed 65 A, but individual runs approach the rating and leave no practical current or control reserve; every 100% run exceeds the rating. Removing both regimes before analysis avoids fitting a local static model in a region dominated by component limits and heat accumulated during preceding runs. The highest retained 80% point remains within the controller rating.

The corresponding current and power trends are shown in Figure 4. The electrical input power U·I exceeds the shaft power because part of the supplied power is dissipated through losses in the ESC and motor. The absolute difference between electrical input power and shaft power increases with loading, which is consistent with the growing influence of current-dependent losses. When efficiency is evaluated separately for each experimental measurement and then averaged across the four repetitions, it rises overall from 40.2% at 10% command to the highest measured value of 65.5% at 70%, before decreasing to 63.8% at 80%.The low-command value is particularly sensitive to measurement uncertainty because both torque and input power are small. Its generally lower value reflects the greater relative contribution of no-load and weakly load-dependent losses, whereas the decrease at 80% is consistent with increasing current-dependent losses. The reported quantity is the electrical-to-shaft efficiency of the tested ESC–motor branch under static propeller loading and does not include the aerodynamic conversion efficiency of the propeller.

Directly measured current is the stronger basis for endurance because it avoids propagating any residual torque-model error through the motor equations. The 10.42% separation between the two Figure 6b curves quantify model sensitivity. The total value 128.29 A at 70% is the sum of four branches and 1 A auxiliary load; it must not be compared with the 65 A rating of one ESC.

Figure 6 remains a conditional analysis. The surface area and drag coefficients were not measured, V_p omits slip and inflow, static data do not represent oblique flow, and the calculation assumes four equally loaded rotors and constant usable battery capacity.

Future validation should combine bidirectional airspeed, attitude, RPM, voltage, current and temperature measurements with controlled battery state. Raw synchronized samples, tachometer redundancy, calibration certificates and repeated zero checks would permit a complete uncertainty budget rather than descriptive between-sweep repeatability alone.

5. CONCLUSION

Four LY-10KGF measurements provide 32 retained points from 10% to 80%. A 40-80% least-squares fit gives $C_T = 0.1506$ and $C_M = 0.0099$. Constrained calibration with $A = 12.7$, $\varepsilon = 0.918$, $\lambda = 0.812$, $\zeta = 0.620961$, $e = 0.80$ and $\alpha_0 = -0.625°$ reproduces both coefficients. Leave-one-run-out MAPE is 2.326% for thrust and 2.419% for torque.

The results indicate that the GEPRC EM3115–HAKRC–10×5×3 combination is adequately, but not optimally, matched within the retained operating range. The 65 A ESC is adequate up to the highest retained 80% command level; however, the limited current margin at 90% and the rating exceedance at 100% indicate that it is not suitable for unrestricted operation near full command. An ESC with a higher continuous-current rating would provide greater transient-current and thermal margin and reduce the risk of controller overload. A broader continuous operating range could also be achieved by reducing the propeller load through a smaller pitch, diameter or blade number, or by selecting a motor with a lower K_V or a higher continuous-current and thermal rating. These changes must be evaluated as a complete motor–ESC–propeller system, since a higher-rated ESC or motor alone would not reduce the required current or necessarily improve efficiency.

Measured current gives hover at 8146 RPM and 41.65% command with t_{fly}=9.26 min. At 70%, t_{fly} falls to 3.741 min, while the conditional force-balance tilt reaches 58.55°. The maximum conditional range is 9.363 km when calculated from measured branch current and 10.338 km when calculated from the analytical current model. These values

support component selection and transparent design comparison, but not flight certification or validation.

Abstract: *At transonic and supersonic operating regimes, shock and expansion waves form and interact with boundary layer forming along the walls of the body moving through the fluid. In such cases, both compressibility and viscosity effects must be considered in order to obtain valid estimations of the pressure field and resulting aerodynamic forces, as well as some specific flow features such as separation point, wake shape, etc. The paper presents several numerical studies of the relatively standard transonic/supersonic flow cases (around the airfoil, inside a duct where reflected waves also appear, etc). Its main goals are to test different numerical set-ups and provide a quantification of the possible accuracy and reliability of the inspected numerical models that can be achieved when shock-wave/boundary-layer interactions might be of importance. Different computational meshes, turbulence models, solvers, etc. are tried and compared. The most significant conclusions and recommendations are provided in the end.*

Keywords: *shock-wave, boundary-layer, interaction, CFD.*

1. INTRODUCTION

Both shock-waves and boundary-layers appearing along the walls are still regarded today as distinct fluid flow phenomena, insufficiently resolved but of great importance for aerospace applications since they directly affect the aerodynamic forces and consequently aerodynamic efficiency [1-7]. They are particularly interesting to study when combined together in viscous, compressible flows (highly-subsonic, transonic and supersonic) since they may produce significant drag increase leading to severe separation zones as well as flow instabilities and difficulties with control, directly affecting flight envelope and safety. For all these reasons, the topic of shock-wave/boundary-layer interaction (SWBLI) is still very important and actively investigated, particularly the ways to lessen its potentially negative effects [4,5].

The most employed research approaches for studying SWBLI are numerical and experimental [1-7]. Ideally, computational fluid dynamics (CFD) methods usually require very fine meshes and advanced turbulence modelling. Due to the great computational cost and small temporal and spatial scales required, unsteady Reynolds-averaged Navier-Stokes (URANS) equations are still very much employed [5,6,7], even though different scale-resolving methods (such as large eddy simulation, LES, and detached eddy simulation, DES) are increasingly tried [1-3,7]. In both cases, experimental validation is preferred since very complex flow phenomena is investigated. Both quantitative (pressure and force measurements, particle image velocimetry, etc.) and quantitative methods (e.g. Schlieren photography) are common [4].

In the past decades, CFD techniques have been utilized very much. They have now reached the level of great accuracy in addition to being much more user-friendly than before (e.g. mesh generation process is much facilitated as is the solving of systems of equations). Available computational power is also much increased. However, CFD methods still perform the best in the cases of attached flows and nominal operating conditions, and additional validation in cases involving any kind of flow phenomena is necessary. Among the recognized flow phenomena, the SWBLI is certainly one of the most important and interesting since most of the governing mechanisms are still not explained in detail. Even though LES and DES technics are recommended today in such flow cases, the extents of (U)RANS applicability should also be determined, particularly when combined with refined numerical grids and spatial geometric models (planar analysis by standard turbulence models proved inadequate).

This paper is organized in the following manner. The flow around the airfoil is studied in chapter 2. The flow in the channel with a shock generator is described in chapter 3. The flow around a bluff body in a channel is presented in chapter 4. All these separate sections contain details regarding the employed computational models, meshes, numerical set-ups and obtained results. Finally, some of the most important conclusions are offered in the last chapter.

2. EXAMPLE 1

Example 1 studies the transonic flow around a supercritical airfoil.

2.1. Expected flow physics (sonic bubble)

Highly-subsonic flows, approaching transonic, usually involve a sonic bubble on the upper surface of the airfoil ending in a shock-wave, and affecting the subsequent flow separation. Additional complexity may be transonic buffet, a transient flow phenomenon, caused by the dynamic interaction of shock and boundary layer. It has often been studied, and some representative cases have been established. Type II transonic buffet where the shock oscillatory moves (back and forth) is particularly interesting [1]. It depends on the combination of angle-of-attack α, Mach number M and Reynolds number Re (and even the type of flow transition), and involves an oscillating sonic bubble on the airfoil suction side.

2.2. Airfoil geometry, operating conditions

This study seeks for the simplest computational setup capable of successfully simulating highly-subsonic flow (that might also include a transonic buffet) around the ONERA OAT15A supercritical airfoil at the different Mach numbers, M = 0.715 and M = 0.730, where transient flow is not and is respectively expected. In both cases, Reynolds number is Re = 3,000,000 (computed with respect to the chord). This airfoil, designed to save fuel, with a flattened top surface and 12.5% maximal relative thickness, is widely used in aerospace research and has a recognized "shaking" effect.

2.3. Computational domain, mesh and numerical set-up

A relatively simple, standard computational domain and meshes are employed. The airfoil OAT15A, generated from the publicly available coordinates [8], is surrounded by a circular domain (extending 10 chord lengths c in radial direction) and extruded by 20% c in the third, spanwise direction. Initially, 2-dimensional flow simulations were tried, but they appeared completely incapable of capturing the flow nuances of interest even though planar buffet is the main focus here (and not a spatial one appearing on a finite wing). Fortunately, even a slight extrusion of the planar computational domain, and quasi-spatial consideration of the flow phenomena, greatly improves the accuracy and stability of the numerical study.

Hybrid, unstructured computational grids were formed, numbering several million cells (a detail is illustrated in Fig. 1). First layer thickness corresponded to the dimensionless wall distance $y^+ \approx 5$, whereas meshes were additionally refined along the airfoil. In the second iteration, adapted numerical grids were used (Fig. 1, bottom).

Flow simulations were performed using ANSYS Fluent where the governing flow equations are solved by finite volume method [9]. Flow is steady or transient, compressible and turbulent. Turbulence was resolved either by k-ω SST turbulence model (as more computationally efficient) or by wall-modeled large eddy simulation (WMLES) (since this relatively recent model should be capable of resolving a large portion of turbulent motion). Air is assumed as the ideal gas. Pressure far-filed boundary conditions were assumed far away from the airfoil (static pressure p and static temperature T corresponding to total values p_o = 101325 Pa and T_o = 300 K, respectively, Mach number and flow direction corresponding to the angle-of-attack α = 3.5°), while the two side faces form a periodic boundary, and airfoil walls are no-slip. Pressure-based coupled solver was employed, and all spatial discretizations are 2nd order. Flow computations are performed until reaching the (quasi-) convergence of the aerodynamic force coefficients.

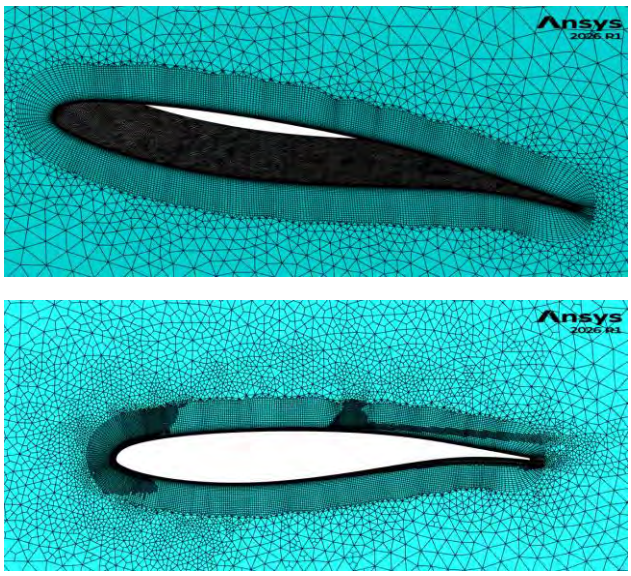

Figure 1. Details of the computational meshes around the airfoil OAT15A, original (top) and adapted (bottom)

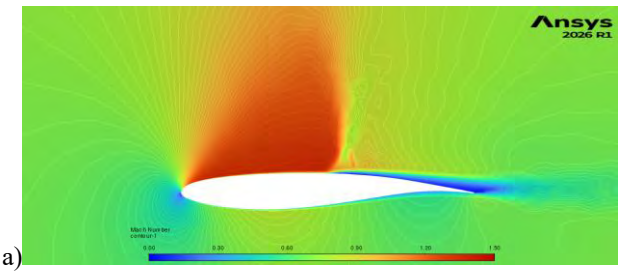
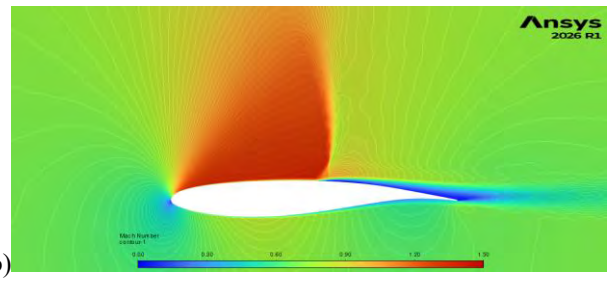
2.4. Results and discussion

Computed flow visualizations are illustrated in Fig. 2 (courser vs. finer mesh and k-ω SST vs. WMLES).

a)



b)



c) 
Figure 2. Instantaneous contours of Mach number around the airfoil OAT15A at M = 0.73, a) k-ω SST, coarser mesh, b) k-ω SST, adapted mesh, c) WMLES, adapted mesh (during buffet)

Overall, by using *k-ω* SST turbulence model, it is possible to obtain the main, averaged flow features. By additionally refining the mesh, the contours of shock-waves can be precisely captured. However, to capture the expected oscillations of the sonic bubble and shock-wave it is necessary to employ one of the scale-resolving turbulence models (here WMLES). Figure 2c illustrates the instantaneous contours of Mach number near its most upstream position, when boundary layer is the longest, and lift coefficient approaches its minimum. The features of the resulting λ-wave are also clearly delineated. In general, the shock-wave moves between approximately 47% to 59% chord length, when moving from its most upstream to most downstream location, respectively [1]. The oscillating shock-wave directly affects the length of the separation zone appearing on the upper airfoil surface, and induces the variability of aerodynamic coefficients.

Lift C_L and drag C_D force coefficient variability in time is depicted in Fig. 3. Mean values of lift coefficient and Strouhal number are close to the experimentally documented ones ($C_{L,\mathrm{exp}}$ = 0.95±0.15 and St ≈ 0.06, respectively [1]). However, for a more precise description of transient behavior, more refined spatial- and time-scales are required.

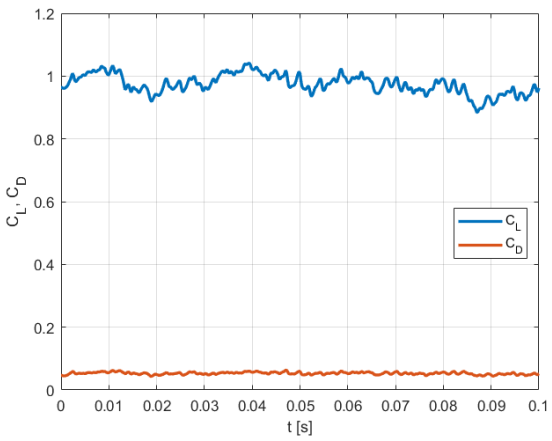


Figure 3. Oscillating aerodynamic coefficients (lift and drag) during buffet

Steady fluid flow obtained at M = 0.715 is visualized in Fig. 4 by Mach number contours. Some differences to the unsteady flow case illustrated in Fig. 2 are apparent. Most distinctly, boundary layer is thinner and λ-wave is less pronounced which leads to improved aerodynamic performance (increased lift and decreased drag coefficient).

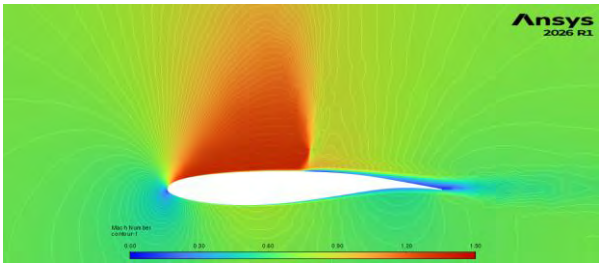

Figure 4. Steady flow at M = 0.715 computed by *k-ω* SST turbulence model

3. EXAMPLE 2

Example 2 studies the channel flow with shock generator and reflected waves.

3.1. Expected flow physics (reflected waves)

Supersonic flow through channels of variable geometry or with shock generators (like steps, wedges, etc.) usually involve a complex pattern of waves (starting from the initial shock wave that is then reflected from the opposite wall, as well as the interference of reflected waves). Additional simulating challenges stem from the interference of waves with the boundary layer that lead to recirculating zones, thickening of the boundary layer and final separation.

3.2. Geometry of the channel and wedge, operating conditions

The current study explores a simple channel flow with a 20° wedge (10 mm in length) positioned at the first third of the channel upper wall [4,5]. Mach number of the flow is M = 2.95, whereas the total length of the channel is 130 mm.

3.3. Computational domain, mesh and numerical set-up

Computational domain corresponds to the previously mentioned channel geometry.

Again, the computational mesh is hybrid (including thin layers of cells along the walls corresponding to the dimensionless wall distance $y^+ \approx 1$), unstructured, as simple and uniform as possible, initially numbering approximately 800,000 cells. Later, in the computation process, this initial mesh was adapted in the zones of increased density gradients, leading to a total number of approximately 2 million control volumes. The differences between the two meshes can be observed in Fig. 5.

In this case, due to the larger undisturbed flow Mach number (in comparison to the transonic flow around the airfoil), density-based solver was employed. Again, the flow is steady, viscous (turbulent, resolved by *k-ω* SST turbulence model) and compressible (with the assumption of ideal gas). Outlet boundary conditions are now more convoluted, i.e. harder to accurately define (due to the

apparition of local losses). Pressure outlet condition was assumed with the same value of static pressure as defined along the inlet, and with the careful monitor of the total mass flux (entering and exiting the domain). Since convergence might be difficult in cases involving complex shock-wave interaction, Courant-Friedrichs-Lewy (CFL) number was reduced to 0.5, together with all the relaxation factors. Simulations were performed until reaching the converged values of outlet mass flow rate and aerodynamic coefficients along the upper wall (where the wedge is located).

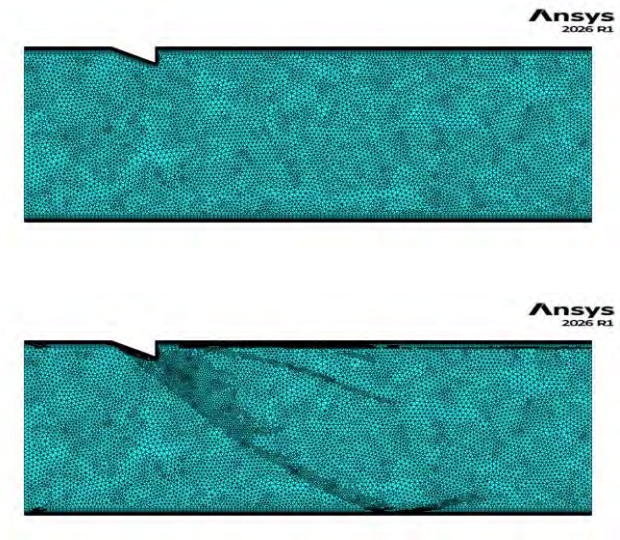

Figure 5. Differences of the initial and adapted meshes in the channel with the shock generator

3.4. Results and discussion

The obtained Mach number contours are depicted in Fig. 6.

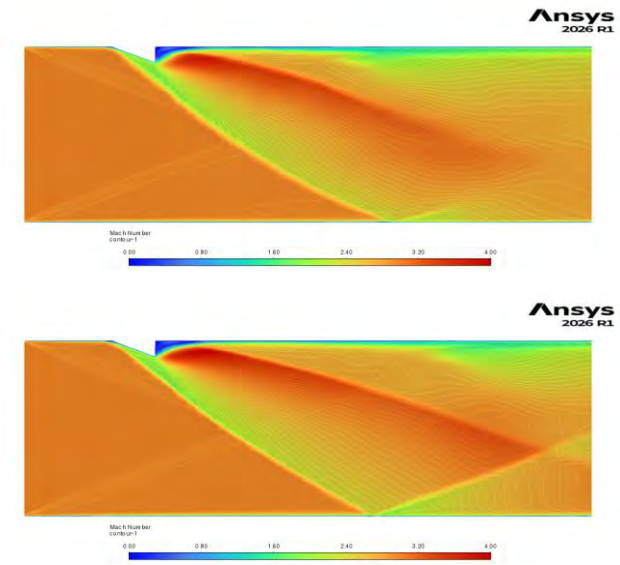

Figure 6. Contours of Mach number inside the channel (original vs. adapted grid)

It can immediately be observed that a much clearer pattern of shock waves can be obtained on the finer (locally adapted) computational grid (again by using *k-ω* SST turbulence model). The original oblique shock, induced by the wedge, forms and then reflects from the lower wall producing a small recirculating zone at approximately x/l = 0.59. At the same time, due to the wake formed at the bottom of the wedge, expansion waves are also noticeable, as well as the accompanying oblique shock, and their subsequent interaction with the reflected wave. Wake behind the wedge narrows fast, but the boundary layer along the upper wall thickens. These flow visualizations are in line with the results of other studies [4,5]. Since the resulting, averaged shock-wave pattern was the main goal here, the *k-ω* turbulence model proved sufficient. For a more accurate and detailed resolution of the wedge wake, a scale-resolving model should be employed.

4. EXAMPLE 3

Example 3 studies the flow around a bluff body with massive separation.

4.1. Expected flow physics (wide turbulent wake)

Modern high-speed, energy-efficient train transportation requires a careful examination of the (choked) fluid flow surrounding a bluff body in a channel where SWBLI is also present. The axisymmetric flow initially accelerates around the body, leading to the shock-wave appearing in the rear part that then interacts with the boundary-layer and results in massive flow separation aft of the bluff body [7].

4.2. Geometry of the bluff body, operating conditions

Geometry of the pod corresponds to the previous studies [7]. It is an axisymmetric body (with the total length of 5 m and maximal radius 0.49 m) comprising ellipsoidal fore and aft sections, with the cylindrical, tangentially-continuing medium part. The pod is located in a cylindrical channel with the blockage ratio 0.2.

4.3. Computational domain, mesh and numerical set-up

One twelfth of the original geometry is modelled, since axisymmetric flow is prevailingly expected (apart from the wake). The channel extends 2 and 5 pod lengths fore and aft of the model, respectively.

Again, the initial computational grid is hybrid unstructured, with the limited cell size across the computational domain, local refinement of the cells representing the pod walls, and layers of thin prismatic cells along both of the wall surfaces (pod and channel walls). Original mesh comprises approximately 320,000 cells (corresponding to 3,800,000 cells for the entire domain), while the adapted one grew to nearly 900,000 cells, Fig. 7.

Since the investigated inlet velocity corresponds to M = 0.625 pressure-based solver is employed (numerical set-

up is similar to the one employed in Example 1). The remaining boundary conditions are as follows: static pressure p = 10,000 Pa, static temperature T = 300 K, turbulence intensity 1% and dynamic viscosity ratio μ_t/μ = 10. Turbulent flow was resolved by both k-ω SST turbulence model and WMLES.

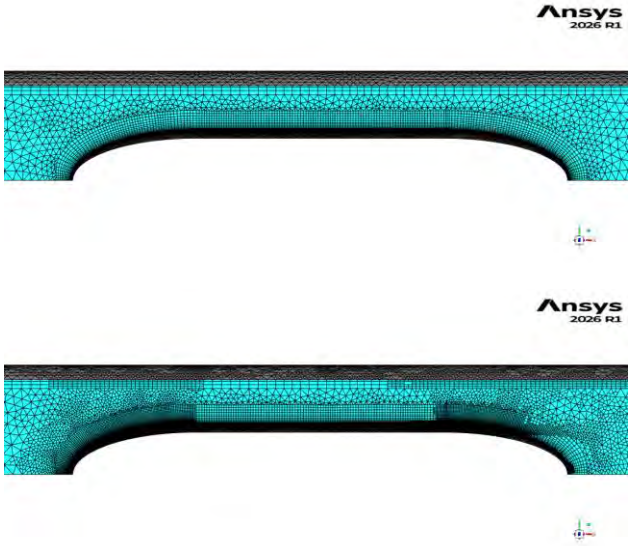

Figure 7. Details of the computational meshes around the bluff body

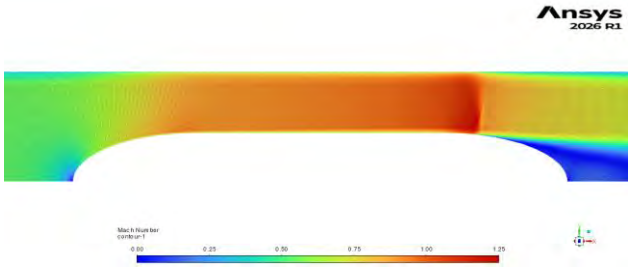
4.4. Results and discussion

According to the available data [7], the expected pod drag coefficient is C_D = 0.8 while the mass flow rate is 7.5 kg/s. Here, the computed mass flow rate closely matches the expected value, whereas the drag coefficient estimated by k-ω SST turbulence model and WMLES is 0.6 and 0.8 (averaged), respectively. Qualitative flow visualization is represented in Fig. 8. Even though steady vs. instantaneous flows are compared, it is apparent that URANS underestimates the size of the wake (attenuates the complex vortical structures appearing along the aft section of the pod). It is also noticeable that both the pod geometry and the shock-wave position directly affect boundary-layers and their separation on both walls, corresponding to both the body/pod and the surrounding channel. Again, when more complex (scale-resolving) turbulence model is employed, the shock-wave moves backwards and strongly affects the wake. However, it must be noted that for the adequate representation of the wake, very fine meshes must be employed.



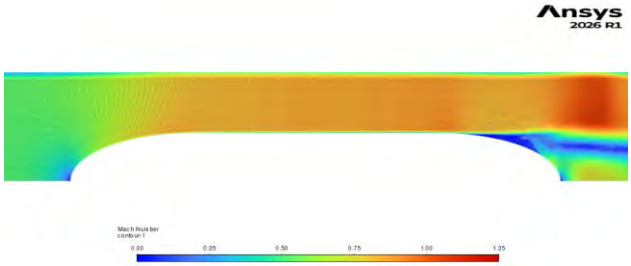


Figure 8. Instantaneous contours of Mach number around the bluff body, URANS (top) and WMLES (bottom)

5. CONCLUSION

This study numerically examined several typical flow cases involving the complex interaction between shock-waves and (turbulent) boundary-layers that are extremely important in aerospace engineering (and can be correlated to flows over isolated wings, inside supersonic inlets, and around isolated fuselages). In the future, studying flows around the full aircraft configuration might also be interesting, as well as extending the study to include the aspects of aeroacoustics.

Whereas some standard numerical setups were employed (prevailingly URANS), representative flow visualizations (such as Mach number and density contours indicating shock patterns, and separation zones pointing to thickened boundary-layers) that were obtained satisfactorily match the results of other authors. However, employing finer numerical grids together with more complex turbulence models should certainly lead to additional increase in the accuracy and reliability of numerical results, particularly when dynamic effects are the research focus, and that course shall be explored further in the future. For now, it is highly recommended to employ at least 2.5D analysis in similar cases, and locally refined meshes, particularly in the zone of expected SWBLI (but also zones fore and aft of it) as well as the wake. If any kind of massive separation is present, scale-resolving turbulence models and very fine temporal- and spatial scales should be employed.

Abstract: *This paper presents the calibration and performance characterization of a high-pressure jet supply system developed for experimental investigations of powered wind tunnel models. The system supplies high-pressure air through a custom flow-through internal strain-gage balance to interchangeable sonic and supersonic nozzles mounted on the wind tunnel model. Tests conducted under no-main-flow conditions evaluated the transient response of the system, quantified pressure losses along the internal flow path, determined actual jet characteristics from direct thrust measurements, and assessed nozzle operating regimes. The obtained results provide essential baseline data on the internal flow behavior and jet performance. These data will support reliable interpretation and analysis of phenomena during subsequent wind tunnel tests with powered models.*

Keywords: *powered wind tunnel model; jet thrust; flow-through balance; pressure losses; reaction control system.*

1. INTRODUCTION

Powered wind tunnel testing plays a critical role in the development of aerospace vehicles, particularly for configurations relying on reaction control systems (RCS), or other propulsion-based control mechanisms. These tests enable the simulation of jet interactions with external flow, providing essential data on aerodynamic interference, thrust vectoring effectiveness, and overall vehicle stability and control under representative flight conditions [1]. Accurate replication of jet exhaust or control thrusters is challenging due to the need for precise matching of jet pressure ratios, mass flow rates, and plume characteristics while integrating high-pressure supply systems within constrained model geometries without compromising force and moment measurements [2,3].

Traditional approaches to jet simulation in wind tunnels often employ cold or heated gas routed through the model support system [2]. Previous studies have highlighted the importance of detailed calibration of jet supply systems to quantify pressure losses, transient response, and actual delivered jet performance. For instance, investigations into RCS jet interactions for planetary entry vehicles, such as the Mars Science Laboratory, underscored the need for high-fidelity simulation to reduce uncertainties in control authority and validate computational predictions [4]. Flow-through balances are utilized to accommodate the high-pressure air supply while simultaneously measuring the resulting aerodynamic loads and jet thrust [5]. Recent advancements in flow-through balance designs have enabled more accurate isolation of jet thrust from external aerodynamic forces in powered wind tunnel testing [6].

At the VTI, ongoing research into side jet interactions on slender missile configurations has necessitated the development of a dedicated high-pressure jet supply system. This system integrates a custom flow-through internal strain-gauge balance capable of delivering high-pressure air to interchangeable sonic and supersonic nozzles mounted on the wind tunnel model [7]. The present paper focuses on the calibration and performance of this high-pressure jet supply system. Key objectives include evaluating the transient response, quantifying pressure losses along the internal flow path, and determining actual jet characteristics via direct thrust measurements. These baseline data are vital for reliable interpretation of powered wind tunnel test results.

2. EXPERIMENTAL SETUP

The details of the test facility, test model, high-pressure jet supply system and the associated measurement techniques are given in the following subsections.

2.1. Test Facility

The test facility is the VTI Belgrade T-38 wind tunnel [8]. The T-38 is a large-scale blowdown wind tunnel designed to fulfill testing requirements across a Mach number range of 0.2 to 4.0. A Reynolds number of up to 100×10^6 per meter is achieved via a controllable stagnation pressure range of 1.2 bar to 15 bar [9–11]. The 1.5 m × 1.5 m test section features a 2-DOF model support system, which permits model movement within ±20º in pitch [12] and ±720 º in roll [13].

The flow is established by discharging compressed air from 2600 m^3 storage tanks, pressurized up to 20 bar, into the atmosphere, yielding a maximum run duration of 60 s. A solid-wall test section is used for subsonic and supersonic testing, where the Mach number is set by a second throat and a flexible nozzle [14], respectively. For transonic testing, a variable-porosity test section [15] with an ejector-assisted blow-off system for active Mach number control is inserted into the wind tunnel circuit.

2.2. Test Model

The generic missile model of VTI [16] is modified to accommodate a high-pressure supply and measurement system for powered wind tunnel testing. It consists of the ogive nose cone, a cylindrical fuselage, and four wrap-around fins. The model has a nominal body diameter of D = 64 mm and a slenderness ratio of L/D = 21.6. The cross-sectional view of the model mounted on the model support sting is shown in Figure 1.

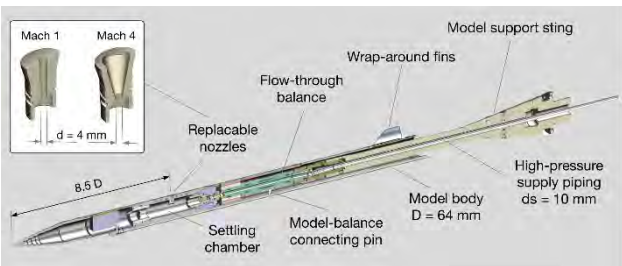

Figure 1 Powered wind tunnel model

The forward part of the model houses the settling chamber which is equipped with a nozzle. Its exit is positioned 8.5D downstream of the tip of the model nose. The nozzle body is threaded into the holder so that it can be easily replaced. Two different nozzles were designed and produced, both having a throat diameter of 4 mm, designed for Mach 1 and Mach 4 exit speeds.

A flow-through balance is integrated into the support sting, with the model mounted onto the balance via a connecting pin. This configuration prevents physical contact between the model and the support sting. Consequently, all mechanical loads acting on the model – including external aerodynamic forces and internal jet propulsion forces – are transmitted exclusively to the balance.

2.3. High-Pressure Supply System

Compressed air for powered model testing is prepared in an adjacent facility near the VTI T-38 wind tunnel. The plant utilizes two Bauer compressor units operating independently or in parallel at a maximum operating pressure of 270 bar. Initial moisture separation occurs within the compressors, followed by final drying via two aluminosilicate desiccant dryers. The conditioned air is stored at a maximum pressure of 200 bar in 14 reservoirs, providing a total volume of 9.8 m^3 (0.7 m^3 each).

The air preparation plant is linked to the VTI T-38 wind tunnel hall via a dedicated pipeline, consisting of metallic tubes with an inner diameter (ID) of 63.5 mm. Supply pressure entering the pipeline is modulated up to a maximum pressure of 150 bar using control valves located on a control panel positioned adjacent to the reservoirs.

A valve panel positioned near the wind tunnel test section enables the air flow to the model. The pipeline terminal is connected to this panel instrumentation via a 32 mm thermoplastic hose with a maximum operating pressure of 310 bar. The panel houses a computer-controlled solenoid valve (550 bar, 13 mm ID) and two manual isolation valves (350 bar, 25 mm ID) arranged in series and parallel. Upstream pressure is monitored by a 160-bar manometer. Downstream, a 25.8 mm ID thermoplastic hose (280 bar rating) routes the air to the model support mechanism, using a 6 m length for subsonic/supersonic testing or a 10 m length for transonic configurations.

Air is routed through the model support strut via a thermoplastic hose (16.3 mm ID, 140 bar rating), which connects to the upstream hose through a quick-disconnect threaded coupling (300 bar rating) for rapid assembly. The upper end of this hose exits the strut and terminates at a flexible rubber pneumatic hose (8 mm ID, 300 bar). The hose spans the junction between the fixed and moving parts of the model support. Its forward end connects to a pneumatic tube (10 mm ID, 200 bar rating) routed through an opening in the conical section of the support sting, establishing the compressed air flow path to the model.

Compressed air is delivered into the model interior via a pneumatic tube passing through the central bore of the support sting. The forward end of the tube connects to a flow-through balance. An internal axial channel (10 mm ID) along the balance body routes the airflow through a downstream tube (10 mm ID) into the settling chamber (44 mm ID, 143 mm length). The flow is then accelerated and discharged to the atmosphere through a nozzle.

2.4. Measurement Techniques and Equipment

For the jet supply system calibration, two measurement techniques were employed: jet reaction force measurement and jet supply flow measurements.

Force measurement was performed utilizing the VTI 1.5” 385 five-component flow-through internal strain-gauge balance. The normal force component (N) features a full-scale range of 2000 N with an accuracy of 0.144% of full scale; notably, only this component was relevant for the present measurement. Furthermore, calibration procedures

verified the balance accuracy under loads combined with internal airflow at a maximum pressure of 60 bar.

The jet supply flow is characterized by total pressure (p_0), static pressure (p), and total temperature (T_0). The mass flow rate is subsequently derived from these properties via standard isentropic relations.

Total and static pressures are acquired at the same axial station immediately upstream of the settling chamber using a Pitot probe and a wall pressure tap, respectively (Figure 2). These sensors are pneumatically connected to model-support-mounted miniature Entran pressure transducers, each featuring a measurement range of 70 bar and an accuracy of 0.05% of full scale.

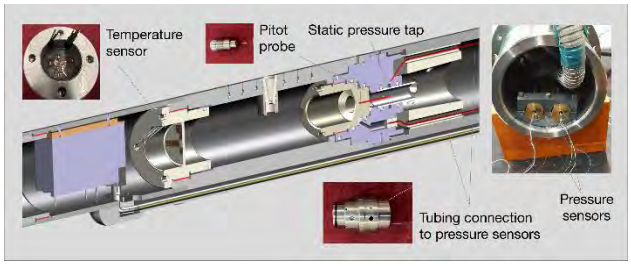

Figure 2 Jet supply flow measurements

The total temperature is measured in the settling chamber via a custom VTI half-bridge Wheatstone sensor. The circuit incorporates two active, high-pressure-rated ETG-50AE gauges (50 Ω ± 0.3%) and two precision resistors (47 Ω ± 0.1%), providing a 300 K measurement range with an accuracy of 0.2% of full scale. Dual-gauge flow exposure provides excellent common-mode rejection of strain and lead-resistance artifacts. Furthermore, the opposed-arm configuration linearizes bridge output and minimizes self-heating errors during constant-voltage operation.

2.5. Data Acquisition and Synchronization

The Pacific Instruments Series 6000 (PI6000) was utilized for high-bandwidth analog signal acquisition. All analog channels from the balance and jet supply flow sensors were conditioned and digitized by PI6000 Model 6052 input modules, each equipped with independent 16-bit A/D converters. A global sampling frequency of 400 Hz was applied across all channels. To suppress aliasing, each channel was filtered using an integrated four-pole low-pass Butterworth filter with a 30 Hz cutoff frequency.

System synchronization was managed via a PI6000 Model E6094A IRIG time-code reader, which decoded the IRIG-B signal and distributed the master sample clock, restricting intra-chassis analog skew to below 50 ns.

3. DATA PROCESSING

Evaluating the jet performance requires an accurate determination of the pneumatic state at the nozzle inlet. Compressed air routes through the internal balance into a settling chamber upstream of the nozzle. Because of frictional resistance along the internal conduits and expansion losses in the settling chamber, the pressure reaching the nozzle inlet drops substantially below the supply source pressure. To account for these losses, a mathematical methodology is developed below to calculate both the mass flow rate and the true stagnation (jet) pressure at the nozzle entry.

The mass flow rate ($\dot{m}_{in}$) delivered to the settling chamber is determined through the isentropic relations given in Eqn. (1), which utilize the jet supply flow parameters acquired just upstream of the chamber:

$$\dot{m}_{in} = \sqrt{\frac{2\kappa}{R(\kappa-1)}} A_{in} \frac{p_0}{\sqrt{T_0}} \left(\frac{p}{p_0}\right)^{\frac{1}{\kappa}} \sqrt{1-\left(\frac{p}{p_0}\right)^{\frac{\kappa-1}{\kappa}}} \tag{1}$$

where A_{in} is the inlet pipe flow area, κ is the specific heat ratio for air, and R is the specific gas constant for air. Recording these specific parameters allows for a complete thermodynamic characterization of the internal flow prior to its entry into the settling chamber.

Upon initiating the jet supple flow, the internal chamber dynamics undergo a transient phase. Steady-state behavior is achieved once the mass flow entering the chamber balances the mass flow discharging through the nozzle throat ($\dot{m}_{jet}$). Assuming choked conditions at the nozzle, this discharge mass flow becomes a function exclusively of the throat area (A_{th}) and the inlet properties (p_{jet}, T_0), as formulated in Eqn. (2):

$$\dot{m}_{jet} = \sqrt{\frac{\kappa}{R}} \left(\frac{2}{\kappa+1}\right)^{\frac{\kappa+1}{2(\kappa-1)}} A_{th} \frac{p_{jet}}{\sqrt{T_0}} \tag{2}$$

Under steady-state conditions, the settling chamber pressure (p_{sc}) represents an ideal jet pressure, derived by equating the mass flow rates from Eqns. (1) and (2). The actual stagnation pressure at the nozzle inlet (p_{jet}) is subsequently related to this ideal value by subtracting the internal pressure losses (Δp_{sc}), as expressed in Eqn. (3):

$$p_{jet} = p_{sc} - \Delta p_{sc} \tag{3}$$

Although the ideal jet pressure (p_{sc}) serves as a theoretical baseline, the true stagnation pressure (p_{jet}) at the nozzle inlet must incorporate irreversible losses within the settling chamber. To achieve an accurate determination of p_{jet}, the analytical model is coupled with empirical data by correlating the measured jet reaction force (F_{jet}) with the thrust equation, Eqn. (4):

$$F_{jet} = \dot{m}_{jet} v_e + (p_e - p_{inf}) A_e \tag{4}$$

Within this framework, p_{jet} serves as the independent variable required to close the system of equations. Given that the nozzle operates in a choked state, its exit Mach number (M_e) is first computed numerically via the isentropic area-Mach relation, Eqn. (5):

$$\frac{A_e}{A_{th}} = \left(\frac{\kappa+1}{2}\right)^{-\frac{\kappa+1}{2(\kappa-1)}} \cdot \frac{\left(1+\frac{\kappa-1}{2}{M_e}^2\right)^{\frac{\kappa+1}{2(\kappa-1)}}}{M_e} \tag{5}$$

The nozzle exit temperature (T_e) is then calculated using the resolved M_e and the measured settling chamber total temperature (T_0) via the isentropic relation, Eqn. (6):

$$T_e = T_0 \left(1 + \frac{\kappa-1}{2} M_e^2\right)^{-1} \tag{6}$$

The exit static temperature (T_e) is subsequently utilized to determine the flow velocity at the nozzle exit (v_e) via the following relation, Eqn. (7):

$$v_e = M_e\sqrt{\kappa R T_e} \tag{7}$$

By substituting these thermodynamic dependencies and the mass flow rate relation from Eqn. (2) into the thrust equation, Eqn. (4), p_{jet} is solved numerically to match the experimentally measured reaction force (F_{jet}). This approach ensures that all internal chamber losses are implicitly captured within the resolved p_{jet} value.

The nozzle exit static pressure (p_e) is calculated assuming an isentropic expansion from the jet pressure (p_{jet}) to the exit Mach number (M_e), Eqn. (8):

$$p_e = p_{jet}(1 + \frac{\kappa-1}{2}M_e^2)^{-\frac{\kappa}{\kappa-1}} \tag{8}$$

For calibration tests conducted without wind tunnel flow, the ambient pressure term (p_{inf}) in Eqn. (4) is taken as the local atmospheric pressure.

4. RESULTS

To isolate the characteristics of the jet supply circuit from external aerodynamic influences, calibration tests were conducted with the model mounted in the VTI T-38 test section under no-wind-tunnel-flow conditions (Figure 3).

Figure 3 Powered model mounted in the VTI T-38 wind tunnel

This approach ensures that the recorded pressure and temperature fluctuations are solely a function of the internal flow physics and valve actuation. Consequently, this methodology serves to calibrate the jet supply system, enabling a comprehensive evaluation of both its transient and steady-state performance characteristics.

4.1. Transient Performance

The previously established analytical framework assumes a steady-state equilibrium between the supply circuit and the nozzle exit. However, in practical wind tunnel testing, the time required to attain this equilibrium represents a critical operational constraint. This section evaluates the temporal behavior of the jet supply system, focusing specifically on the pneumatic latency and the filling dynamics of the settling chamber.

The test sequence was executed across nine discrete pressure steps, increasing the supply pressure (p_s) from 20 bar to 60 bar in 5 bar increments. For each step, data acquisition was triggered simultaneously with the opening of the computer-controlled solenoid valve. The measured quantities were continuously recorded for a 10-second duration, ensuring a sufficient window to capture the entire transition from the initial rest state to a stabilized steady-state plateau. All data channels were acquired at a sampling frequency of 400 Hz. This entire testing sequence was first performed for the Mach 1 nozzle configuration and subsequently repeated for the Mach 4 nozzle.

Figure 4 illustrates the transient mass flow rate ($\dot{m}_{in}$) response for the Mach 1 nozzle configuration across the evaluated range of supply pressures (p_s). To suppress experimental noise while preserving the transient peak characteristics, the raw time-series data were conditioned using a second-order Savitzky-Golay filter with a 50-point moving window (corresponding to 0.125 s).

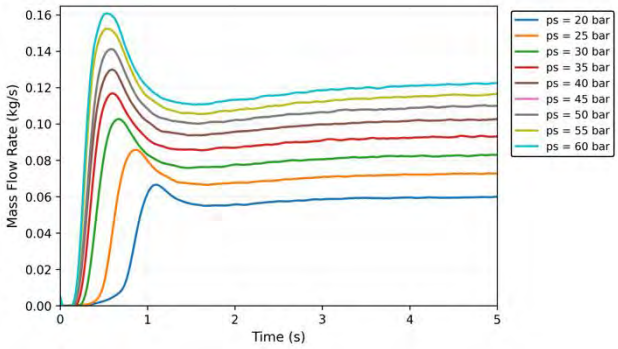

Figure 4 Transient response of the jet supply circuit

Comparative testing revealed no significant discrepancy in transient response between the Mach 1 and Mach 4 nozzle configurations. This indicates that pneumatic latency and filling dynamics are dominated by the upstream supply circuit and chamber volume rather than nozzle geometry.

The time-dependent mass flow rate ($\dot{m}_{in}$) exhibits several distinct operational phases. Following the valve trigger, a distinct dead time occurs before initial flow detection. This latency is inversely proportional to the supply pressure – decreasing from 0.5 s at 20 bar to 0.2 s at 60 bar – and is attributed to the pressure wave propagation time through the internal piping. Post-latency, the flow exhibits a steep gradient ($d\dot{m}_{in}/dt$) leading to a significant transient overshoot. At 60 bar, the mass flow peaks at approximately 0.16 kg/s, which is nearly 33% higher than its eventual steady-state value.

This overshoot stems directly from the volumetric filling of the settling chamber. Initially, the maximum pressure differential between the supply line and the empty chamber drives a high inflow, while the nozzle exit flow is restricted by the low chamber pressure. As the chamber fills, the rising internal pressure (p_{sc}) simultaneously reduces the inflow rate and increases the nozzle discharge rate. Equilibrium is established roughly 4.0 s after the initial rise, when the filling and exhaust mass flows balance.

Consequently, this dynamics dictate the wind tunnel testing protocol. To ensure true steady-state conditions, a minimum dwell time of 4.0 s is required post-activation before recording valid aerodynamic data. This delay ensures the pneumatic system has fully transitioned into the steady-state regime assumed by the analytical model.

4.2. Steady-State Performance

This section characterizes the steady-state pneumatic efficiency of the jet supply circuit. By coupling the analytical framework from Section 3 with empirical force and pressure data, internal losses between the upstream supply lines and the settling chamber are quantified for both the Mach 1 and Mach 4 nozzle configurations.

The tests were conducted across nine discrete supply pressure steps (p_s= 20 bar to 60 bar in 5 bar increments). Steady-state data acquisition simultaneously captured the total duct pressure (p_0), static duct pressure (p), total temperature (T_0), and jet reaction force (F_{jet}). To exclude the transient filling dynamics, data logging was initiated only after a 4-seconds post-activation dwell time. For each pressure step, parameters were sampled at 400 Hz for 10 s. This approach yielded a statistically robust dataset that minimized high-frequency pneumatic noise and ensured a precise determination of the mean properties.

Prior to testing, system integrity was verified via a pressure-decay leak check. The isolated circuit was pressurized to 60 bar and monitored for 10 minutes using the internal transducers (p_0, p); no detectable pressure drop occurred. This verified zero mass leakage into the model interior, preserving force measurement accuracy.

The Mach 1 and Mach 4 nozzle comparative performance at tested supply pressures are summarized in Figure 5. The total pressure drop across the system (Δp_{tot}) is decomposed into two primary components: losses within the piping upstream of the model (Δp_{up}) and losses generated inside the settling chamber itself (Δp_{sc}). The latter is resolved by comparing the ideal jet pressure (Δp_{sc}) with the actual jet stagnation pressure (Δp_{jet}) according to Eqn. (3) of the analytical model.

Although the upstream piping constitutes the largest portion of the total pressure drop, the settling chamber contribution remains significant. Specifically, for the Mach 1 nozzle, the settling chamber's share of total losses increases from 21.0% at p_s= 20 bar to 31.7% at p_s= 60 bar. This trend indicates that internal chamber inefficiencies driven by intensified turbulence and irreversible expansion become increasingly dominant at higher mass flow rates.

The jet stagnation pressure p_{jet} as a function of supply pressure p_s for both nozzle configurations is presented in Figure 6, together with the ideal settling chamber pressure p_{sc} calculated from mass-flow continuity. At the lowest supply pressure (p_s = 20 bar), both nozzles deliver nearly identical jet stagnation pressures (p_{jet} ≈ 14.8 bar). As supply pressure increases, however, a clear divergence emerges. The Mach 4 nozzle consistently achieves higher values of p_{jet} than the Mach 1 nozzle, with the difference becoming progressively larger above 40 bar. At p_s = 60 bar, the Mach 4 nozzle reaches p_{jet} ≈ 44.7 bar compared to 42.6 bar for the Mach 1 nozzle.

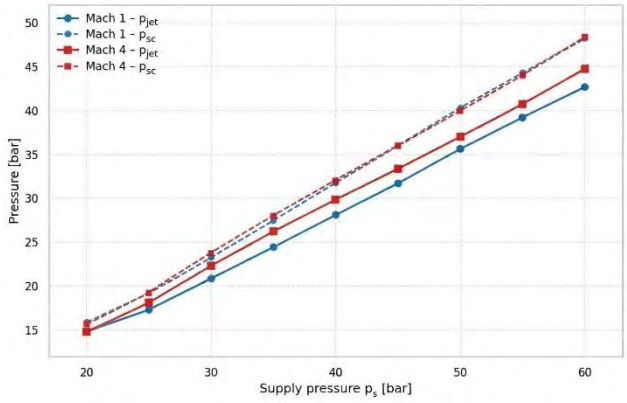

Figure 6 Comparative pressure recovery analysis

This performance advantage is directly attributable to differences in internal flow behavior within the settling chamber. As shown in Figure 5, the absolute internal pressure losses ($\Delta p_{up} + \Delta p_{sc}$) are lower for the Mach 4 nozzle at higher supply pressures, despite nearly identical upstream losses in both configurations. The contribution of settling chamber losses (orange segments) is visibly smaller for the Mach 4 geometry across the entire range, and the gap widens with increasing mass flow rate. Consequently, the deviation between the measured jet stagnation pressure p_{jet} and the ideal settling chamber pressure p_{sc} remains smaller for the supersonic nozzle, indicating reduced irreversible losses associated with flow expansion and turbulence inside the chamber. In addition, this deviation demonstrates that internal flow losses are successfully captured by the force-based method.

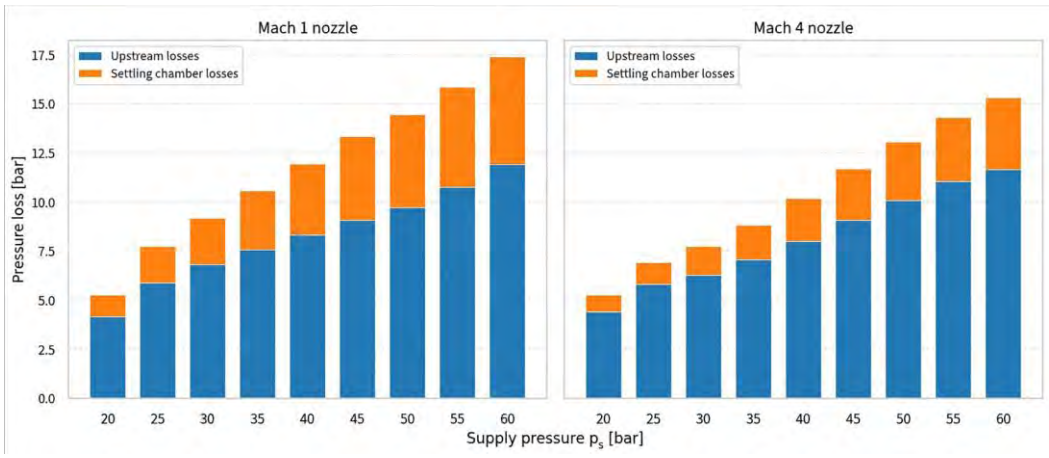

Figure 5 Pressure loss contribution analysis

Figure 7 presents the directly measured jet reaction force F_{jet} as a function of the jet stagnation pressure p_{jet} determined from the thrust equation for both nozzle configurations under atmospheric (no-wind-tunnel-flow) conditions. A clear linear relationship is observed for both the Mach 1 and Mach 4 nozzles, consistent with the theoretical thrust equation for choked nozzles. The Mach 4 nozzle exhibits a steeper slope, producing higher reaction force at the same jet stagnation pressure due to its higher exhaust velocity resulting from supersonic expansion in the divergent section. The data points remain well within the uncertainty bands across the entire tested range. The two curves intersect at low jet stagnation pressures; below this intersection the Mach 1 nozzle yields slightly higher force, while above approximately 20 bar the trend reverses and the Mach 4 nozzle maintains progressively higher reaction force with increasing p_{jet}.

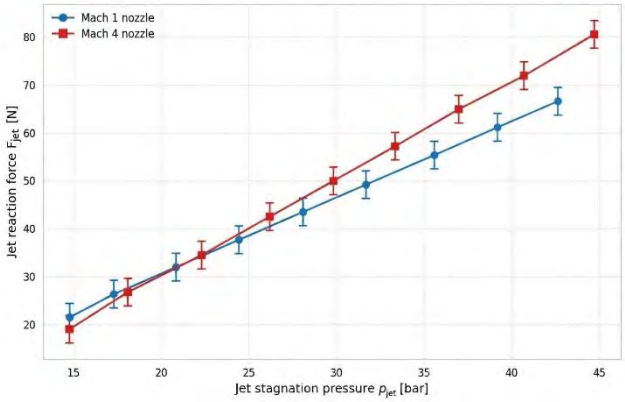

Figure 7 Jet reaction force under atmosphere conditions

In the wind tunnel, the nozzle exhausts into a local test section static pressure that can differ significantly from the atmospheric pressure present during the static calibration. Consequently, the jet thrust (F_{jet}) obtained here must be adjusted analytically using the classical thrust equation. In the pressure thrust component $(p_e - p_{inf})A_e$, the atmospheric reference pressure is replaced with the actual local test section pressure, allowing the true jet thrust force to be isolated in the subsequent wind tunnel tests.

5. CONCLUSIONS

The high-pressure jet supply system was calibrated under no-main-flow conditions using direct jet reaction force measurements. A dwell time of 4 s was required to reach steady-state conditions in the internal settling chamber. Upstream piping losses represented the dominant contribution to the total internal pressure drop for both nozzle configurations. Settling chamber losses were lower for the Mach 4 nozzle and increased with supply pressure for both nozzles. The Mach 4 nozzle delivered higher jet stagnation pressure and jet reaction force than the Mach 1 nozzle at supply pressures above 25 bar. A linear relationship between jet reaction force and jet pressure was obtained for both nozzles, consistent with the theoretical thrust equation. The force-based method enabled determination of actual jet stagnation pressure, providing validated baseline data for powered wind tunnel testing.

Abstract: *This paper presents experimental data obtained in testing of the generic missile model in the VTI T-38 blowdown wind tunnel. Two internal strain gauge balances were used to measure aerodynamic load. Force-type six-component balance with two measurement sections, placed in both the forward and the aft section of the balance, was used in the initial part of the tests. In the subsequent tests, aerodynamic load was measured using monoblock moment - type five-component balance with three measuring section shaped as a five-bar cage. The five-component balance has cylindrical cavity that allows flow of high-pressure gas through its load-bearing parts. The tests were conducted in the subsonic, transonic and supersonic conditions. The aerodynamic load values measured using these two balances are compared for the angle of attack of the missile model in the range from -12° to +12°.*

Keywords: *wind tunnel, strain gauge balance, missile model, aerodynamic load*

1. INTRODUSCTION

The paper presents the results of testing the generic missile model at VTI T-38 blowdown wind tunnel [1-3]. The main aim of the tests was investigation of the side jet interactions with crossflow. Tests were done in two phases: in the initial phase of the testing, i.e. in the first phase of the testing, measurements of the aerodynamic forces and moments were conducted on the generic missile model without side jet system and with six-component internal wind tunnel balance [4]. In the second phase of testing, measurements of aerodynamic forces and moments were conducted with side jet system and with five-component flow-through balance. Nominal load ranges of the flow-through balance, used in the tests with side jet system, is significant lower compared to the nominal load ranges of the six-component balance. The experimental results obtained in tests with six-component balance were used to determine the optimum position of the five-component balance within the model and maximum Mach number in supersonic testing of the model with side jet system.

During the second phase of the testing a certain number of tests were done without side jet system operating. Aerodynamic loads measured in these tests represent the aerodynamic loads without the influence of the jet's reactive force. Also, these tests without the side jet system operating were used as control measurements for comparing the aerodynamic loads measured using the six-component balance and aerodynamic loads measured using flow-through balance. The paper presents comparative values of the aerodynamic loads measured using both wind tunnel balances without side jet system operating in the subsonic, transonic and supersonic speed ranges.

2. GENERIC MISSILE MODEL

Generic missile model has a cylindrical body, ogive nose and wing section with for wraparound wings. The model is characterized with large slenderness ratio. Ratio of the model length to the model base diameter is L/D=21.6.

Generic missile model, in the initial phase of the testing with six-component balance, in the VTI T-38 wind tunnel is shown in Figure 1.

Figure 1. Generic missile model in the VTI T-38 wind tunnel test section [4]

For the tests with the side jet system, it was necessary to make some modifications on the front part of the model. Modification of the model baseline geometry enabled high pressure air supply from through flow-through balance to the settling chamber installed inside the model. On the upper surface of the settling chamber two interchangeable nozzles, a sonic (Mach 1) nozzle and supersonic (Mach 4) nozzle, can be installed. Generic missile model on the flow-through five-component balance are shown in Figure 2.

Figure 2. Generic missile model on the flow-through five component balance

Center of the six-component balance was located at 13.3*D* downstream of the model nose tip, while center of the flow-through balance was located at 13.7*D* downstream of the model nose tip. The reference point for force/moment calculation is located at 10.9*D* downstream of the model nose tip.

3. DESCRIPTION OF THE WIND TUNNEL BALANCES

3.1 Six-component wind tunnel balance

Six-component internal wind tunnel balance is shown in Figure 3. This is assembled balance with 50.8 mm-diameter (2 inch), marked as 2″Mk XVIII. This balance has construction and arrangement of measuring elements that are standard for balances produced by Able Corporation, USA. The 2″Mk XVIII balance is "force" balance, measuring five components of force and one moment component. From these six balance components six components of the aerodynamic load can be determined: the three total forces and three total moments. Two normal force elements (aft normal force element and forward normal force element) are used for measurement of the total normal force and pitching moment. Also, two side force elements (aft side force element and forward side force element) are used for measurement of the total side force and yawing moment. Rolling moment and axial force are directly measured using a dual roll element, i.e. dual axial element. The measuring bridges of all measuring elements are formed from Micro-Measurements strain gauges with a resistance of 350Ω. Rolling moment gage section is torque tube type, while all other gauge sections are bending beam type.

The nominal balance components load range is given in Table 1. Load range of the balance components relative to the balance center is given in Table 2 in the form of the "load rhombs", i.e. as maximum side/normal force at zero yawing/pitching moment and as maximum yawing/pitching moment at zero side/normal force.

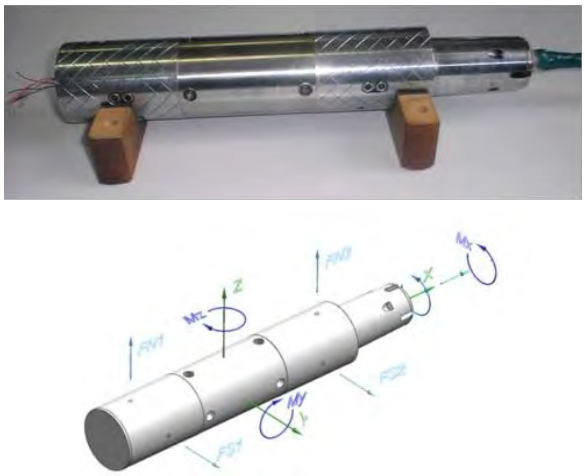

Figure 3. Six-component 2″ Mk XVIII balance

In Table 3 Err is maximum difference between applied and measured load in the balance calibration, P.Err is maximum difference between applied and measured load calculated in relation to the component full scale (FS) load range, Std.d is standard deviation of the errors, Acc is balance component accuracy.

3.2 Five-component flow-through wind tunnel balance

Five-component flow-through wind tunnel balance is shown in Figure 4. The VTI 1.5” 385 balance is “direct-read” balance with 38 mm-diameter (1.5 inch) and three measuring sections shaped as a five-bar cage. All measuring bridges are formed from Micro-Measurements strain gauges with a resistance of 350Ω. The normal force and pitching moment, as well as side force and yawing moment are measured using four measuring bridges formed from strain gauges located on the forward and backward measuring sections. Output signals from these four measuring bridges are proportional to the bending stresses in the measuring sections. Half bridges on the forward and backward measuring section are directly wired to the force bridges for measurements of normal and side force, while the other set of half bridges are directly wired to the moment bridges for measurements of pitching and yawing moment. Rolling moment measuring bridge is located on the central measuring section [5]. Due to action of the rolling moment, the four external bars are simultaneously twisted and bended, while the central bar is loaded only in rolling. By the balance design, it is ensured that the bending stress in the external bars is more significant than the twisting stress. The part of rolling moment taken by the central bar is a small portion of the total rolling moment. The appropriate geometry of the central measuring section enables indirect measurement of the rolling moment by bending stress in the external bars. One strain gauge that detects bending stress is located on each external bar.

High-pressure gas for a side jet flows through a cylindrical cavity in the balance, Figure 4. The cylindrical cavity is 10 mm diameter and it is threaded at both ends to connect the high-pressure gas supply tube.

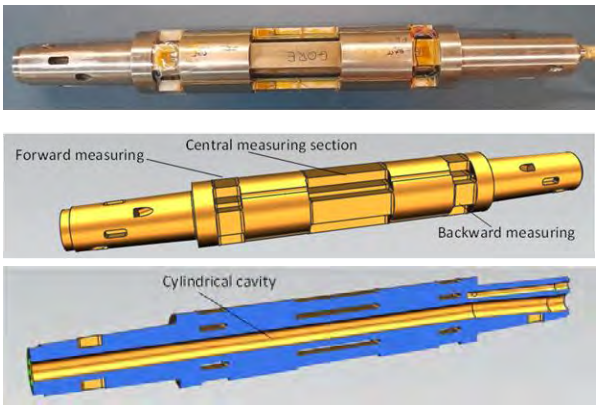

Figure 4. Five-component flow-trough wind tunnel balance

The nominal balance load range relative to the balance center is given in Table 4.

4. EXPERIMENTAL RESULTS AND DISCUSSION

Aerodynamic loads, measured in the subsonic, transonic and supersonic speed range, with both wind tunnel balances are presented. In the subsonic speed range stagnation pressure in the wind tunnel tests section was

2.0 bar, while in transonic and supersonic speed range stagnation pressure was 2.3 bar. The results refer to Mach number 0.3, 0.5, 0.9, 1, 1.2, 1.5 and 1.6.

Nondimensional aerodynamic coefficients in the non-rotated axes system are calculated from the aerodynamic forces and moments according the following equations:

$$C_N = \frac{Z}{q \cdot S_{ref}} \quad C_M = \frac{M_y}{q \cdot S_{ref} \cdot l_{ref}}$$

where C_N is normal force coefficient, C_M is pitching moment coefficient, S_{ref} is model reference area, l_{ref} is model reference length, q is dynamic pressure in the wind tunnel test section.

The model angle of attack was in the interval -12° to +12°. Pitching moment coefficient is calculated for the reference point located at 10.9 *D* downstream of the model nose tip.

Figures 5-11 show measured values of the normal force and pitching moment coefficients in all three speed ranges.

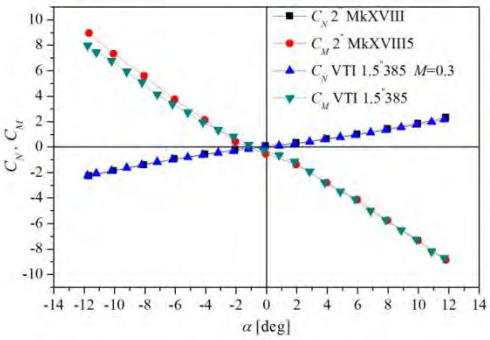

Figure 5. Normal force and pitching moment coefficients, $M = 0.3$

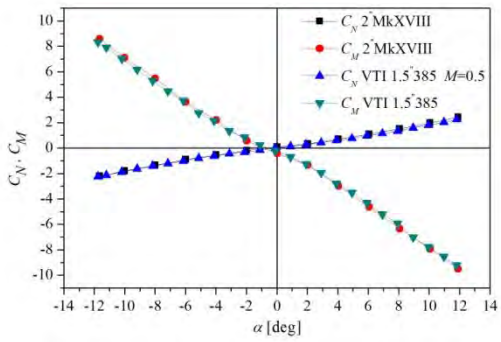

Figure 6. Normal force and pitching moment coefficients, $M = 0.5$

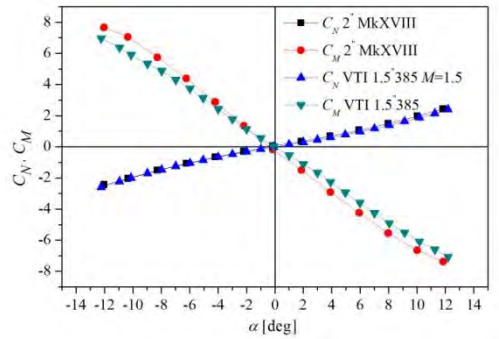

Figure 10. Normal force and pitching moment coefficients, $M = 1.5$

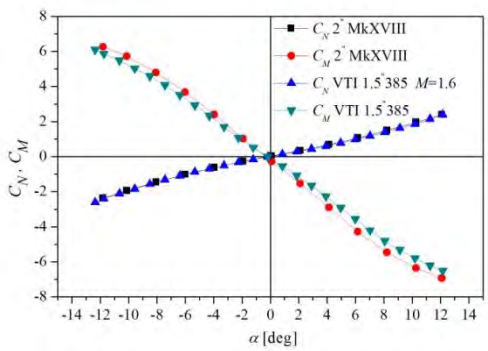

Figure 11. Normal force and pitching moment coefficients, M = 1.6

Figures 12-15 show comparative values of the normal force measured using 2″Mk XVIII and VTI 1.5” 385 wind tunnel balances.

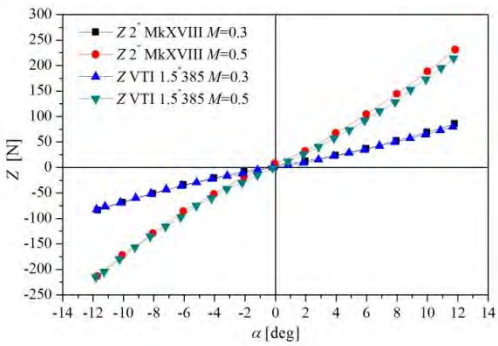

Figure 12. Normal force M = 0.3 and M = 0.5

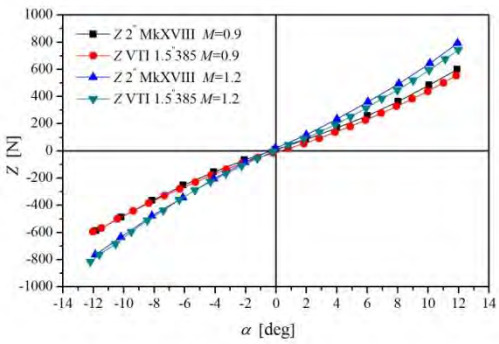

Figure 13. Normal force M = 0.9 and M = 1.2

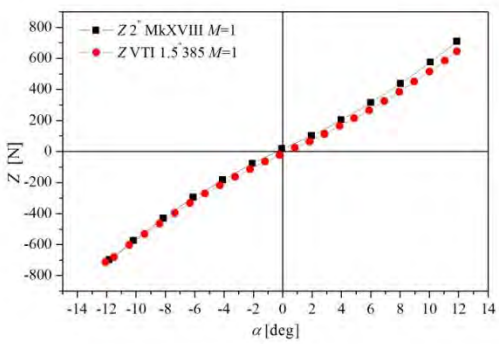

Figure 14. Normal force M = 1

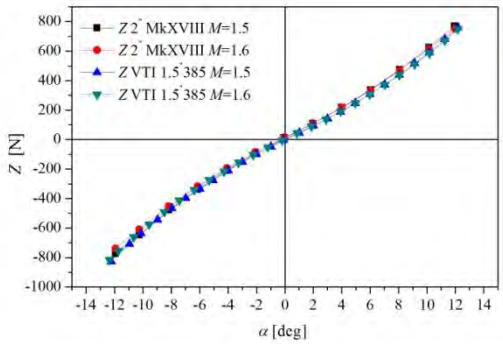

Figure 15. Normal force M = 1.5 and M = 1.6

5. CONCLUSIONS

The diagrams in Figures 5-15 show a good agreement between the normal forces measured using 2″Mk XVIII balance and VTI 1.5” 385 balances. Slightly larger difference in the normal force values can be observed in the transonic speed range. At Mach number M=1, and for the model maximum angle of attack, the difference in normal force measured values is 63.74 N. These deviations can be explained by the significantly larger 2″Mk XVIII balance normal force load range compared to the measured value.

A certain difference in the measured values of the pitching moment coefficient can be noticed at higher values of the model angle of attack. When analyzing these differences, it should be taken into account the significantly larger 2″Mk XVIII balance pitching moment load range. Also, the pitching moment measured using 2″Mk XVIII balance are calculated based on the measured forward and aft normal force components. On the other hand, using the VTI 1.5” 385 balance, the pitching moment is measured directly, i.e. it is achieved using a single measuring bridge.

Abstract: *This paper examines the interaction between a free stream and side jet flow. Experiments were conducted in the VTI T-38 trisonic wind tunnel. The internal side jet system was configured with either sonic or supersonic nozzles, integrated on a generic missile model. Tests were performed at the free stream Mach numbers ranging from subsonic through transonic to supersonic regimes. This interaction generated unique boundary layer profiles and oblique shock wave structures. The resulting tests yielded evaluated pressure distributions and quantified data regarding the interference between the free stream and side jet flows. Such data is essential for analyzing the side jet effects on flow separation, the location of the center of pressure, and the overall maneuverability and stability of missiles.*

Keywords: *trisonic wind tunnel; side jet; pressure distribution; flow interference and separation.*

1. INTRODUCTION

Control of missile systems designed for high agility and maneuverability is increasingly being achieved using side jet control. In contrast to control surfaces that become ineffective at low pressures, side jet control maintains its effectiveness under these conditions. The side jet's effects depend primarily on: the diameter of the side jet nozzle, jet pressure, the Mach number and static pressure of the external flow. In aerodynamic laboratories, various methods and equipment are being developed for wall pressure measurements to investigate the interference of a side jet with cross flow [1-3].

This paper presents results of the pressure distribution measurements on the generic missile model with side jets. Measurements were conducted in the VTI T-38 trisonic blowdown wind tunnel in the subsonic, transonic and supersonic speed range [4]. Tests were conducted with a sonic and supersonic side jet nozzle installed on the generic missile model and for two different values of the side jet mass flow.

2. TEST FACILITY

The VTI T-38 test facility is large scale blowdown wind tunnel. Depending on the Mach number and stagnation pressure, the facility permits run duration from 6 to 60 seconds. The 1.5 m x 1.5 m test section is equipped with a two-degree-of-freedom model support system that permits pitch angles of ±20° and roll angles of 720°. Stagnation pressure can be in range from 1.2 to 15 bar, enabling unit Reynolds numbers, R_e/m, from 5 x 10^6 m^{-1} to 110 x 10^6 m^{-1}. Mach number range in the VTI T-38 wind tunnel test section is 0.2-4.0. Subsonic and supersonic tests are performed in the solid-wall test section, where the Mach number is set by second throat and the variable-geometry nozzle, respectively. For transonic tests, a porous-wall test section is with variable porosity and an ejector-assisted blow-off system is inserted into the wind tunnel circuit for active Mach number control.

2.1 Model description

The generic missile model is developed in VTI, Figure 1. This model is designed for testing primarily in supersonic speed range. The generic missile model consists of an

Corresponding author: B. Simović;
E-mail: simovic.bozidar@gmail.com
DOI: 10.5937/OTEH26007S

ogive nose cone, cylindrical fuselage and four wrap-around fins. Its nominal body dimeter is D = 64 mm. The total length of the cylindrical fuselage, which consists four segments, is 18 D. The ogive nose cone has a length of 3.6 D. The generic missile model is characterized with large slenderness ratio. Ratio of the model length to the model base diameter is close to L/D = 22. Four movable wrap-around fins are installed on the rear fuselage segment and can be individually set to different deflection angles. For the present test campaign, the fins were positioned at 0° deflection. In the initial phase of the testing the model was tested without side jet system and with six-component internal wind tunnel balance [6]. In the measurements with side jet system, aerodynamic forces and moment were measured with five-component flow-through balance. The experimental results obtained in tests with six-component balance were used to determine the optimum position of the five-component balance within the model and maximum Mach number in supersonic testing of the model with side jet system.

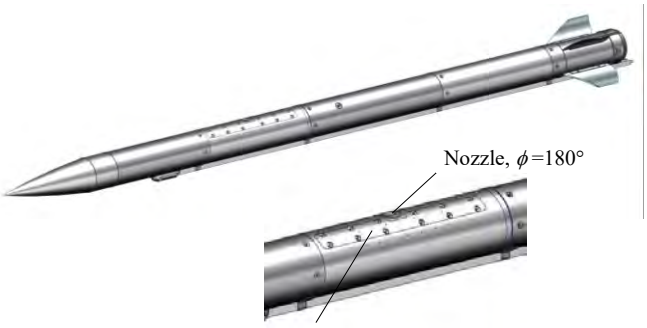

Figure 1. The generic missile model

For investigation of side jet interactions with cross-flow two interchangeable side jet nozzles were designed and manufactured: a sonic (Mach 1) and supersonic (Mach 4) nozzle, both with throat diameter of d = 4 mm. The side jets are positioned at 8.5 D downstream of the model nose and at an azimuth angle of ϕ = 180°. The side jet nozzles are supplied with high-pressure air from an external source through five-component flow-through balance and internal settling chamber that houses the nozzles [7].

2.2 Pressure distribution measurements

For measurements of the wall pressure distributions, the model has 34 static pressure taps with a diameter of 0.8 mm. The static pressure taps are arranged in five longitudinal rows around the nozzle exit, Figure 1. The pneumatic tubing from the taps are connected to a Scanivalve MPS4264 miniature digital pressure scanner module, Figure 2. The MPS4264 is a 64-channel scanner with a full-scale range of 1 bar, long-term accuracy of ±0.06 % of full scale, integrated 24-bit analog-to-digital conversion, and maximum scan rate 850 Hz. Reference pressure for all scanner channels is static pressure measured in the tunnel tests section, i.e. pressure of the external flow.

Each scanner channel directly outputs the pressure difference between local surface static pressure and static pressure of the external flow, p-p_∞ , which is used to calculate the pressure coefficient according to next equation:

$$Cp = 2\,(p-p_\infty)/(p_\infty k M^2) \qquad (1)$$

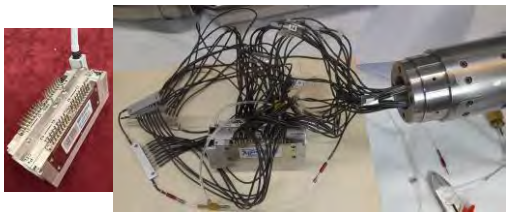

Figure 2. Miniature pressure scanner module

By varying the external source pressure, it was possible to set a predefined side jet pressure ratio p_{ojet}/p_∞. The pressure ratio of the side jet was set to a constant value before the start of cross flow in the wind tunnel test section. The model was traversed in 5° steps in the range -10°≤ α ≤ 10°, or through -12°≤ α ≤ 12° angles during more dynamic and faster sweep regime of measurement. The shock structure is visualized by schlieren technique. The schlieren system for the VTI T-38 wind tunnel is a Toepler parallel beam folded Z-type system.

3. EXPERIMENTAL RESULTS AND DISCUSION

The generic missile model with side jet system in the VTI T-38 wind tunnel test section is shown in Figure 3.

Figure 3. The generic missile model in the VTI T-38 wind tunnel

Experimental results of the side jet interaction with cross flow for Mach numbers M = 0.5, 0.9 and 1.6 are presented. The results refer on sonic nozzle (Mach 1) and the model angle of attack 0°.

The measurements were carried out under test conditions shown in Table 1.

Table 1. Test condidtions

M	M_{jet}	Re	p_o [bar]	p_∞ [bar]	p_{ojet}/p_∞
0.5	1	2.15×10^7	2.0	1.675	18.55
0.9	1	3.06×10^7	2.3	1.360	23.955
1.6	1	3.24×10^7	2.3	0.561	49.72

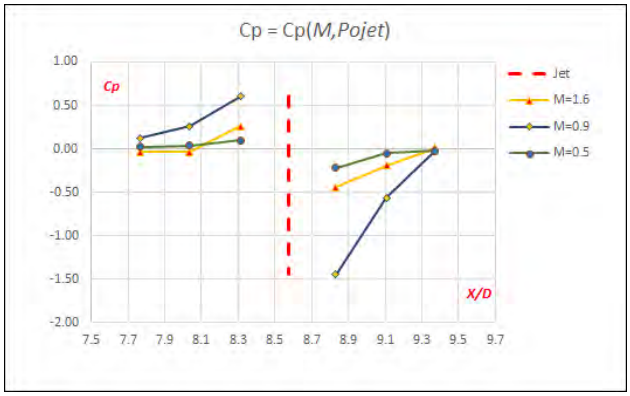

Figure 4. Pressure coefficient distribution: dependence on Mach number and side jet flow characteristics

Pressure distribution across different Mach numbers, shown in figure 4, exhibits close similarity in its overall curve character. Observation reveals that free flow loses velocity (indicated by higher *Cp* values) as it approaches the jet. This interaction between the free flow and the jet effectively acts as a barrier, reducing dynamic pressure and contributing to the overall force generated by the side jet. Consequently, the nozzle produces not only a reactionary force inherent to its design but also a secondary aerodynamic force, acting in the same direction and, though smaller, significantly impacting the overall behaviour.

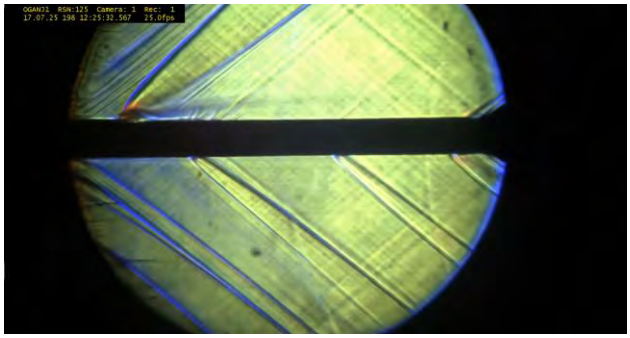

Figure 5. Schlieren system visualisation of shock waves generated by free stream and side jet interaction.

Schlieren system visualization provides a detailed view of the array of aerodynamic effects generated by the interaction. Visualization based on density differences provides an implicit view of changes in fluid properties – specifically, the shear layer, Figure 5. Rapid expansion of gas into the free stream field acts as a blunt obstacle against the free stream, resulting in the formation of a bow shock in front of the visible barrel shock. A small separation region is observed near the bow shock zone.

Shear layer vortices and more turbulent flow develop downstream and gradually recirculate into the main flow. Expansion of the side jet generated a Mach disc, along side the expected bowshock.

A heatmap overlay further revealed asymmetry in the pressure distribution, Figure 6. Subsequent analysis indicated that this asymmetry was a consequence of material discrepancies, which subsequently disrupted the already turbulent flow near the nozzle. In other words, the observed pressure asymmetry was primarily a result of the model's physical construction and had no direct relationship to the interaction of the side jet.

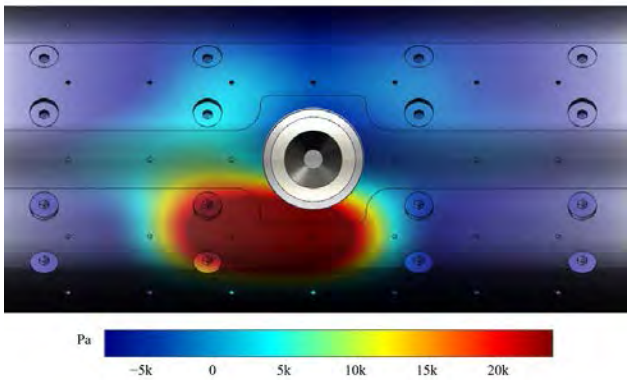

Figure 6. Pressure distribution over area near nozzle for supersonic crossflow (external flow *M*=1.6, side jet flow M=1)

With this data, it was possible to confidently deduce that the overall pressure distribution, under similar conditions, remained within a range of no more than 10 kPa.

Furthermore, Figure 6. provides in quantity and quality more broad view of general interaction between free stream and side jet. The stagnation zone can clearly be observed in front of the nozzle, along with zone of recirculation further downstream.

4. CONCLUSION

Effective control of aerodynamic bodies utilizing side propulsion systems depends not solely on the impulse generated by the reactive force, but also on a comprehensive understanding of the aerodynamic effects produced under these conditions.

The resulting bowshock, Mach disk, intensified turbulence, and flow separation further complicate the necessary control strategies.

Tests conducted under transonic conditions demonstrated that transonic flight generates the greatest aerodynamic contribution to the overall force, along with significant flow separation.

During these tests, it was clearly demonstrated that pressure distribution and flow separation, when considering the interaction between the freestream and the side jet, should not be dismissed. Indeed, careful consideration of flow separation is crucial in real flight conditions.

SM2-M UAV AND Q GROUND CONTROL: SYNERGY OF AUTONOMOUS GUIDANCE AND REAL-TIME MISSION MONITORING IN MODERN MILITARY OPERATIONS

MILOŠ UGRENOVIĆ
Mixed Artillery Brigade, Niš, ugren.srbin@gmail.com

Abstract: *This paper analyzes the synergy between autonomous guidance and real-time mission tracking of the SM2-M unmanned aerial vehicle (UAV), with the aim of improving the reliability, accuracy and operational efficiency of the mission. The proposed system architecture integrates autonomous navigation, flight control and mission tracking algorithms with embedded sensor and communication subsystems, enabling continuous data exchange and real-time situational awareness. Special emphasis is placed on adaptive flight path management and decision-making in dynamic operational conditions. The analysis shows that an integrated approach to autonomous guidance and mission tracking improves situational awareness, reduces operator workload and increases mission success. The analysis was performed during flights with the SM2-M unmanned aerial vehicles that were implemented at the Pasuljanske livade test site. The results obtained indicate the potential for further development and application of advanced autonomous capabilities in the SM2-M unmanned aerial vehicle, contributing to the efficiency of next-generation military unmanned aerial vehicles.*

Keywords: *SM2-M UAV, autonomous guidance, mission monitoring, real-time systems, autonomous systems.*

1. INTRODUCTION

Unmanned aerial vehicles (UAVs), commonly known as drones, have become one of the most important tools in modern warfare. Thanks to advances in technology, they are used for reconnaissance, surveillance, intelligence gathering, artillery fire adjustment, electronic warfare, and carrying out precision strikes against military targets.

One of the main advantages of unmanned aerial vehicles is their ability to perform dangerous missions without putting pilots' lives at risk. Drones can remain airborne for extended periods, transmit real-time video and data, and operate in areas that are difficult to access or too dangerous for manned aircraft.

The ground Control Station (GCS) is one of the most important components of an unmanned aerial vehicle (UAV) system. It enables the operator to plan missions, control the aircraft, monitor its flight in real time, and supervise the operation of all critical onboard systems. Without a reliable ground control station, the safe and efficient operation of a UAV would be significantly more difficult. The function of the ground control station is to control the UAV and present all flight data to the operator. This communication allows the exchange of data such as the aircraft's position, speed, altitude, battery or fuel status, as well as information collected by onboard sensors and cameras. At the same time, the operator can transmit commands to modify the flight route, altitude.

In addition to controlling the aircraft, the ground control station plays a vital role in ensuring flight safety. The operator can promptly detect technical malfunctions, communication failures, or adverse weather conditions and take appropriate actions, such as modifying the flight plan or activating the automatic return-to-home function.

The importance of the ground control station becomes even more evident during complex operations, where multiple parameters must be monitored simultaneously and rapid decisions are required. For this reason, the development of modern ground control stations focuses on improving communication reliability, intuitive user interfaces, process automation, and protection against cybersecurity threats.

1. SM2-M VEHICLE MODEL

The SM2-M is a modern unmanned system that belongs to the category of loitering munitions. Unlike conventional reconnaissance unmanned aerial vehicles, whose primary purpose is to gather intelligence and return after completing their mission, the SM2-M (show in Fig. 1) is designed to locate a target, carry out an attack, and be expended during that single mission. This concept combines reconnaissance capabilities with precision strike functions in one integrated system. The system is designed as a lightweight modular platform, allowing for easier transportation and rapid deployment.

The aircraft is launched from the ground using a pneumatic launcher and is powered by a two-stroke internal combustion engine. It uses a Global Navigation Satellite System (GNSS) for navigation, enabling accurate guidance and the successful execution of assigned missions.

Figure 1. UAV on the launch pad

One of the most important features of the SM2-M is its ability to engage a variety of ground targets. The vehicle can be equipped with a warhead intended for attacking personnel and lightly armored vehicles, making it an effective means of conducting precision strikes. Before engaging its target, it can loiter over the operational area, observe the terrain includes a ground control station used for mission planning, flight control, communication with the vehicle, and pre-flight system checks, and identify the target, thereby increasing the likelihood of mission success.

The basic UAV physical characteristics are shown in Table 1 [1].

Table 1. UAV SM2-M physical characteristics

Parameters	Range
Drone length	2900 mm
Wingspan	4850 mm
Drone weight	75 kg
Flight autonomy	2 h
Communication range	23 km
Maximum speed	151 km/h
Engine displacement	178 cm³
Maximum tilt angle	40°

Component part of the system:

- drone CM2-M,
- remote controller,
- ground control station,
- transport vehicle [1].

2. GROUND CONTROL STATION

The ground control station (show in Fig. 2) is used to create a mission for the SM2-M unmanned aerial vehicle. Q Ground Control (QGC) is an open-source software application designed for mission planning, control, and monitoring of unmanned aerial vehicles (UAVs). It is developed as a universal ground control station (GCS) that supports a wide range of autopilot systems, with PX4 and ArduPilot being the most widely used. One of the primary functions of Q Ground Control is autonomous mission planning. Users can define flight paths by creating waypoints, specifying flight altitude, speed, mission actions, and other mission parameters. Once the flight plan is completed, it is uploaded to the UAV's autopilot, allowing the aircraft to execute the mission.

During flight operations, the application provides real-time telemetry monitoring. The operator can observe the UAV's position on a digital map, altitude, speed, heading, battery status, communication link quality, GPS signal strength, and many other parameters that are essential for safe mission execution. This real-time visualization enables rapid decision-making in unexpected situations. Autonomous guidance is one of the most important features of **Q Ground Control**, enabling an unmanned aerial vehicle (UAV) to execute a predefined mission without continuous operator control.

Figure 2: Ground Control Station

The basic Q Ground Control physical characteristics are shown in Table 2 [1].

Table 2. Q Ground Control physical characteristics

Characteristics	Description
Application type	Software for unmanned aerial vehicle control
License	Open-source software
Supported autopilots	PX 4, ArduPilot
Communication protocol	MAVLink
Flight monitoring	Real-time display of aircraft position, flight path, telemetry data
Navigation	Support for GPS/GNSS navigation
Mission planning	Creation of autonomous flight route using waypoint
Telemetry	Display of altitude, speed, heading, battery voltage, GPS status

The mission is planned (show in Fig. 3) within the application by creating a flight path consisting of a series of waypoints. For each waypoint, the user can define parameters such as flight altitude, speed, aircraft orientation, and specific actions, including taking photographs, hovering at a designated location, or returning to the launch point.

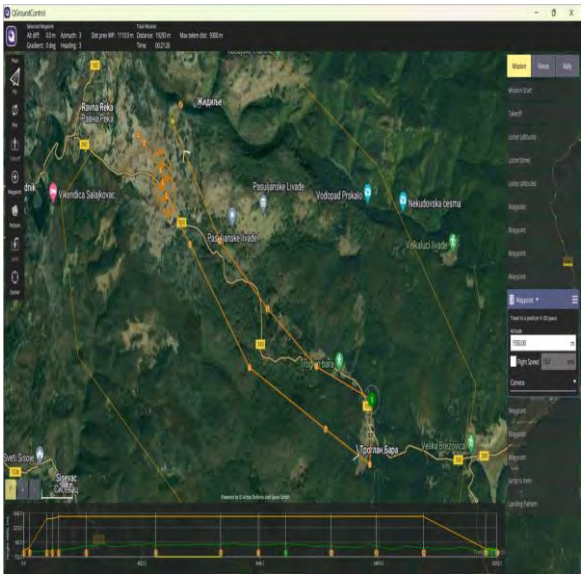

Figure 3. Mission planning

Once mission planning is completed, the flight plan is uploaded to the flight controller via the **MAVLink** communication protocol. The flight controller uses data from the Global Navigation Satellite System (GNSS) receiver, the Inertial Measurement Unit (IMU), magnetometer, barometer, and other onboard sensors to continuously determine the UAV's position and orientation. Based on this information, the autopilot continuously adjusts the motor outputs and control surfaces to ensure that the aircraft follows the planned flight path.

Q Ground Control also supports dynamic mission possible management during flight. The operator can add new waypoints, modify the existing route, adjust the flight altitude or speed, and switch between different autopilot flight modes without interrupting the mission. In the event of communication loss or other emergency situations, built-in safety features can be activated, such as **Return-to-Launch (RTL)**, automatic landing, or **Loiter** mode, depending on the system configuration.

During mission execution, Q Ground Control displays the position of the unmanned aerial vehicle on a digital map in real time. The operator can monitor the aircraft's current location, completed flight path, planned route, and the relationship between the actual and desired trajectory. This type of visualization allows deviations from the planned route to be detected quickly and enables timely responses if problems occur during the flight.

In addition to geographic position, the application displays a wide range of telemetry data continuously transmitted from the aircraft. The most important parameters include flight altitude, airspeed, heading, battery status, communication link quality, number of available GPS satellites, autopilot operating mode, and the status of individual aircraft systems. Based on this information, the operator can evaluate the current condition of the mission and make appropriate decisions.

One of the important capabilities of Q Ground Control is the display of data from sensors and cameras installed on the unmanned aerial vehicle. Depending on the system configuration, the operator can monitor live video transmission, analyze collected data, and associate it with the current position of the aircraft. This function is particularly important for tasks such as terrain surveillance, infrastructure inspection, mapping, and research missions.

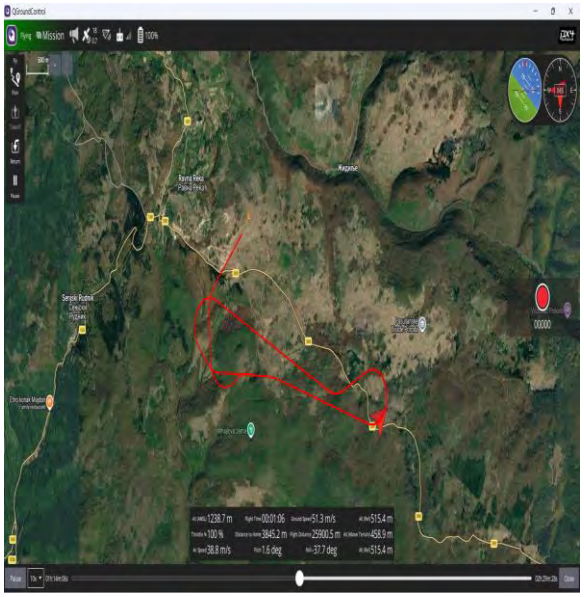

Figure 4. Real-time mission monitoring

Real-time mission monitoring (show in Fig. 4) also contributes significantly to flight safety. Q Ground Control provides warnings about potential issues such as low battery level, loss of GPS signal, communication failure, or exceeding predefined flight limits. In emergency situations, the operator can modify the mission plan, take manual control, or activate safety procedures such as an automatic return to the launch location.

During the execution of a mission that integrates autonomous drone guidance with a real-time mission tracking system, the role of the operator has significantly changed from that of traditional unmanned aerial vehicle (UAV) control. Instead of continuously piloting the drone, the operator has taken on the role of a mission supervisor, monitoring the operation of the autonomous system, analyzing the collected data, and making decisions whenever necessary. This approach allows for a more efficient distribution of tasks between the human operator and the autonomous system.

The operator at the ground control station received the following data:

- Flight mode: Mission
- Number of satellites: 18
- Battery level: 100%
- Flight altitude: 1238.7 m
- Throttle percentage: 100%
- Airspeed: 38.8 m/s
- Distance from launch point: 3845.2 m
- Pitch: 1,6 deg
- Flight distance: 25900,5 m
- Relative height: 515,4 m

The operator's primary responsibility was to continuously monitor telemetry data, including the drone's position, altitude, flight speed, battery status, communication link quality, and sensor status. At the same time, the operator viewed and other data collected during the mission, providing a comprehensive overview of the mission's progress and allowing for an assessment of whether the mission was being executed according to plan. An especially important aspect of the operator's work is the analysis of information generated in real time by the autonomous system and artificial intelligence algorithms.

Automatically detected objects, obstacles, or potential hazards are presented to the operator, who evaluates their relevance and, when necessary, decides whether to modify the flight plan, or perform a more detailed inspection of a specific area. In this way, human judgment complements the capabilities of the autonomous system.

In addition to monitoring, the operator retains the ability to intervene at any stage of the mission. In the event of changing weather conditions, loss of communication, reduced battery capacity, or the appearance of unexpected obstacles, the operator can modify the flight route, assign a new mission target, initiate the drone's return-to-home procedure, or take over manual control.

A ground station operator should have knowledge of satellite communications and radio systems, antenna systems and tracking equipment, TT&C & (Telemetry, Tracking and Command) operations, the fundamentals of flight dynamics, emergency procedures and operational risk management.

5.CONCLUSION

The synergy between autonomous onboard decision-making and ground-based supervision allows drones to adapt to dynamic environments while maintaining communication with operators and mission control systems. Autonomous algorithms can respond instantly to changing flight conditions, whereas real-time monitoring provides situational awareness, verifies mission execution, and enables timely human intervention whenever necessary. This balance between autonomy and human oversight significantly reduces operational risks, improves mission reliability, and increases the overall resilience of UAV systems.

As autonomous technologies continue to evolve, supported by advances in artificial intelligence, sensor fusion, communication networks, and edge computing, the interaction between onboard autonomy and real-time mission monitoring will become even more sophisticated. Future UAV systems are expected to operate with greater independence while remaining fully integrated into supervisory control architectures that ensure transparency, accountability, and operational safety.

Abstract: *Aircraft overhaul is a process of thorough restoration and upgrade, with a purpose of tackling exploitation and time-affected wear, eventually resulting in significant service life extension, update of the existing, and integration of additional, modern, features, while enhancing reliability and maintaining compliance with regulatory requirements. Timely overhaul is essential for ensuring safety, reliability and airworthiness of a long serving aircraft, and keeping it's systems up-to-date and compatible with new regulations. It begins with detailed inspection, accompanied by disassembly and refurbishment of major components wherever appears necessary. Inspection includes visual checks, non-destructive testing (NDT), and electronic diagnostic procedures to detect defects, wear or damage, particulary structural, mostly omitted in periodic checks. The components that undergo overhauls include engines, propellers, landing gear, avionics, built-in systems, control surfaces and aircraft structure. After the repair work is complete, overhauled aircraft undergoes rigorous testing and quality assurance checks to verify its performance, functionality, and airworthiness.*

In this work, a comprehensive overhaul process of Lasta aircraft will be shown as an example of such an undertaking.

Keywords: *Overhaul, inspection, NDT, defects, QA checks.*

1. INTRODUCTION

Serial Lasta 3 (military designation V-54) highly manoeuvrable light trainer aircraft were produced by Utva Aircraft Industry and delivered to Serbian airforce by 2015. Having flown extensively ever since, some are close to or have already reached its operational limit period and are in need of detailed examination and evaluation of current condition to continue safe operation.

One of these aircraft with S/N 54204 has recently undergone a thorough examination and repair work i.e. overhaul within Utva facilities.

This document will present contents and volume of work that overhaul requires, especially inspections with their findings and test results that had been needed to obtain in order to announce the airplane airworthy, shown on the sample with focus on NDT inspection, corrosion tackling and flight controls proper operation.

2. THE OVERHAUL PROCESS

The overhaul process is divided in stages, each with typical demands and scope of work. These stages and brief display of its contents are listed in Table 1.

Table 1. Overhaul stages and contents

1. Aircraft reception
Current state inspection; Antennae & sensors removal; Airplane transport to overhaul facility
2. Reception inspection, cleaning, scheduled maintenance
Disassembly, cleaning and inspection (DCI) of wings, stabilizers, controls & control surfaces, electrical wiring, fuel system, hydraulic system, pitot system, air conditioning system, engine, engine mount, avionics
3. Repair work, global & components
Wing, fuselage & empennage structure NDT and repair; Fuel tank integrity; Corrosion removal & protective coatings re-application; Windshield, windows; Interior equipment, furniture; Actuators; Instruments & electronics testing, calibration;
4. Repair work, outsourced
Engine; Propeller; Landing gear; Engine mount, wing & other main mounts radiography; Special protective coatings

Corresponding author: M. Ostojić;
E-mail: majce74@yahoo.com
DOI: 10.5937/OTEH26009P

5. Components assembly
Wing completion, fuel, hydraulic, electric and pitot systems assembly; Flight controls completion; Fuselage completion, fuel, hydraulic, electric and pitot systems assembly; Flight controls completion; Secondary controls installation; Control panel & avionics installation;
6. Airplane assembly
Wing installation; Main landing gear installation; Control surfaces installation; Engine mount installation; Nose landing gear installation; Fairings installation; Engine, propeller & exhaust installation; Interior equipment & canopy installation;
7. Completion and final tests
Painting and marking; Jacking and levelling; Geometry, weight measurement, centre of gravity check; Lubrication; Flight controls adjustment; Pitot system final test; Fuel system test & instruments calibration; Hydraulic system refill & Landing gear test; Final engine and engine control system tests; Air conditioning system tests; Antennae and sensors installation; Final electric & avionics tests; Engine de-conservation, run-up & propeller dynamic balancing; Engine controls adjustment; Detonation cord installation
8. Transportation and flight testing preparation
Compass calibration; Aircraft preparation, engine start-up; Engine parameter monitoring; Pre-flight check

While stages might overlap, depending on progress being made and pace at which separate jobs are being done, there are certain dependencies between many of them, preventing convenient deviations off the prescribed order of work most of the times.

Chosen part of overhaul process to be presented in details further in this work includes NDT inspection, corrosion reparation and flight controls test.

2.1. Non-destructive testing - NDT

Non-destructive testing methods were performed on various aircraft structural components, including fittings of the horizontal stabilizer, vertical stabilizer, fuselage, left and right wings, also primary flight control components and so on, in order to assess the condition of these vital parts.

The following NDT methods were applied:

- Visual Inspection (VI)
- Penetrant Inspection (PI)
- Eddy Current Testing (ECT)
- Ultrasonic Testing (UI)

Visual inspection

Inspections by means of close and detailed observation, aided or not with convenient tools, optical devices, measuring equipment including go/no go and angular fixing tools etc. make for VI methods. These methods are the most common and first to be used to notice obvious and measurable defects, being convenient to use, economic and always on-hand. Its main limitation is low sensitivity and inability to detect sub-surface and micro level damage.

Liquid Penetrant Inspection

Liquid penetrant inspection is a non-destructive method used to detect surface-breaking discontinuities in non-porous materials. It is suitable for detecting cracks, laps, porosity, shrinkage cavities, laminations, and similar discontinuities. It is simple, cost-effective, and capable of detecting very small surface cracks; however, it is limited to surface-breaking defects only.

Ultrasonic Inspection

Ultrasonic testing uses high-frequency sound waves to detect both surface and subsurface discontinuities. It is widely used for detecting cracks, laminations, voids, bonding defects, and corrosion. It provides high accuracy in determining defect location, size, and orientation.

Eddy Current Inspection

Eddy current testing is based on electromagnetic induction and is used for detecting surface and near-surface defects in electrically conductive materials.

It is commonly used for detection of fatigue cracks and stress corrosion cracking around fastener holes. The method does not require direct contact and provides fast inspection capability, but penetration depth is limited.

2.2. NDT methods used

• VI was performed on all fittings using 5× magnification lenses and a borescope. A borescope inspection was carried out in all inaccessible areas to detect hidden defects and corrosion.

• PI was performed on primary control fittings, bushings, wing front and rear attachment fittings, and spars.

• ECI was performed on all metallic and non-metallic conductive fittings to detect cracks and surface defects.

• UI was performed on all structural joints and fittings.

Aircraft inspection and repair

Proper identification of aircraft structural materials is essential to ensure continued airworthiness and to prevent improper repairs.

Effective structural repair design requires understanding of applied stresses, including tension, compression, bending, torsion, shear, and bearing.

Aircraft repairs must balance structural strength and weight efficiency. Repairs must provide adequate load-carrying capability with the required safety factor, while avoiding excessive stiffness that may introduce stress concentrations and secondary cracking.

2.3. NDT detected defects

A couple of examples of inspection findings are listed in the Table 2. Based on the results obtained by the applied inspection methods, it can be concluded that no unacceptable defects were found on fuselage fittings, left and right wing fittings, vertical and horizontal stabilizer fittings, and aircraft flight control components.

Table 2. Defect examples

1. Horizontal stabilizer to elevator joint hinge fitting	
Methods used: VI, ECI, UI	Findings: Mechanical damage (Ø4 mm, Ø5 mm, Ø7 mm) – **Figure 1**
2. Bellcrank, elevator control	
Methods used: VI, PI, ECI, UI	Findings: Mechanical damage, L = 10 mm, D = 0.3 mm
3. Bellcrank, rudder control	
Methods used: VI, PI, ECI, UI	Finding: Mechanical damage, L = 15 mm, D = 0.5 mm
4. Cylinder fitting, right wing	
Methods used: VI, ECI, UI	Finding: Damage of anodized coating (B+S7)

Figure 1. Example of VI noticeable mechanical damage

Some of typical defect mostly sought after at overhaul are signs of fatigue, corrosion and cracks. Here they are going to be explained more closely, particularly referring to EASA regulations.

2.4 Fatigue

The objective of fatigue related requirements is to ensure the retention of both limit and ultimate load capability throughout the service life of the aircraft.

For wings, empennage, and associated structures, compliance may be demonstrated by comparison with a similar, service-proven design with equivalent stress levels, materials, stress concentrations, and operational usage.

For small aircraft certification categories, these requirements apply to the pressurized cabin, wings, empennage, and associated structures. Landing gear and engine mounts are excluded.

2.5 Corrosion

Metals corrode due to chemical or electrochemical interaction with the environment. Corrosion worsens significantly by salt contamination, moisture presence, dirt deposits and so on. Alclad alloy 2024 used for aircraft skins is protected by a pure aluminium layer, surface protection systems, and paint coatings. At dissimilar metal interfaces (e.g., steel-to-aluminium), contact surfaces are protected with PS 892 C12 sealant.

Three criteria are used to determine whether a corroded component may be repaired:

- Component classification.
- Repair category.
- Corrosion severity.

The most common types of corrosion observed during aircraft service life are:

- General corrosion - most frequently found on steel and ferrous components, it appears in the form of reddish rust. Since it is easily detected by VI, it is generally not considered a hazardous form of corrosion. It usually develops where protective coatings have been damaged, particularly on cadmium-plated steel components.
- Pitting corrosion - the most common form of corrosion on polished aluminium surfaces. It appears as white or grey powdery deposits. After removal of the deposits, small pits become visible on the surface.

Pitting corrosion develops in three stages: pit initiation, early pit growth and stable pit growth. It is normally detected during the second stage. The coalescence of several pits may result in crater formation.

- Galvanic corrosion – it occurs when two dissimilar metals are in electrical contact in the presence of an electrolyte.

A typical example is the interface between an aluminium alloy component and a steel fastener. The greater the difference in electrochemical potential between the materials, the faster the corrosion process. For example, aluminium in contact with Monel may experience rapid and severe corrosion.

- Intergranular corrosion – the type that develops within the material structure and attacks the internal microstructure. It is often not detected until severe deterioration has already occurred.

Rapid intergranular may occur in 2024 and 7075 alloys if improper heat treatment has been applied.

Although material loss may be minimal, mechanical properties are severely degraded. The material becomes brittle and may fail under relatively low static or dynamic loads.

Exfoliation corrosion is an advanced form of intergranular corrosion characterized by separation of material layers.

- Crevice corrosion occurs at metal-to-metal interfaces, particularly at the edges of joints or between closely fitted surfaces.
- Filiform corrosion is a special form of crevice corrosion occurring beneath organic protective coatings.

It is recognized by thread-like patterns beneath the coating surface. This type of corrosion develops at relative humidity levels between 78% and 90% and temperatures above 30°C.

Repair categories

1st category

1.1 Components identified during corrosion inspections for which material removal during repair will not reduce the thickness below the minimum allowable thickness.

1.2 Components whose damage exceeds the minimum allowable thickness and whose repair is non-standard and not commonly encountered on other aircraft of the same series. Such repairs shall be specifically defined and approved by the manufacturer.

1.3 Components that repeatedly exhibit minor corrosion during service and are identified during every corrosion inspection. If it is determined during the latest inspection that corrosion removal would reduce the remaining thickness below the minimum allowable value, repair may still be permitted provided that the repair is specifically defined and approved by the manufacturer.

2nd category

Includes components corresponding to Class 1 and Group 1.3; however, these components shall be reinforced during repair.

3rd category

Includes components for which initial or subsequent corrosion inspections reveal severe corrosion levels that may present a significant hazard to aircraft operation.

Corrosion Severity

Three levels of corrosion severity are defined:

Level 1 – Surface Corrosion

Surface corrosion affecting material to a depth of up to approximately 0.0254 mm.

Level 2 – Moderate Corrosion

Corrosion affecting between approximately 0.0254 mm and 10% of the material thickness.

Level 3 – Severe Corrosion

Corrosion affecting more than 10% of the component thickness and potentially reaching up to 15% of the material thickness.

Repair of corroded components

Several standard methods are used for corrosion removal, including chemical treatment, manual sanding using aluminium oxide abrasive paper or metallic wool made of material compatible with the surface being treated, and mechanical sanding or polishing using abrasive wheels or pads.

During the inspection of Lasta S/N 54204, the airplane was found to be remarkably clear of corrosion, requiring only minimum intervention and cleaning actions. This is a testimony of surface protection well done during manufacture and assembly, combined with proper greasing and lubrication during service and timely periodic maintenance.

3. FLIGHT CONTROLS INSPECTION

After the airplane assembly stage is complete, it is time for completion and final tests stage. One of the most significant tasks in this stage is flight controls functional test and adjustment. There are multiple requirements that controls and control surfaces have to meet to acquire final approval, most important of which being proper deflections, proper input to output force ratio, acceptable free play and low friction. In this chapter, results of some of these tests are displayed that quantify proper state of controls after the assembly.

Results of measurements of flight control system free play, static friction and control forces on aircraft v54204

Control stick - elevator free play: 1,2 mm (maximum permissible value 2 mm) (**Figure 2**)

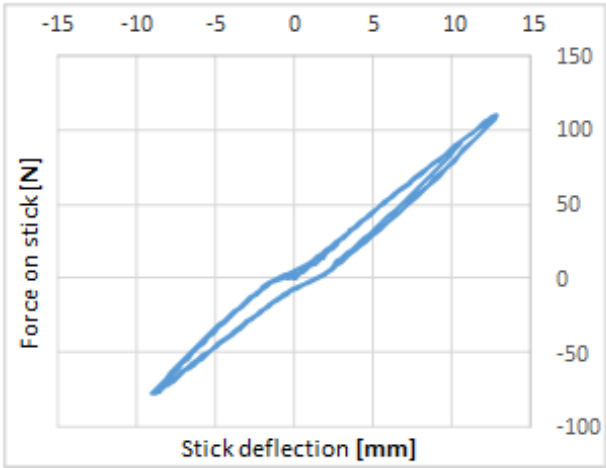

Figure 2. Control stick – elevator, free play

Elevator control system static friction force: 0,66 daN (maximum pesrmissible value 1 daN) (**Figure 3**)

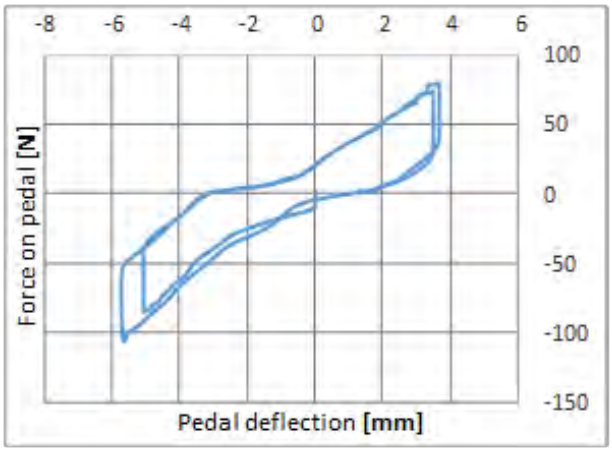

Figure 10. Rudder control, free play

4. CONCLUSION

During the overhaul process, Lasta 3 (V-54) airplane with S/N 54204 has been inspected, refurbished and tested. After successful completion of factory and flight tests, its airframe has been announced airworthy for a period of at least another 6 years or 1000 flight hours, whichever expires first, with periodic inspections and maintenance carried out as prescribed in AMM.

While overhaul goal is 10 years airframe service life extension, it is constrained to 6 years with an expiry date set by design at the time of production of the airplane S/N 54204 to be the year 2032.

Individual components' service life is subject to periodic maintenance, and can be extended depending on condition far beyond airframe service life expiry.

Conducting airplane overhaul and repair work on demand positions Utva Aviation Industry as a valuable MoD asset that continues successful work in maintaining Serbian air force's fleet of light trainer aircraft up and running for new generations of cadet pilots to improve and master their flying skills before advancing to jet fighters.

Abstract: *Drone military testing include a wide range of experiences, from technical challenges to practical problems in the field. Here is what it usually looks like in practice: Technical tests checks how the drone functions externally: Field Experiences Real-world and real-time conditions are often the greatest challenge: Wind can significantly affect small drones; Temperature, cold quickly drains the battery; Signal interference, power lines, and carbon-metallic constructions; Pilot visibility loss of visual contact increases risk. In practice, testers often say that an „ideal laboratory result is rarely achievable outdoors". Our, Serbian army way of testing is standard military drone certifications. A critical standard testing resistance to extreme temperatures, mechanical shock, vibration. EMI/EMC Compliance: Ensures the drone's electronics do not interfere with other friendly military communication or radar systems. What is the quality of drones made in the Republic of Serbia from domestic development, state projects and private manufacturers is presented in this paper.*

Keywords: *drone, examination, rule, swarm drone*

1. INTRODUCTION

Drones have become the hit of limited-intensity conflict in the early 21st century. War has become a game again, and drones are the enforcers of punitive measures. However, the main drawback of drones as a perfect weapon for now is its limitations in terms of the payload it can carry and the possibility of electronic jamming. When these issues are resolved, we will be able to talk about weapons that can bring victory in the war and create the conditions for the penetration of larger army groups on the front line. For now, we can say that victory in the war cannot be achieved only through use of drones.

However, even this previous claim became questionable during the conflict in Ukraine. The latest generation of drones has enabled a nearly permanent blockade of logistic supply routes used to resupply units, not only those on the front line but also throughout its strategic depth.

In this way, drones have become weapons that determine the outcome of armed conflicts, and as such, their quality must be verified before they are introduced into operational use.

Our, Serbian army way of testing is standard military drone certifications. A critical standard testing resistance to extreme temperatures, mechanical shock, vibration influence testing and EMI/EMC compliance.

2. DRONE TESTING RULES

According to Article 85 of the Rulebook on equipping the armed forces with weapons and military equipment, the procurement of weapons and military equipment as a finished product from the domestic or foreign market is carried out when a market procurement model is envisioned by a previous analysis, an Urgent equipping elaborate, or an Implementation program.

In the process of procuring weapons and military equipment from the market, the contract with the supplier must provide for the testing of the equipment, which is to be conducted during the acceptance of the equipment by a commission formed by the decision of the tactical holder.

The results of the verification testing of samples, or the testing results obtained during factory acceptance at the manufacturer's facility or final acceptance of the equipment, form the basis for the adoption of the equipment into the inventory of the Serbian Armed Forces.

The testing of military drones includes a series of rigorous technical, tactical and combat tests to determine their operational readiness, resistance to electronic interference and precision in destroying targets. In the modern context, the focus of the testing has shifted to flight autonomy driven by artificial intelligence, integration of drone swarm and action in conditions of active anti-aircraft defense [1].

Corresponding author: S. Jovičić
E-mail: msmjovicic@gmail.com

DOI: 10.5937/OTEH26010J

The examination covers several areas such as:

- Software and laboratory simulations: Verification of flight algorithms, resistance examination to electronic interference and operation of navigation systems.
- Climate-mechanical tests in the form of checking resistance to environmental influences.
- Operational service trials: Flights on military training grounds to test payload, durability, thermal imaging camera characteristics and operational range.
- Tactical evaluation: Examination of accuracy in hitting targets.

3. DRONE TESSTING EXPIRIENCE

Upon initial inspection of the assets received for evaluation, it is immediately apparent that drone manufacturing relies predominantly on components sourced from the Far East, specifically Asia, China, South Korea, and Taiwan.

Not only are the components sourced from the Far East, but every single software package shares that same origin. After an unusually prolonged development period, the domestic „Pegaz" project finally had to go and „"borrow brains" from Chinese partners. Operational service trials of military drones represent a key phase in which unmanned aerial vehicles are tested in realistic atmospheric, geographical and electronic conditions at dedicated military training ground.

These tests aim to verify the tactical-technical characteristics of the drone before it enters serial production or operational use.

- Flight performance check: Testing of maximum speed, flight ceiling, operating autonomy and behavior of the aircraft in extreme wind gusts, figure 1.

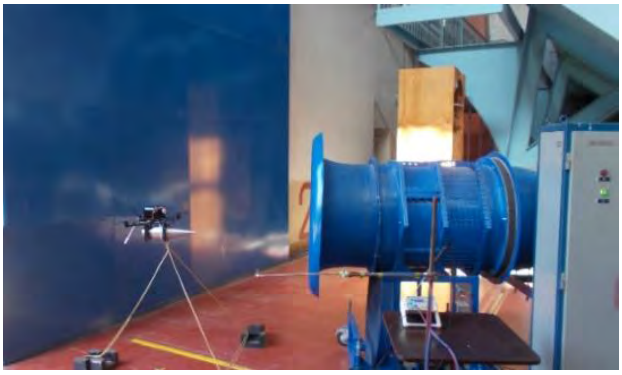

Figure 1. Testing of wind influence on drone flight characteristics

- Payload and stability testing: Monitoring the stability of a drone with a maximum payload, including electro-optical reconnaissance systems or ordnance.
- Immunity to electronic jamming: Simulate enemy counter-electronic (EW) activities to verify the stability of satellite navigation and radio communications.
- Optoelectronic equipment testing: Checking the range and accuracy of thermal imaging cameras, laser rangefinders and automatic target tracking systems.
- Maneuvering under load: Performing sharp maneuvers and simulating anti-aircraft defense (ADF) evasion.
- Combat shooting: Testing the accuracy of launching rockets, guided bombs or activating a kamikaze drone against static and moving targets.
- Take-off and Landing Systems: Checking the reliability of catapult, vertical take-off (VTOL) or parachute systems for forced descent.

Current domestic project

The „Komarac" drone

FPV kamikaze drone and interceptor family of drones represents the most massive domestic project in the segment of stray ammunition with following technical characteristics: Quadcopter with an operational range of 10 to 15 kilometers and a payload capacity of up to 5 kilograms.

Figure 2. „Komarac 1" drone, general appearance

Armament: The „Komarac 1" version carries a 64 mm cumulative warhead from the M80 „Zolja" hand-held rocket launcher, capable of penetrating up to 300 mm of homogeneous steel armor.

The latest development (Komarac 2V): During the last military demonstrations, Komarac 2V, a specialized disposable interceptor drone intended for the kinetic destruction of other enemy drones and missiles in the air, was presented for the first time.

„Pegasus" -reconnaissance-combat aircraft

„Pegasus" is the largest and most complex domestic unmanned aerial vehicle project, developed in cooperation with partners from China to integrate advanced data transmission and fire control systems.

Figure 3. „Pegasus" drone during take-off

Role in the field: It is intended for deep reconnaissance, observation, marking targets with a laser beam and carrying out attacks with guided air bombs and missiles.

Tests: The aircraft went through a long cycle of polygonal checks of the stability of the connection in the presence of electronic jamming and the precision of laser guidance on polygonal targets, figure 3.

„Vrabac"-tactical scout

The „Vrabac" is a smaller, easily portable aircraft that has been in operational use by the Serbian Army for years and serves as a basic tool for day and night reconnaissance at close distances, figure 4.

Figure 4. „Vrabac" drone in flight

Operational application: It is launched by hand or by means of an elastic rope (catapult), and it lands with a parachute.

Improvements: Its modified versions with more advanced electro-optical systems (thermal imaging cameras) and software for automatic recognition of targets on the ground are regularly tested on training grounds.

In addition to the mentioned, other domestic systems are increasingly appearing in military tests:

IKA (Bomber) drone

Domestically produced multicopters that are being tested for precise dropping of mortar mines on enemy positions. A product of the private company PRDC that has passed testing at TOC. It showed its quality at the recent demonstration at the „Pasuljanske livade" training ground, figure 5.

Figure 5. IKA bomber drone in flight

VTOL „Shadow":

Shadow is the VTI's latest project with vertical take-off and landing, which combines the speed of a classic airplane and the flexibility of a helicopter, figure 6.

Figure 6. „Shadow" drone, general appearance

Various producers offer various types of Tactical Drones and Military Drones for emergency management and mission-critical operations. These rugged military drones are designed to meet the demanding needs of Border Security and Armed Forces and are optimal for a range of applications such as high-altitude logistics delivery, ISR, mine detection and neutralization, combat, and target decoys, among others. On the market can be found customized tactical drones based on user-specific requirements, to meet the varying demands of weight, flight altitude, payload capability, endurance, armament and ammunition integration, electro-optical features and ruggedness.

The advanced AI technologies and visual algorithms in tactical drones and tactical military drones aid intelligent mapping of defined geographical areas; detect and classify objects of interest at low light and harsh weather conditions. These cutting-edge features make tactical military drones ideal for cross-border surveillance and to gather crucial situational awareness during a conflict and gather intelligence on border activities.

The rugged tactical drones are designed to transport in small SUVs and trucks and can be deployed in minutes from any terrain. These tactical military drones have a varying operational range of 3-10 km and can fly at an altitude of 1.500 m to 6.800 m, based on the payload, electro-optical sensor specifications.

Tactical military drones are equipped with advanced technology that enables them to perform a variety of

functions, including surveillance, reconnaissance, target acquisition, and even weapon delivery.

The tactical drones usually come with three flight modes, Manual, fully Autonomous and pre-mapped Autonomous. The user can define the mode of flight based on operational needs in these rugged Military Drones. For instance, for periodic cross-border surveillance at a defined area, a fully autonomous mode would be ideal. However, during a conflict wherein every second is crucial, Manual or semi-autonomous operation would provide quick insights to the operator. In case of link loss (loss of connectivity with GCS) due to signal jamming or extreme weather conditions, the Auto Return Home feature aids the drones to return to the launch safely. Producers also offers Tactical Military drones for distant surveillance with a range of up to 45 km, especially with stealth capabilities.

Rugged tactical drones come with ergonomically designed, user-friendly Ground Control Stations (GCS). The multi-layered safety protocols ensure secure communication between GCS and the drones. Based on the application and use case, the GCS can be designed to have single or dual displays to provide maximum usability and operational convenience to the operator on the field.

5. NEW THREAT FROM DRONES

China has for the first time publicly demonstrated the complete operation process of the Atlas system for operations with swarm drone units, thereby further emphasizing the accelerated development of autonomous military technologies. The system was presented through testing in real-world conditions, where drones carried out coordinated reconnaissance and precise attack on the target.

Figure 7. „Atlas" drone swarm launcher

The Atlas system consists of several components, including the Swarm-2 combat vehicle, command vehicle and logistical support. One Swarm-2 vehicle can launch up to 48 drones, while the command vehicle simultaneously manages up to 96 units in the row. During the demonstration, the system independently performed target recognition, drone launch and precise attack, without direct human control over each individual device. Drones in flight coordinated movement, avoided collisions and adjusted the formation in real time. The system's special strength lies in so-called "royal intelligence", where each drone functions as part of a wider network.

Thanks to advanced algorithms and AI processing, units exchange data, adjust positions and optimize the tension and output tasks [3].

The conflicts of 2025 proved that the electromagnetic spectrum is no longer a secondary domain. It is a primary arena of competition. Jamming, spoofing, cyber intrusions and attacks on satellite infrastructure changed the tactical landscape more than artillery or armor in multiple theaters.

This means one thing. Systems deployed in 2026 must be capable of operating through degradation. They must navigate without GPS, communicate across multiple resilient channels, and continue missions even under heavy interference. This reshapes how platforms are designed, procured and evaluated [4].

Producers offer Tactical military drones in a range of sizes and capabilities, from small quadcopters to large Octocopters or UAV plane shape drone.

The tactical drones usually come with three flight modes, Manual, fully Autonomous and pre-mapped Autonomous. The user can define the mode of flight based on operational needs.

6. FUTURE TESSTING

Coordination of drone swarm: Testing the ability of mutual communication and synchronized attack of multiple aircraft simultaneously without human assistance.

The past decade has seen an enormous increase in the use and importance of the "electronic battlefield." As a result of the continuing growth in this area, this volume has been prepared to serve as an introductory reference to the process of testing and evaluating Electronic Warfare Systems. Electronic Warfare (EW) is the mission area responsible for establishing and maintaining a favorable position in the electromagnetic domain.

Test and evaluation (T&E) of those devices used on modern military aircraft to prosecute this critical mission area requires the use of a wide range of test techniques and analytical methods to assure users of the readiness of EW systems to meet the challenges of the combat environment. Actual in-flight testing comprises a relatively small portion of the EW T&E process [5].

7. CONCLUSION

Drones have become the hit of limited-intensity conflict in the early 21st century. War has become a game again, and drones are the enforcers of punitive measures. However, the main drawback of drones as a perfect weapon for now is its limitations in terms of the payload it can carry and the possibility of electronic jamming.

When these issues are resolved, we will be able to talk about weapons that can bring victory in the war and create the conditions for the penetration of larger army groups on the front line.

Future tests will require the test center to be equipped with equipment that will be able to respond to the test tasks of characteristic drones driven by artificial intelligence and not one but rows. Basic tests will remain an important segment of the overall test but the control systems and ways of intercepting communications between operators and drones or their communications with AI will become a matter of survival on the front.

CRITICAL LOAD CALCULATION FOR SOME KIND OF NONUNIFORM STRUTS

BOGDAN S. BOGDANOVIĆ
SERBIA, bogdanovic00@gmail.com

TONKO A. MIHOVILOVIĆ
UTVA AI, SERBIA, tonkojetonko@gmail.com

Abstract: *Struts of different types and shapes, made of different materials, are very freequently used as structural elements in aircraft and some other constructions. They are exposed to different types of loadings, and their dimensions should defined so (to be capable) to have sufficient capacity for such load transfering. Perhaps, the most important detail (data) for dimensions determination is definition of critical load (force). In this paper one of the well known numerical method for critical load definition, double integrated method, will be applied to some special kind of struts, having nonuniform cross section shapes This kind of struts isn´t often used, but it appears sometimes in constructions, and usualy it was solved using some kind of rough approximations. Double integrated method is quick and more reliable procedure for critical load (force) calculation. Also a numerical examples are given.*

Key words: *critical load, strut, nonuniform shape*

1. INTRODUCTION

In the greatest numbers of load cases, structural elements like struts are loaded in axial direction; these loads produce tension or compression in element. In the case of axial tension load transfering dimensions definition is quite simple. Here it depends only of strut´s cross section shape and dimensions; length of strut doesn´t have any influence. On the other side, in the case of axial compression load transfering, the length of strut must also be taken in consideration. Length of strut together with a cross section dimensions will be used for definitin of critical load (force), or BUCKLING load value; which is always the most important in considering struts load transfering capacity. Usually, struts have uniform cross section area shape along the whole length, but in some special cases, it could be partly changed; such struts type is named nonuniform. For both struts types uniform and nonuniform the double integration method could be used for BUCKLING load value definition.

2. DOUBLE INTEGRATION METHOD

This method could be used quite easy for critical load (force), or BUCKLING load calculation (estimation) of uniform, or nonuniform pin ended struts, but it loses simplicity for non pin ended struts. It should be noted, that pin ended boundary conditions always give the lowest critical load (force), or BUCKLING load value, so the obtained results could be used as a minimum value. It means, obtained results are conservative, on the safety side. The method ivolves a double integration of an assumed deflection curve. In [1] the differential equation for the displacement (w) of pin ended strut with a nonuniform cross section(flexuralrigidity)is:

$$Eiw'' + Pw = 0$$

Hence

$$w'' = -\frac{P*w}{EI} \qquad (1)$$

Assumed deflected shape (w_1) is a first step in calculation. Here P is treated as unknown quantity. It means that equation (1) could be used to determine the curvature w´´ in terms of P at any point x. Curvature is integrated twice in order to to obtain a new set (shape) of deflection, (w_2) which include P as a common factor. Dividing assumed deflected shape (w_1) with a new deflection set (w_2) the estimated value of P is obtained. This P value can maintain the assumed deflection (w_2); it means it is the critical load (force). There are two types of nonuniform shape struts:

- Cross section (EI) varies in steps, one or more, along the strut length (variant a), and (or)
- Cross section (EI) varies continously along the strut length (variant b)

Corresponding author: B. Bogdanović;
E-mail: bogdanovic00@gmail.com
DOI: 10.5937/OTEH26011B

These two types are quite similar, but the method procedure will be shown using strut where cross section varies in steps, because there it is less complicated and easier for understanding. For simplicity whole calculation is divided in several steps:

1. The strut is divided into several (usualy ten) segments of equal length), but because of symetry, only one half of strut´s length will be used,
2. Ends of segments are doubled in places where are stepped cross sectional changes
3. Assumed deflection curves are sine or parabola; maximum deflection (amplitude) is labeled as 100; it´s position is in the middle point of strut´s length.
4. Values of relative cross section characteristics EI are specified, at the ends of segments,
5. (w/EI) value calculation at the ends of strut segments,
6. Area under (w/EI) line calculation (using trapezoidal rule for every segment,
7. Slope change calculation along each segment $i_x = \int_0^x \left(\frac{P*w}{E*I}\right) dx,$
8. Obtaining (w´) cumulative values of (i_x) on the segments ends
9. Slope values (displacement changes w´) calculation at the segments ends
10. Area under (w´) line calculation (using trapezoidal rule for every segment)
11. Obtaining displacement values (w2) simply by taking cumulative total of numbers in preeceding row (step),
12. Finaly, an estimated value for relative critical load (force) in every segment can be obtained by dividing displacement values of assumed deflection curve (w1) with modified values (w2) and multiplying this ratio by 100

Results obtained in 12. th step will be different from segment to segment, and should be treated as a first iteration. Good aproximation for relative strut critical load (force) final result could be the average values (w1/w2) for all ten segments. Perhaps, it is better to take one or several more calculation cycles, (second, third iteration), taking modified value (w2) from preceeding iteration as assumed value (w1) for the next one:

$$w2_{n} = (w1_{n+1})*w_{\text{STRUT middle place}}$$

The procedure should be stopped when obtained results become the same for all segments. Results obtained in 12 th row of last iteration are also relative values, and to get absolute (real) strut critical load (force) it is necessary to multiple them with (EI/h2); it is obtained using equation:

$$P = (w1/w2)*(E*I)/h^2 \qquad (2)$$

Replacing h = L/10 in equation (2), it is obtained:

$$P = 100 * (w1/w2)*(E*I)/L^2 \qquad (3)$$

Here is: L = length of whole strut.

Now, it should be reminded that critical force for uniform cross section strut is defined by [2]:

$$P_{UNIFORM} = \pi^2*E*I/L^2 \qquad (4)$$

Comparing values obtained using equation (3) and (4), a reduction factor (coefficient) for strut critical load force produced by cross section nonuniformity is obtained:

$$\mu = (100 *(w_1/w_2))/\pi^2 \qquad (5)$$

3. NUMERICAL EXAMPLE

As a numerical example a critical load (force) for two types of nonuniform struts will be calculated. They both have equal length, and are made of the same material - alluminium alloy:

L = 100 [cm] , E = 749000 [daN/cm^2]

One of them is:

- reinforced in the middle section, STRUT 1, and the other is
- reinforced near the ends (supports) STRUT 2

Changes of their shapes along length are shown schematicaly in Fig. 1 and 2.

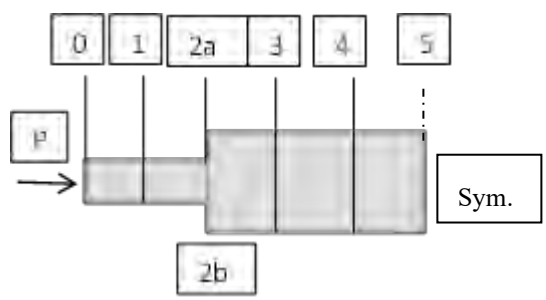

Figure 1 STRUT 1 - Shematic diagram

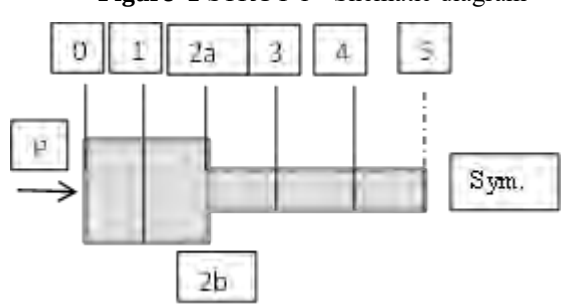

Figure 2 STRUT 2 - Shematic diagram

3.1 STRUT 1 critical force calculation

Calculation procedure and obtained results for STRUT 1 is shown in tables 1 - 4, 1 - 4 (cont), All necessary relative dimensions for STRUT 1 are shown in the second row in tables 1 - 4, and tables 1 - 4 continued

Table 8 Dimensions of full strut cross section

b [cm]	h[cm]	h^3[cm]	I [cm^4]
3	3	27	6.75

Using equations (3), (4) and values from Tables 4, 5 and 7 the real STRUT 1 and STRUT 2 (nonuniform cross

section) critical force and critical force for uniform cross section strut are :

P = 100*0.0873*749000*6.75/100^2, Pcrit. = 4413.67 [daN] (nonuniform cross section) STRUT 1

P = 100*0.0424*749000*6.75/100^2,Pcrit. = 2122,417 [daN] (nonuniform cross section) STRUT 2

P = 3.14^2*749000*6.75/100^2, P = 4989.83 [daN] (uniform cross section)

4. CONCLUSION

The simplified and reliable procedure for critical force (load) values definition for struts having non uniform cross section shapes along length is shown. Only limiting condition for applying of this procedure is that struts are always pin ended. It could be applied to any kind of non uniformity, it means that cross section shapes can vary in steps, perhaps in several steps, or continously. Here the integration procedure is realized using trapezoidal rules; perhaps something better accuracy could be achieved using some other procedure (fitting cubic curve to the deflection line through segments). Two numerical examples are shown in detail.

Abstract: *Increased actuation energy of morphing wings, caused by elastic deformation, could potentially diminish the aerodynamic benefits they offer compared to wings with conventional control surfaces. This paper proposes a rotary mechanism based on pre-buckled plate springs that exhibits negative stiffness and stores energy to balance the torque required for camber morphing. Plate springs benefit from near-constant post-buckling force output and could potentially simplify the negative stiffness mechanism. A combined analytical and numerical method for sizing the mechanism for camber morphing wings is developed and verified, accounting for stiffness requirements, range of motion, material properties, spatial constraints in small UAVs, and spring stability. Results indicate that the proposed mechanism is a viable solution for passive energy balancing of camber morphing wings.*

Keywords: *negative stiffness, morphing wing, energy balancing, compliant.*

1. INTRODUCTION

One of the challenges associated with morphing wings is the increased actuation energy required. This is due to the need to overcome the elastic forces caused by the deformation of the morphing wing structure. Consequently, larger actuators are required, increasing the overall system weight and potentially diminishing the aerodynamic performance benefits enabled by the smoother morphing geometry [1].

Morphing wing mechanism designs and concepts differ greatly in the materials used, types of morphing, and complexity. Camber morphing wings actuated by standard servo motors are of particular interest in this paper due to their simplicity and use of conventional means of actuation. Many variations exist, such as the FishBAC mechanism inspired by a fishbone [2], the corrugated spine mechanism [3], or the mechanism based on additively manufactured compliant composites, which was demonstrated in UAV flight [4].

Multiple solutions have been proposed to counteract the elastic deformation forces of morphing wings, specifically those actuated through a pulley and tendon mechanism. One such solution was a negative stiffness torsional mechanism proposed by Zhang et al. [5], which utilized pre-compressed springs arranged in a rotary mechanism. Wang et al. [6] opted for a somewhat more complex mechanism using a custom spiral pulley and extension springs.

1.1. Proposed Concept

This paper presents another solution for static balancing of an elastic camber morphing wing. It is based on the principle of strain energy conservation through pre-buckled plate springs. The springs are connected to a rotating shaft, as shown in Figure 1, providing the negative stiffness needed to counter the positive stiffness of the deforming wing, as the wing's deformation also produces torque on the shaft.

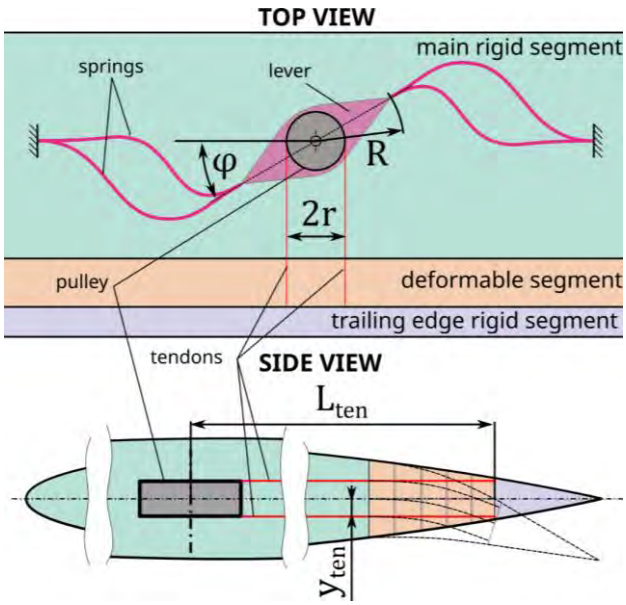

Figure 1. Proposed plate spring rotary mechanism morphing wing implementation

Corresponding author: M. Vučinić;
E-mail: 1088-2023@studenti.mas.bg.ac.rs
DOI: 10.5937/OTEH26012V

The lever and the pulley are tied and rotate together. In an ideal case, positive elastic deformation torque, acting on the mechanism through the pulley, and negative stiffness mechanism torque would cancel each other. This effect can be illustrated by the linear mechanism shown in Figure 2.

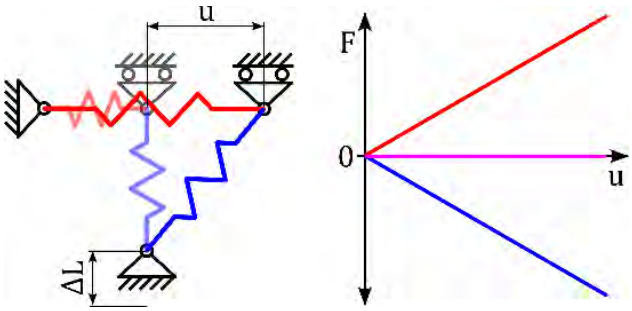

Figure 2. Negative stiffness mechanism based on a pre-compressed spring (blue) coupled with positive stiffness (red) yielding zero stiffness (magenta)

One of the goals of the proposed mechanism is to improve the scalability and simplicity in comparison to the previously mentioned works, as it would not depend on off-the-shelf components such as helical springs and rotary joints, and could even be manufactured as a monolithic piece.

A mixed analytical–numerical method is developed for designing such a mechanism and is demonstrated on a case study wing.

2. ANALYTICAL METHOD

2.1. Reference Wing Properties

Even though the proposed mechanism is not limited to a specific camber morphing design, for the purpose of this study, the FishBAC mechanism was chosen for the morphing wing segment due to its simplicity and wide literature coverage. The analytical method proposed by Woods et al. [7] was used to obtain a rough estimate of the stiffness and spatial constraints of the FishBAC mechanism, for which the negative stiffness mechanism was developed. This method is based on the reduction of the FishBAC model to a simple Bernoulli cantilever beam with variable stiffness along its length and calculation of the resulting deflection and needed torque for the given tendon material and cross-sectional area, where tendons are modeled as axially loaded rods. It is important to note that the required torque and pulley rotation for the given deflection depend strongly on the tendon material and dimensions:

$$M_{\text{ten}} = \frac{2k_{\text{ten}}y_{\text{ten}}\delta_R}{1 + 2k_{\text{ten}}y_{\text{ten}}\int_0^{L_m}\frac{1}{E(x)I(x)}\,dx} \tag{1}$$

where δ_R represents the change of tendon length due to the pulley rotation only, $E(x)$ and $I(x)$are the distribution of the elastic modulus and the axial moment of inertia of the equivalent beam along its length, and

$$k_{\text{ten}} = (E_{\text{ten}} * A_{\text{ten}}) \,/\, L_{ten} \tag{2}$$

represents tendon stiffness. The remaining terms from equations 1 and 2 are shown in Table 1.

Results were verified against the source (Woods et al. [7]) using the original input data, but for further analysis most of the dimensions and material properties were taken from the more recent work of Wu and Woods [8] and are presented in Table 1. The authors analyzed the wing at a freestream velocity of 30 m/s and demonstrated the benefits of a shorter morphing region near the trailing edge. As the method presented by Woods et al. [7] works only for symmetrical airfoils, the NACA 23012 airfoil from the work of Wu and Woods [8] was replaced with NACA 0012. Figure 3 shows the layout of the analyzed morphing segment and its maximum deflection.

The resultant moment-pulley angle relationship is linear, as expected. The maximum torque needed for the given parameters is $M_{\text{ten}} = 390$ N mm, occurring at the pulley angle $\varphi = 15°$, and the maximum deflection of the morphing segment end of $u_{\text{max}} = 3.3$ mm. Note that this deflection does not represent the trailing edge deflection as the morphing section stops at 90% of the chord; therefore, the actual wingtip deflection is larger. Additionally, it was estimated that the springs should not be wider than 25 mm due to spatial constraints.

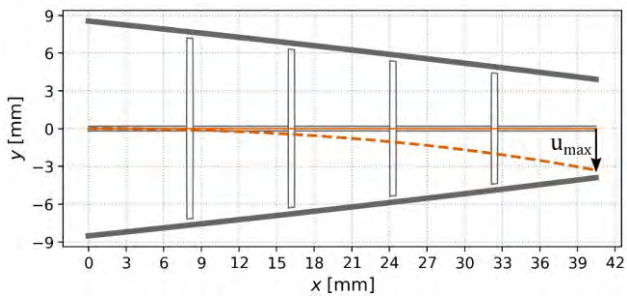

Figure 3. Morphing segment dimensions and calculated deflection for the pulley angle of 15°

Table 1. Reference wing parameters

Name	Symbol	Value
chord	c	270 mm

required torque	$\mathbf{M_{ten}}$	**390 N mm**

2.2. Spring Analysis

Based on the required torque and the maximum pulley rotation angle calculated in the previous chapter, it is now possible to size the negative stiffness mechanism. The rotational mechanism presented in Figure 4 consists of two springs approximated as two fixed-guided beams. The actual mechanism would have springs on both sides of the shaft, making it axisymmetric and canceling out the transverse forces acting on the shaft. Therefore, the model can be reduced to a single side and designed for half of the required torque, since the full system is symmetric and would double the torque output.

Dijksman [9] presented a detailed simplified linear analytical method for the analysis of translational mechanisms utilizing pre-buckled plate springs of undeformed length L and stiffness $B = (Ewt^3)/12$, where E is the elastic modulus, w is the spring width, and t is the spring thickness. According to their work, the moment M, force D parallel to the translation direction v in Figure 4, and force N perpendicular to the translation direction, all acting at the moving end, can be calculated as

$$D_i = \alpha_i^2 \left(\frac{\theta \sin\left(\frac{1}{2}\alpha_i\right) + \alpha \frac{v}{L} \cos\left(\frac{1}{2}\alpha_i\right)}{2\left(\sin\left(\frac{1}{2}\alpha_i\right) - \frac{\alpha_i}{2}\cos\left(\frac{1}{2}\alpha_i\right)\right)} \right) \cdot \frac{B}{L^2}, \quad (3)$$

$$N_i = \frac{B\alpha_i^2}{L^2}, \quad (4)$$

$$\frac{M_i L}{B} = \alpha_i \frac{\left(\theta\left(\frac{\frac{\alpha_i}{2}}{\sin\left(\frac{\alpha_i}{2}\right)} - \alpha_i \sin\left(\frac{\alpha_i}{2}\right) - \cos\left(\frac{\alpha_i}{2}\right)\right) - \alpha_i \frac{v}{L} \sin\left(\frac{\alpha_i}{2}\right)\right)}{2\left(\sin\left(\frac{\alpha_i}{2}\right) - \frac{\alpha_i}{2}\cos\left(\frac{\alpha_i}{2}\right)\right)}. \quad (5)$$

Here $i = 1,2..$ represents the spring index, θ is a constant initial spring angle at the sliding end of the mechanism, and $\alpha_i = 2(\pi - \varepsilon_i)$, where

$$\varepsilon_i = \pm \frac{1}{4}\theta \sqrt{\frac{L}{L - L_{0t}}} \quad (6)$$

depends on how bent the spring is at a given moment. In Figure 4, the left spring ($i = 1$) is more bent at $v = 0$ with given θ than in the case where $\theta = 0$, therefore $\varepsilon_1 < 0$. The right spring ($i = 2$) is less bent than in the $\theta = 0, v = 0$ case, therefore $\varepsilon_2 > 0$.

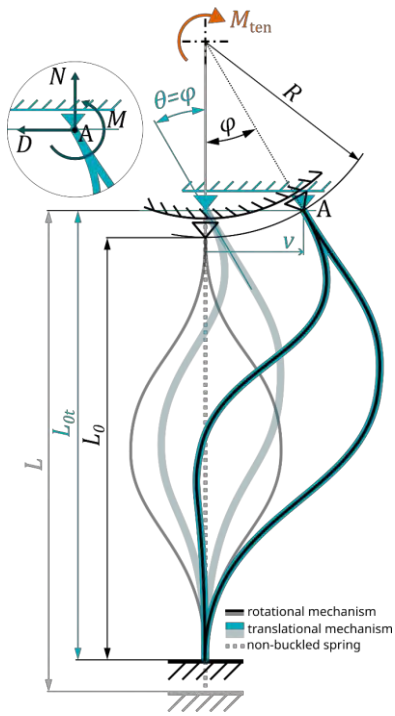

Figure 4. The rotating mechanism with its equivalent translational mechanism at the given moment

Given its path independence, the above-mentioned approach is modified here to account for rotational motion instead. The forces and moments of the rotational mechanism analyzed here and shown in Figure 4, with lever arm radius R and lever angle φ, can be calculated by substituting

$$v = R \sin \varphi, \quad (7)$$

$$L_{0t} = L_0 + R(1 - \cos \varphi), \quad (8)$$

$$\theta = \varphi, \quad (9)$$

into equations 3, 4, and 5.

Therefore, it is possible to calculate the moment generated in the pulley shaft by each spring of the negative stiffness mechanism as follows:

$$M_{Ri} = -\left(M_i + R(\sin \varphi \, N_i - \cos \varphi \, D_i)\right) \quad (10)$$

The minus sign is due to the tendon moment's positive direction defined in Figure 4. The more bent spring is inherently unstable. The left spring in Figure 4, in both the translational and rotational mechanism, would lose its stability after a certain displacement or rotation. It would snap to the same shape as the less bent spring on the right. Dijksman [9] also presented an equation

$$v_{\max,\mathrm{mb}} = 2L \sqrt{\frac{L - L_{0t}}{3L}} \left(1 - \frac{L - L_{0t}}{L}\right) \left(1 - 0.6\varphi \sqrt{\frac{L}{L - L_{0t}}}\right) \quad (11)$$

where $v_{\max,\mathrm{mb}}$ represents the maximum displacement v that the observed translational system can have before the more bent spring becomes unstable. The author also presented the equation to calculate the maximum displacement at which the less bent spring loses its spring action:

$$v_{\max,\mathrm{lb}} = 2L\sqrt{\frac{L-L_{0t}}{3L}}\left(1-\frac{L-L_{0t}}{L}\right)\left(1-0.26\varphi\sqrt{\frac{L}{L-L_{0t}}}\right). \quad (12)$$

It can be noted that in the case of the rotational mechanism only the more bent spring ($i = 1$) is the limiting factor, as $\varphi = \theta$ and v always have equal signs.

3. NUMERICAL ANALYSIS

3.1. Geometry Optimization

As the bending stress of a buckled spring is proportional to the change in length of the spring after buckling, it is essential to set adequate limits during the design phase so that the springs are stable but not unnecessarily overstressed.

In the mathematically ideal case, the more bent spring should be at its stability limit for the maximum pulley angle. This is impractical and, in aerospace applications, even unsafe, as the mechanism is very sensitive to any input around the stability boundary. For this reason, a safety factor of around 1.1 was implemented to ensure that the mechanism does not approach the stability boundary during operation.

The factor that limits the working range of the rotary mechanism is $v_{\max,1}$. Therefore, the following method was developed to find the combinations of relative changes in length and relative radii for which the mechanism operates at the stability limit for the given lever angle φ.

The contours shown in Figure 5 were obtained by computing the level set

$$q_1\left(\frac{R}{L}, \frac{\Delta L}{L}, \varphi\right) = 1 \quad (13)$$

where q_1 depends on the properties of the equivalent translational mechanism for the given R/L, $\Delta L/L$, and φ in a way that

$$q_1 = \frac{v_{\max,1}}{v} \quad (14)$$

The results are shown in Figure 5. The maximum pulley angle φ the spring can sustain depends solely on its length and the buckling displacement. Several points along the $\varphi \approx 16.6°$, equal to around 110% of the needed 15° of working range, were selected for the FEM analysis described in the following section, with the goal of determining output torque and stresses for each combination.

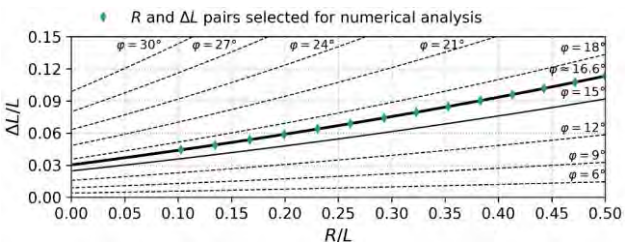

Figure 5. Curves of radius-length combinations at loss of stability for constant lever angle

3.2. FEM Analysis

An iterative static structural analysis was performed using Abaqus solver for each combination of R/L, $\Delta L/L$ and L, where L is a set of undeformed spring lengths shown in Table 2. Spring width and thickness were held constant at each iteration, as shown in the same table.

Table 2. Spring dimensions

spring width	w	25 mm
spring thickness	t	0.2 mm
spring undeformed length	L	[110, 120, 130, 140] mm

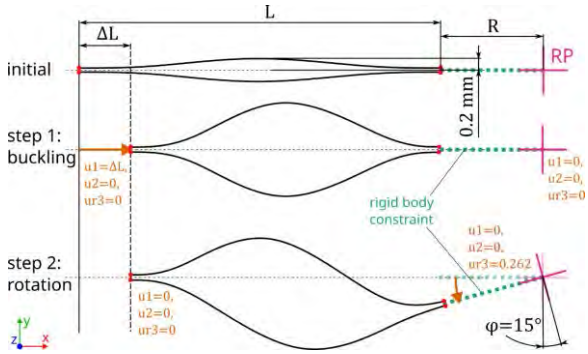

Figure 6. FEM analysis steps

Each analysis consisted of three steps shown in Figure 6. The beams were of a slightly sinusoidal shape with an amplitude of 0.2 mm (as shown in the initial step in Figure 6), to induce buckling in the right direction. Left end nodes of the springs had a displacement boundary condition prescribing translation to induce buckling in the first step (step 1 in Figure 6), and the remaining degrees of freedom constrained to zero. A rigid body constraint was used to connect the right end nodes to a reference point (RP) positioned to represent the pulley axis. The RP had a displacement boundary condition prescribing rotation (0° during buckling, 15° in the following step, as shown in Figure 6), and the remaining degrees of freedom were constrained to zero.

The model was two-dimensional. Linear Timoshenko beam elements in 2D space with the hybrid formulation (B21H) were used due to the simplicity of the geometry and computational efficiency. They were expected to have very similar results to those of Euler-Bernoulli theory, due to the very large slenderness of the beams. The hybrid formulation provided robustness during the initial buckling step. Mesh size was set to 2 mm. The large displacement solver option was used. The material used was linear elastic with the elastic modulus from Table 3.

Material properties of spring steel 1.4310, listed in Table 3, are based on typical values reported by spring steel manufacturers, used to assess the general viability of the proposed model rather than to represent a specific tested material batch.

Table 3. Assumed spring material properties

material name		1.4310 spring steel
Young's modulus	E	190 GPa
tensile strength	UTS	1600 MPa
fatigue strength	S_f	450 MPa

Reaction moment was calculated at the reference point, representing the shaft of the pulley. The rotation step maximum time increment was set to 0.05 to obtain the stress distribution and reaction moments at multiple points along the working range. The stress distribution for a selected configuration is shown on Figure 7 and Figure 8.

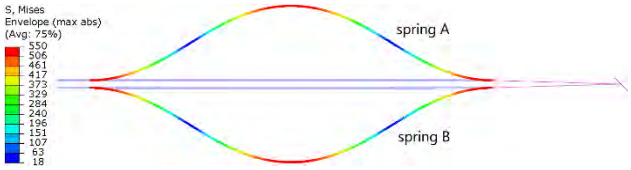

Figure 7. Maximum von Mieses stress (MPa) along the beams after the buckling step for $\Delta L = 8.9$ mm, $R = 35.14$ mm, $L = 120$ mm. The unbuckled spring and the rigid body are shown

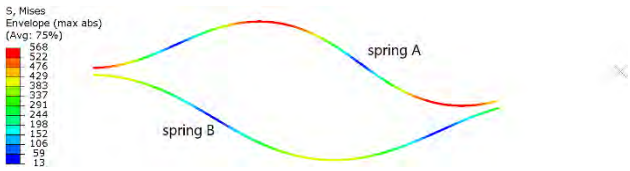

Figure 8. Maximum von Mieses stress (MPa) in the rotation step for $\varphi = 15°$, $\Delta L = 8.9$ mm, $R = 35.14$ mm, $L = 120$ mm

3.3. Mechanism Sizing

The FEM analysis results provide information about the torque exerted along the working range for each combination of R, L and ΔL from Figure 5 and Table 2. These results can be directly used to find the combinations that satisfy the torque requirement established in Section 2.1., or to be more precise, half of the torque required, as only one half of the mechanism is analyzed. However, raw stress values are not indicative of a given configuration's viability, as they do not consider fatigue life of the spring, which is a major design constraint.

To account for the fatigue effects, the Goodman criterion is selected as another condition to be satisfied together with the required torque. For the fatigue analysis, it is assumed that the mechanism cycles through its full range of motion each cycle. This is an intentional overestimation, as this would rarely happen during flight if the morphing structure were, for example, part of an aileron, and used as the theoretically worst possible case. In general form, the Goodman criterion is calculated based on the stress amplitude σ_a and the mean stress σ_m, as

$$\eta_\mathrm{G} = \frac{\sigma_\mathrm{a}}{\mathrm{S_f}} + \frac{\sigma_m}{\mathrm{UTS}} = \frac{\frac{\sigma_\mathrm{max} - \sigma_\mathrm{min}}{2}}{\mathrm{S_f}} + \frac{\frac{\sigma_\mathrm{max} + \sigma_\mathrm{min}}{2}}{\mathrm{UTS}} \quad (15)$$

where σ_max and σ_min represent maximum and minimum stress at the examined point.

It is important to note that the range of rotation in the FEM model is from 0° to 15°, which is only half of the actual working range from -15° to 15°. The mechanism's symmetry can be used to account for this. Beam B (spring B in Figure 8 and Figure 7) is a mirrored version of beam A (spring A in Figure 8 and Figure 7). In case $\varphi < 0$, beam A would take the mirrored shape of beam B for $|\varphi|$. This practically means that for $\varphi < 0$ beam A's top surface has values corresponding to beam B's bottom surface for $|\varphi|$. This enables the introduction of an equivalent spring for which the maximum Goodman criterion for each node j is equal to

$$\eta_{\mathrm{G}j} = \max\left(\frac{\sigma_{\mathrm{a}j}^{\mathrm{top}}}{\mathrm{S_f}} + \frac{\sigma_{\mathrm{m}j}^{\mathrm{top}}}{\mathrm{UTS}}, \frac{\sigma_{\mathrm{a}j}^{\mathrm{bot}}}{\mathrm{S_f}} + \frac{\sigma_{\mathrm{m}j}^{\mathrm{bot}}}{\mathrm{UTS}}\right) \quad (16)$$

The maximum overall Goodman criterion of the mechanism is now equal to

$$\eta_{G_\mathrm{max}} = \max_{j\in\{1,\dots,n\}} \eta_{G_j} \quad (17)$$

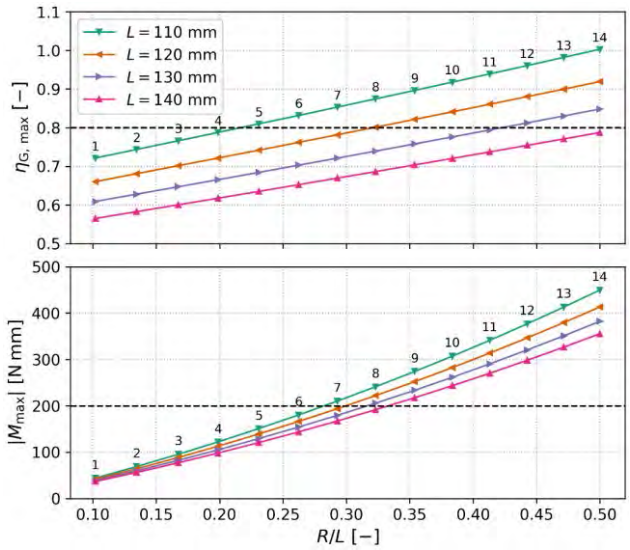

Figure 9. Maximum moment and Goodman criterion for each combination of R, L, and ΔL

The maximum moment measured at the reference point and the maximum Goodman criterion are shown in Figure 9 for each analyzed configuration.

Out of all the discretized combinations used for the FEM analysis, geometric combination 7 with $L = 120$ mm was selected for the experiment. This decision was based on the fact that it is the closest match to the required moment that doesn't overshoot it, with the moment of -193.6 Nmm compared to the 195 Nmm needed. Having the negative stiffness mechanism stiffer than the positive stiffness mechanism would produce overall negative stiffness which is undesired. The Goodman criterion value at just under 0.8, which is selected as the upper limit considering a factor of safety, also satisfies the fatigue condition.

4. EXPERIMENTAL VERIFICATION

The experimental setup, shown in Figure 10, consisted of an adjustable anchor used to fix one end of the springs after buckling them, an adjustable lever arm and a pulley segment, whose rotation was limited by the adjustable stopper, and a string attached to the pulley. The pulley radius was 25 mm and the string diameter was 1 mm.

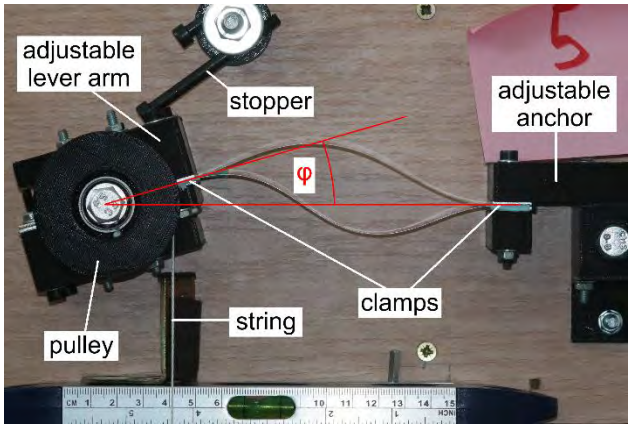

Figure 10. The experimental setup with its components

The springs were inserted in clamps and fastened to desired length, while keeping the pulley angle as close to zero as possible. The adjustable anchor was moved to buckle the springs. The stopper was adjusted to the desired position, and the mechanism was left to rest on it. Weight was incrementally added through the spring acting on the pulley until the system lost stability and snapped back to the other stable state.

The maximum moment at the given stopper position was calculated after measuring the weight with ± 3 g precision. The corresponding angle was measured using ImageJ from photographs taken with a telephoto lens with minimal distortion, as shown in Figure 10. These measurements were repeated for multiple stopper positions.

The springs used were cut from a sheet of 1.4310 steel, with the width of 25 ± 0.5 mm, and thickness of 0.2 ± 0.008 mm. The length of the springs between two clamps was set to $L \approx 120$ mm, the lever arm radius to $R \approx 35.1$ mm, and the translation of the adjustable anchor after clamping the springs was set to $\Delta L \approx 8.9$ mm. The results are shown in Figure 11.

5. RESULTS AND DISCUSSION

Results presented in Figure 11 show a strong match between numerical and analytical solutions for the moment curve, and somewhat lower values for the experimental curve. This difference is deemed acceptable and expected considering the measurement uncertainty mentioned in Section 4 and other effects that are not accounted for in the analysis, such as the stiffness of the experimental setup. Aside from that, the material batch used for the springs in the experiment was not tested, and slight variations in the Young's modulus are possible.

The relationship between the moment and the angle is nearly linear, and the measured stability boundary slightly above the calculated one, as expected due to the slight initial curvature of the springs used in the experiment.

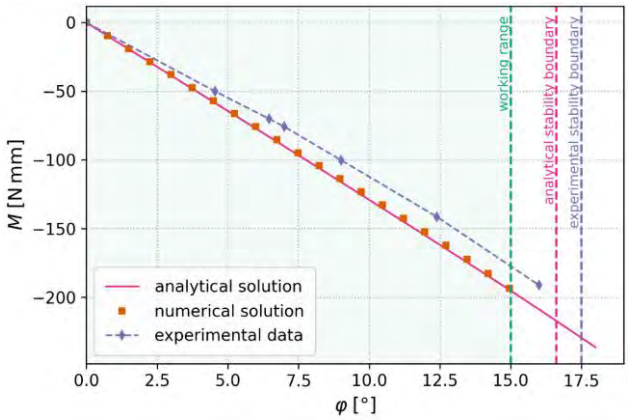

Figure 11. Calculated moment versus angle curves for $L = 120$ mm, $R = 35.14$ mm, $\Delta L = 8.9$ mm, $h = 0.2$ mm, $w = 25$ mm and $E = 190$ GPa, and measured experimental data for values stated in Section 4

It was observed that that the stiffness of the mechanism is highly sensitive to the change in initial spring length L. For example, increasing the spring length from 120 to 125 millimeters leads to strong agreement with the experimental results. At 16°, the model with $L = 125$ mm predicts a moment of -190.5 Nmm, compared to -191.1 Nmm from the experimental data, whereas the model with $L = 120$ mm predicts -208.9 Nmm. This effect can be used to tune the mechanism's stiffness during its assembly in the wing.

Nonetheless, the buckling displacement ΔL has a minor effect on the generated moment, but a major effect on the stability range of the spring and stress.

6. CONCLUSION

Overall, the constraints and requirements of the reference wing were successfully satisfied, proving the potential this mechanism has in morphing wing applications. The plate-spring mechanism decreased the net required actuation torque significantly, as shown in Figure 12.

The plate-spring based mechanism has lower part count and fewer connectors when compared to the helical spring mechanisms. Another opportunity plate-spring based system offers when compared to helical spring mechanisms is the possibility of additive manufacturing of a monolithic mechanism version.

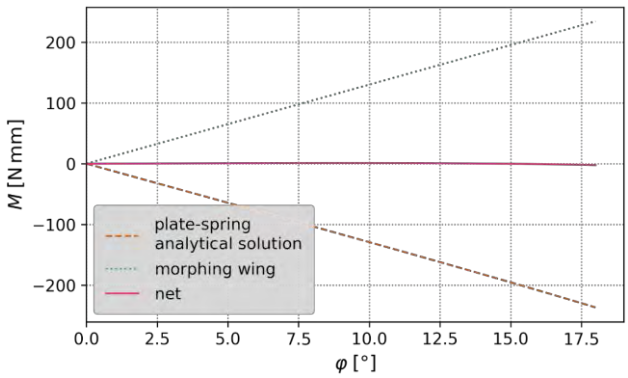

Figure 12. Required torque with the plate-spring mechanism

TONI D. IVANOV
Faculty of Mechanical Engineering, Belgrade, tivanov@mas.bg.ac.rs

Abstract: *This paper presents an approach to topology optimization of a small quadcopter's structure, with particular emphasis on the optimization and load validation of the drone arm. The priority of this approach is to reduce the structural mass while maintaining adequate stiffness and load-bearing capacity, based on the propulsion requirements of the motor system. A finite element numerical model of the arm was developed and compared with an analytical calculation based on beam theory, in order to validate the simplified mathematical model. Topology optimization was carried out using the tools available in Ansys Workbench 25, reducing the arm's mass from 148 g to 106 g (~28%), while satisfying the imposed deflection and strength criteria. The optimized model has been prepared for manufacturing via FDM 3D printing, while fabrication and experimental validation will be the subject of future work.*

Keywords*: topology optimization, small quadcopter, 3D printing, optimization algorithm, structural integrity.*

1. INTRODUCTION

Bearing in mind that drones have no capability to remain airborne without propulsion (unlike gliders and aircraft, which possess an aerodynamic glide ratio), it is essential to address the issue of unnecessary drone mass. The largest share of a quadcopter's mass is taken up by the electric propulsion system [1]. Since we had a propulsion system that needed to be tested, we designed a small quadcopter capable of adequately accommodating all the components required for autonomous flight. Such a drone is expected to be compact, easy to manufacture, transport, and assemble. In order to remove the unnecessary mass of the drone structure that carries no load during flight, it was decided to subject the arm of the classic "X-configuration" to structural (topology) optimization.

The drone arm's role is to accommodate the electric motor with propeller and transfer its action to the frame. The greatest load on the arm is the bending moment caused by the motor thrust, which tends to bend it around the point where it connects to the structure. Due to the high rotational speed, the motor also transmits vibrations that, over prolonged operation, can cause fatigue of the arm material. When dimensioning the arm, the torsional moment about the longitudinal axis, caused by the eccentric thrust force during sharp turns, must also be taken into account.

The significance of topology optimization lies in its ability to produce a more economical, lighter, and cheaper product in virtually any branch of engineering. Its goal is to distribute material geometrically within a component so as to achieve a desired physical parameter under given conditions. In this paper, the structurally optimized model is required to have the lowest possible mass while retaining adequate stiffness. The first published scientific work on topology optimization was by the Danish researcher Bendsøe Martin Philip and co-workers [2].

The optimized geometry should be aesthetically more pleasing, simpler to use, or occupy less space than the original model. By applying the finite element method and the topology optimization theory explained in references [3, 4], software tools generate a model that satisfies the specified conditions. Such a model is often very demanding to manufacture using conventional processes (e.g., mold casting or machining) and requires further post-processing. In this case, it is most convenient to prepare the model for the FDM 3D printing process, which builds the part layer by layer.

Regarding the structure of a multirotor, the greatest potential for optimization lies in the arms and the frame. Removing excess, unnecessary mass saves battery energy and creates space for mounting the electronic components required for filming or flight control. For the selected electric propulsion system, it was necessary to design as light a drone as possible, with an arm span of about half a meter, intended to test the correct operation of the motors and to fly autonomously. The goal is to design an optimized arm with significantly reduced mass while retaining adequate stiffness and strength properties, so that the arm can withstand all loads caused by the operation of the propulsion system.

2. APPLICATION OF TOPOLOGY OPTIMIZATION TO THE DRONE ARM

2.1. Description of the Drone Structure and Arm Geometry

The drone is a quadcopter of the "X-configuration". Its propulsion system uses 4 electric motors coupled with electronic speed controllers (ESCs), powered by a 4-cell (4S) lithium-polymer battery. The motors are fitted with 10×4.5 propellers, whose diameter was one of the main factors in determining the arm spacing. The arms are bolted to an octagonal drone frame consisting of 2 plates: the top plate carries the Pixhawk PX4 autopilot and GPS module, while the upper side of the second plate holds the Power Management Board PM07 and the radio receiver, with the battery mounted on its underside.

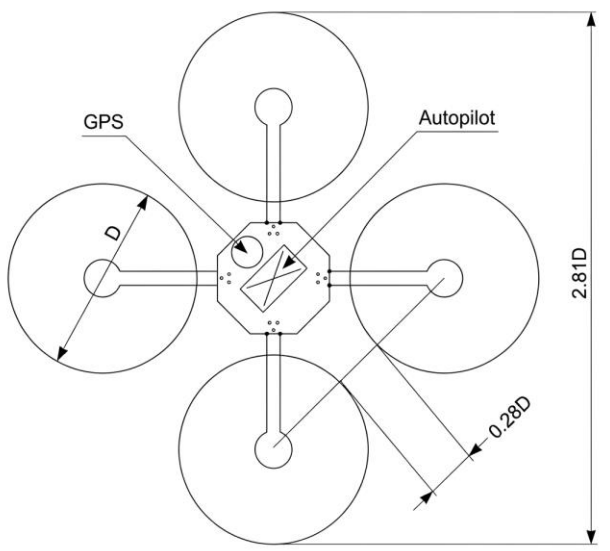

Figure 1. Drone sketch

When determining the arm span, it was considered that the distance between propellers should be as small as possible, so that the central body has room only for the arm mounts and the required components. On the other hand, this distance must not be too small, in order to avoid interaction between the propeller tips. Three M3 screws are used to clamp the arm to the frame. At the end of the arm is the flange for mounting the motor. The ESC controllers are positioned along the arms. The wiring of all electrical components has been shortened to simplify the connections as much as possible.

2.2. Analytical Model of the Arm

For dimensioning purposes, an analytical model of the arm is constructed. The arm is idealized as a cantilever beam clamped at the frame mount, loaded at its free end by a radial force representing the propeller thrust. A force value of $F = 3 \cdot g \approx 30$ N was adopted, corresponding to the manufacturer-specified value for the case in which the motor enters a safety (critical) operating regime. The point of application of this force is offset from the centroidal axis and positioned with an eccentricity of $e = 10.6$ mm from the center of the flange, at the location of the motor-mount hole. Such a position of the force application point can occur if the bolted connection between the mount and the flange loosens due to vibration or loading.

A square cross-section was chosen for the arm. The primary condition governing the dimensioning of the arm is the maximum-deflection condition, i.e., the maximum deformation of the free end must not exceed 1% of the arm length. The point of force application is located at a distance $l_F = 175$ mm from the arm's clamped end (the thrust acts at the center of the flange where the motor is mounted), giving an allowable deflection of $\delta_{perm} = 1.75$ mm. The second dimensioning condition is the allowable stress, comprising bending and torsional components (a combined stress state), due to the offset of the force with respect to the longitudinal axis of symmetry.

The arm is manufactured by the FDM (Fused Deposition Modeling) 3D printing process, using PLA-CF material. This material is a standard PLA plastic reinforced with carbon fibers, which improve the plastic's mechanical properties while retaining ease of manufacturing. The properties of the PLA-CF material, with a fiber length of 8 mm and a fiber content of 16% [5], adopted in the calculation are given in Tables 1-3. The material density is $\rho = 1760$ kg/m^3, and the tensile strength is $\sigma_T = 68$ MPa.

Table 1. PLA-CF material properties – Young's modulus

E_1 [MPa]	E_2 [MPa]	E_3 [MPa]
3774.8	2820.9	2976

Table 2. PLA-CF material properties – shear modulus

G_{12} [MPa]	G_{13} [MPa]	G_{23} [MPa]
1114	1121	983

Table 3. PLA-CF material properties – Poisson's ratio

ν_{12}	ν_{13}	ν_{23}
0.33	0.3	0.33

It is necessary to determine the unknown side length of the square cross-section of the arm based on the governing condition of allowable deflection at the free end. The deflection consists of a bending component and a shear component, and their sum must be less than the allowable deflection. It is calculated according to the equation:

$$\delta_{max} = \frac{F l_F^{\,3}}{\frac{3E_1 a^4}{12}} + \frac{F l_F}{k_s G_{12} a^2} \leq \delta_{perm} \qquad (1)$$

where $k_s = 0.833$ is the shear correction factor. A minimum required safety factor of $S_F = 1.1$ was imposed to account for imperfections inherent to 3D printing manufacturing. After carrying out the calculation taking these conditions into account, and rounding the side length up to the next value permitted by printing precision, the required side length is found to be $a = 18.2$ mm, with a deflection safety factor of $S_{def} = 1.115$. When checking the stress under the

combined loading state (bending and torsion), the cross-section is dimensioned according to the HMH (von Mises) criterion of maximum equivalent stress. The following four equations describe this process:

$$\sigma_{bM} = \frac{M_{max}}{W} = \frac{Fl}{\frac{a^3}{6}} \quad (2)$$

$$\tau_{tM} = \frac{T}{\alpha_t a^3} = \frac{Fe}{0.208 a^3} \quad (3)$$

where $\alpha_t = 0.208$ is the Saint-Venant torsion coefficient for a solid square cross-section.

$$\sigma_{ekv} = \sqrt{\sigma_{bM}^2 + 3\tau_{tM}^2} = 5.244 \text{ MPa} \quad (4)$$

$$S_{str} = \frac{\sigma_T}{\sigma_{ekv}} = 12.97 \quad (5)$$

This procedure yields a strength safety factor of $S_{str} = 12.97$, indicating that such a cross-section is over-dimensioned for this loading case. Since the maximum-deflection condition is governing, the side length is adopted according to this condition. With this calculation, the maximum deflection is $\delta_{max} = 1.57$ mm.

2.3. Theoretical Basis of Topology Optimization

The goal of topology optimization is to find, within a predefined design domain, boundary conditions, and loads, a material distribution that satisfies the imposed condition. The problem is formulated as a mathematical optimization task: an extremum of the objective function (e.g., compliance — a measure of structural flexibility) is sought, subject to the imposed constraints (mass/volume, displacement, etc.) [3].

From [2], the density-based method of structural optimization, known today as SIMP (Solid Isotropic Material with Penalization), evolved into the most widespread approach [3], [4]. Each finite element of the design domain is assigned a pseudo-density in the range from 0 to 1 (0 meaning no material, 1 meaning solid material), whereby the element stiffness is scaled by a power of this density using a penalization exponent.

An alternative approach is the Level-Set method, which, unlike the previous approach, does not operate on element-wise density, but instead directly describes the shape boundary as the zero contour (isosurface) of a scalar function defined over the whole domain [6]. By evolving this function through iterations, the shape boundary progresses toward the optimal solution. Also noteworthy is the Mixable Density method, which combines these two approaches — merging the smooth solution of the Level-Set approach with the flexibility of element-wise density.

Regardless of the chosen formulation, the resulting nonlinear constrained optimization problem is solved iteratively using appropriate numerical algorithms. For the classical case (compliance objective function, mass/volume constraint), the Optimality Criteria method is most commonly used, being well suited to this type of problem. When additional constraints are introduced — such as a local stress constraint — a more general solution approach is required, based on Sequential Convex Programming, within which several concrete algorithm implementations exist, such as the modified Method of Feasible Directions (MFD) and the SCPIP method, based on an interior-point approach [7].

2.4. Application of Topology Optimization in Ansys Workbench 25

The first step after launching Ansys Workbench 25 is to create a Static Structural analysis environment. The solution of this analysis must be linked to the Topology Optimization block, so that all settings from the original model are carried over to the optimized one. After entering the material property values from Tables 1, 2 and 3, the software reports the model mass as 148 g. The MultiZone tool was used to generate the model mesh, producing a structured, predominantly hexahedral mesh. The fixed-support region was defined on the elements around the screw holes where the arm connects to the frame. The location of the applied force was defined on the flange, on the elements around the motor-mount screws, on one side only.

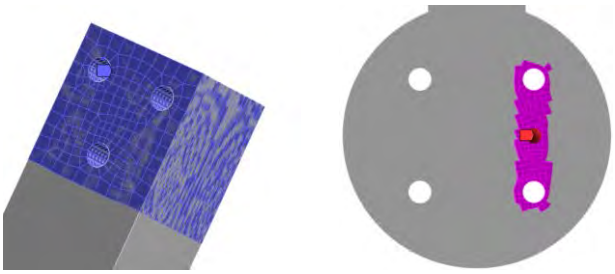

Figure 2. Fixed support – left, force location – right

The static structural analysis yields a maximum deformation of $\delta = 1.403$ mm, which is about 10% lower than the value obtained analytically. This is expected, since the analytical model is a simplified cantilever beam that deviates from the full 3D finite element model — it does not account for the Poisson's effect, the local stiffness of the cross-section, the stress distribution across the cross-section, etc. The equivalent (von Mises) stress amounts to $\sigma_{vM} = 8.466$ MPa. This is a concentrated stress present in a small region around the arm's fixed support.

When selecting the region for topology optimization, the areas where boundary conditions and loads are applied are excluded. The optimization method used here is Level Set, since the Mixable Density method does not accept the deflection criterion as a valid constraint, while the Density Based method is deprecated. This applies to the software version used in this work, Ansys Workbench 25, and does not imply that the other two methods cannot be verified in other versions. For the Level Set type, the C-MFD algorithm was selected — an enhanced version of the classical MFD algorithm, offering significantly faster solution convergence and more efficient mesh handling during the optimization process. The solver was set to run at most 500 iterations, with a convergence accuracy of 0.1%. An objective was defined for the optimized model to retain 65-70% of the original mass while maintaining

the minimum allowable stiffness, as well as a maximum deformation of 1.59 mm, preserving a safety factor of 1.1.

The geometry obtained directly from topology optimization is rarely suitable for manufacturing by conventional processes, which is why it is nowadays most commonly associated with additive manufacturing. For this reason, additional manufacturing constraints are introduced into the optimization process itself: a minimum (and maximum) member thickness, and a maximum overhang-angle constraint characteristic of FDM technology. A minimum member size of 4 mm was imposed for the optimized model, in order to prevent the formation of structurally meaningless, thin branches (or isolated, unconnected elements) that would be neither printable nor load-bearing. The default value of 45 degrees was used for the overhang angle, in the direction in which the model is printing (Z-axis). This setting ensures that the resulting shape can be printed without requiring excessive support structures.

stress state. To simplify the model for printing, the edges of the I-profile were straightened, and small mesh fragments were removed from the motor mount. The segment removed between the flange and the central part was restored, so that this refined model retains a longitudinal axis of symmetry. After this modification, the part proceeds to the final analyses.

For the refined model, the force was assigned to the elements around the joint with the motor mount. The mass of this new model version is 106 g, about 3% higher than that of the optimized model. The maximum deflection is 1.58 mm, while the maximum von Mises stress is 9.225 MPa, occurring concentrated in the regions around the fixed support.

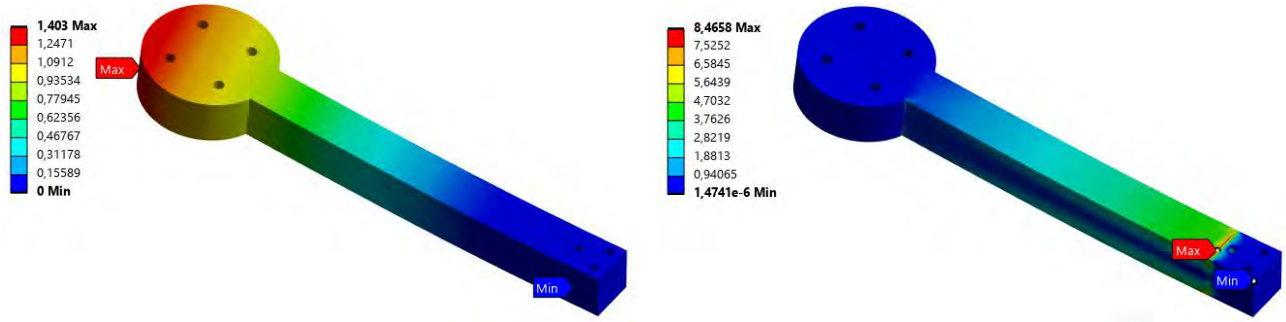

Figure 3. Total deformation [mm] – left, von Mises stress [MPa] on the original model – right

Figure 4. Optimized model – left, refined model – right

Following the optimization, material was removed from the flange, while enough material was left around the screw holes to allow the nuts to be fully threaded on. On the right-hand side of the arm (viewed from above), at the transition from the flange to the central part of the arm, material was removed, since Figure 3 shows that the right side of the arm experiences a lower load, due to the force being positioned on the left half of the motor mount. The model's mass is 103 g, which is 30% less than the original part; the maximum deformation is 1.53 mm, while the maximum normal stress is 5.284 MPa. In its central part, the optimized model has a non-symmetric I-profile cross-section, a shape well suited to resisting the combined

3. CONCLUSION

The optimized model successfully achieves what was intended: excess material has been removed, mass has been significantly reduced, and less time is required for printing. The model satisfies the maximum-deflection and equivalent-stress criteria. Following the optimization, the model's mass was reduced from 148 g to 106 g (~28%), while the maximum deflection (1.58 mm) and equivalent stress (9.225 MPa) both remain within the imposed limits, with the deflection safety factor retained at approximately 1.1. It has been shown that the Level-Set method can effectively optimize the model for the loading case considered here. Once the optimization is complete, the

model remains subject to free-form modeling by the designer, who prepares it for printing; this step requires modifying the model in line with the optimization recommendations from the software and with the principles of 3D printing.

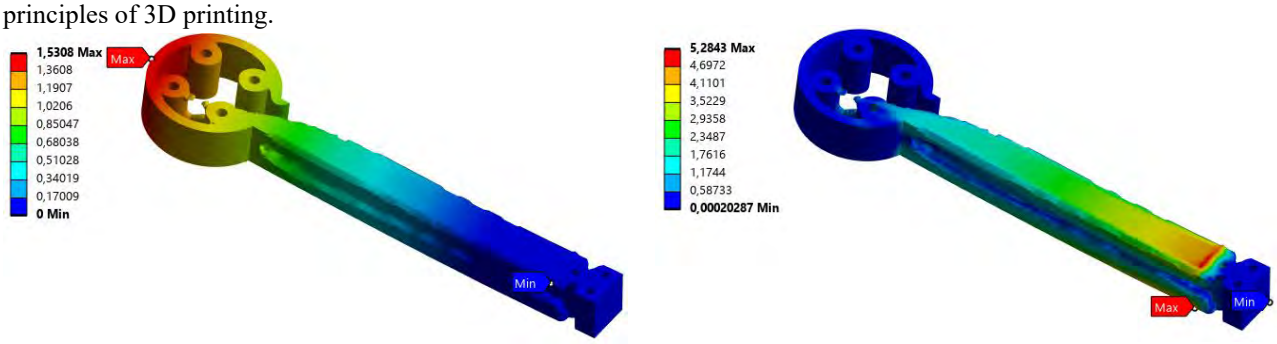

Figure 5. Total deformation [mm] – left, von Mises stress [MPa] on the optimized model – right

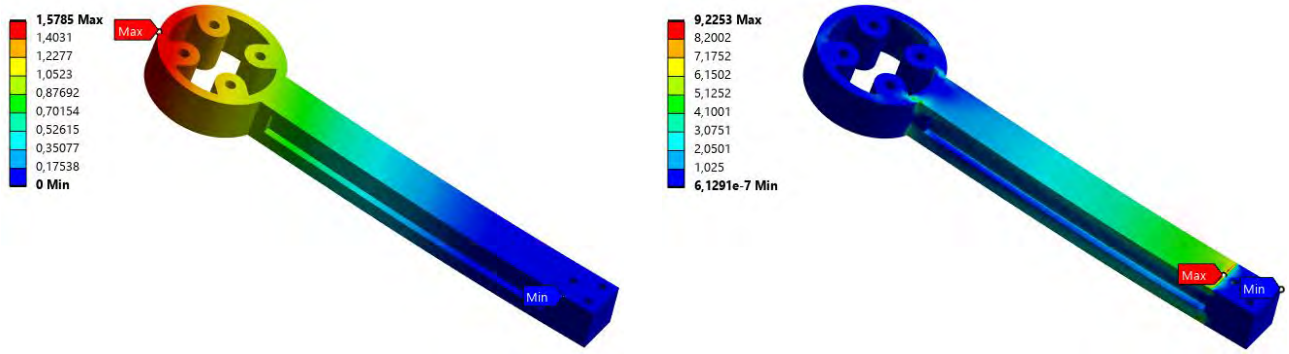

Figure 6. Total deformation [mm] – left, von Mises stress [MPa] on the refined (final) model – right

This is a drawback of this method, as it requires rework that takes up the designer's time, particularly for more complex geometries. For structural optimization purposes, it would also be worthwhile to try other approaches such as Lattice, Shape, and Topography optimization; such an approach would exceed the scope of this paper. As a continuation of this project, the printed, optimized arm needs to be fitted with the propulsion system, and its maximum deformation measured, in order to compare it with the numerical model. It is possible to consider variations in the way the arm is connected to the drone structure, so as to require fewer machine parts. It is also expected that the arm design will change as the project develops, should an alternative location be found for the ESC controllers, which currently occupy space along the drone arms — not an ideal solution.

Abstract: *Unmanned Aerial Vehicle design and implementation are evolving rapidly to meet the stringent demands of civil and commercial applications. In particular, Miniature Unmanned Aerial Vehicles with a maximum take-off mass below 15 kg have seen widespread use in various sectors. Continuous technological improvements require the development of new propulsion systems in order to satisfy these new challenges. In this paper, the AXI 4130/20 Gold Line V3 brushless direct current motor, equipped with Aeronaut CAM Folding propellers, will be evaluated using a commercial-off-the-shelf test bench: the LY-10KGF Micro-Max Test Stand. The identified propeller-motor characteristics could be used as a guide for selecting the optimal propeller for small Unmanned Aerial Systems.*

Keywords: *UAV, propeller, BLDC motor, testing.*

1. INTRODUCTION

Small Unmanned Aerial Vehicles (UAVs) were initially primarily used for recreational purposes by aeromodelling enthusiasts. They subsequently found applications in the military sector, and the 21st century [1-8] has seen an expansion in their use for both military and civilian surveillance and reconnaissance missions. Today, multicopters dominate the hobbyist market due to their ease of use and Vertical Take-Off and Landing (VTOL) capabilities, which totally eliminate the need for a runway. Most of these small UAVs are powered by brushless direct current (BLDC) motors and batteries that supply energy to the UAVs. Furthermore, they can carry various types of sensors, including Electro-Optical/Infrared (EO/IR) sensors, rangefinders, weather and pollution sensors, and other specialized equipment.

For conceptual UAV design, there are numerous software tools and textbooks [9-12] available for preliminary UAV sizing and performance estimation. The accuracy of these methods is in direct correlation with the motor-engine performance data, which are often difficult to obtain or estimate accurately. In this paper, the AXI 4130/20 GOLD LINE V3 BLDC motor is evaluated alongside its propeller to estimate static propeller performance. The motor characteristics were previously validated and documented in [13]. According to the manufacturer data [14], this motor is designed for large sailplanes weighing up to 7 kg and sports aerobatic models up to 5 kg. The recommended propellers for various UAV configurations are 15×10, 15×12, 18×10, 18×8, 18.5×12, and 16×10 inches. The specifications of the AXI 4130/20 BLDC motor used in this study are summarized in Table 1.

Table 1. Technical specifications of the AXI 4130/20 GOLD LINE V3 BLDC motor

Number of cells	6-8s Li-Poly
RPM/V	305
Maximal efficiency	90%
Maximal efficiency current	18-40 A (>84%)
No load current	1.1 A
Current capacity	56 A/60 s
Internal resistance	43 mΩ
Dimension (diameter x length)	49.8 x 64.4 mm
Shaft diameter	6 mm
Weight	0.410 kg
Maximal Power	1650 W

Corresponding author: M. Milenković-Babić;
E-mail: miodragmbm@yahoo.co.uk
DOI: 10.5937/OTEH26014M

As shown in Table 1, the maximal motor power is 1650 W, which is sufficient to power small UAVs of even greater weight (up to 15 kg). However, for such higher weights, the take-off is usually performed using an external launch mechanism. The most commonly used launchers are pneumatic and mechanical systems [15, 16], favored for their reliability and compact design. To evaluate UAV performance, propeller data must be analyzed. During the take-off phase, the sufficiency of the control authority must be considered [13, 17, 18]. In order to select an adequate propeller, or to narrow down the number of potential candidates, the data from [13, 19, 20] should be used as a guide.

In this paper, the AXI 4130/20 Gold Line V3 BLDC motor, equipped with Aeronaut CAM folding propellers, is evaluated under static conditions using a commercial-off-the-shelf test bench: the LY-10KGF Micro-Max Test Stand. The results presented in this paper, together with the motor characteristics identified in previous work [13], serve as a valuable basis for optimizing the propeller–BLDC motor combination across various UAV configurations, and are especially useful for multicopter design. By analyzing measured performance parameters specifically: torque, power, and thrust, this dataset enables the selection of the optimal propeller for a defined UAV mission.

2. EXPERIMENTAL TESTING OF MOTOR-PROPELLER PERFORMANCE

In previous work, the AXI BLDC motor characteristics were defined at various supply voltages [13]; therefore, that procedure is not repeated here in detail. Typically, the battery supplies energy to the electronic speed controller (ESC), which converts direct current (DC) into a three-phase trapezoidal supply that drives the BLDC motor. The characteristics of the battery and ESC can be assumed constant in the presented experiment, as they primarily depend on the manufacturing and production processes. Based on this assumption, and the fact that all propellers are tested under identical operating conditions, any differences in the measured results are directly correlated with the specific propeller types.

In order to identify the characteristics of the different propellers, testing must be performed at defined supply voltages. In the presented analysis, an 8S battery configuration with a nominal operating voltage of 29.6 V was used. The characteristics of the AXI 4130/20 Gold Line V3 BLDC motor, based on the data from [14], are marginally different from the AXI 4130/20 Gold Line BLDC motor identified in previous work [13]. Therefore, the identified characteristics of the AXI 4130/20 Gold Line BLDC motor shown in Figure 1 will be used, with a sufficiently small error that will not affect the final results.

Propeller performance was tested by using the LY-10KGF Micro-Max Test Stand [21], shown in Figure 2. The system is designed for static thrust and torque measurements of small propulsion units. It enables the simultaneous measurement of thrust force, torque, rotational speed (RPM), current, and voltage. These measurements allow for the accurate determination of power and efficiency.

The calibration of the test bench was performed before the experimental measurements according to the manufacturer's recommendations in order to zero the thrust and torque sensors. The tests were conducted under laboratory-controlled conditions with a constant ambient temperature of 20°C. This constant temperature ensures a consistent air density throughout all experimental measurements.

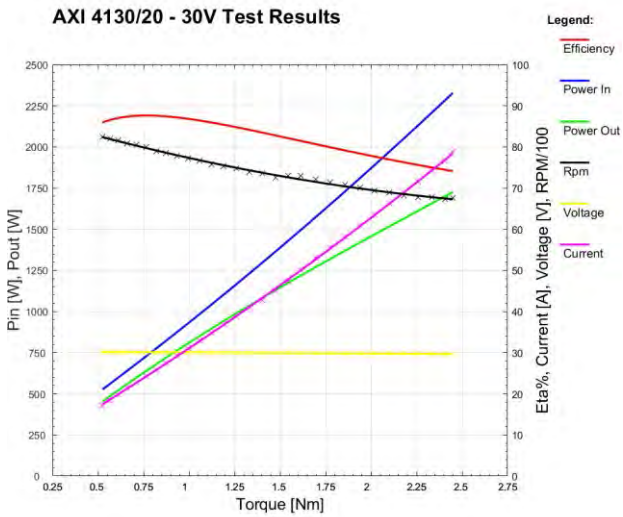

Figure 1. AXI 4130/20 test results at supply voltages of 30 V: Experimental measurements (markers) and identified (solid lines)

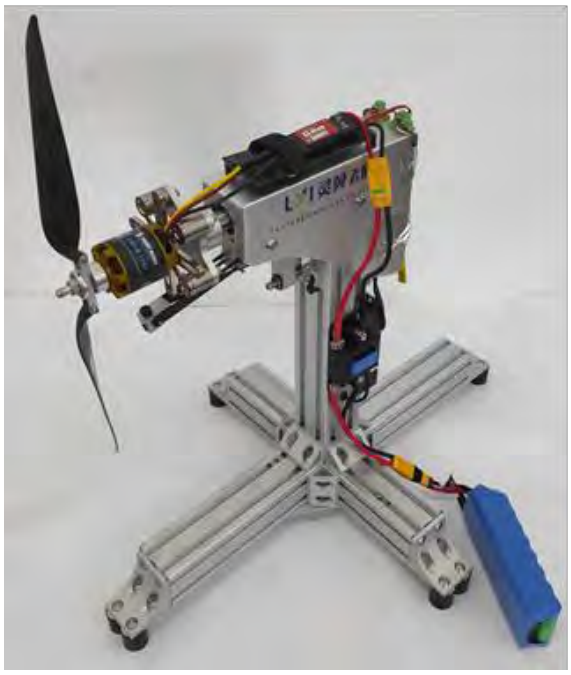

Figure 2. LY-10KGF Micro-Max Test Stand

The experimentally obtained results for motor–propeller torque, thrust, input and output power, and motor efficiency for five Aeronaut CAM Folding propellers (16×10, 16×13, 17×11, 17×13, and 18×11) at 100%, 90%, 80%, 70%, 60%, and 50% throttle settings are presented in Table 2. These measurements were conducted using a

propeller spinner with a diameter of 52 mm.

It must be noted that propeller efficiency could not be defined, as static performance was evaluated, and under such conditions, propeller efficiency is mathematically undefined (since output power, as the product of thrust and airspeed, is zero during static tests).

3. DISCUSSION OF THE RESULTS

First, the characteristics of the AXI 4130/20 BLDC motor were identified to provide a solid basis for an accurate estimation of motor-propeller performance.

From an initial analysis of the data in Table 2, it is evident that propellers with a 13-inch pitch (17×13 and 16×13) are less efficient than propellers with a smaller pitch at maximum throttle settings. Based on the identified data, it can be concluded that the optimal throttle for a UAV using a runway for take-off is not necessarily the maximum throttle, according to the recommendation in [18]. The AXI 4130/20 BLDC motor equipped with the 16x10 in propeller exhibits the highest efficiency within the throttle range of 60% to 90%. This high efficiency likely explains why this specific propeller is suggested for sailplane UAVs weighing approximately 7 kg.

The data from Table 2 indicate that the 18×11 in propeller provides the highest static thrust, which enables the shortest take-off distance from a runway. Additionally, it features the best thrust-to-torque ratio, making it an ideal choice for the take-off phase, especially for unconventional UAV designs [8]. Additionally, the identified static thrust and the remaining motor–propeller data can be used to optimize the hover capability of UAVs designs.

3. CONCLUSION

The conducted experimental and numerical investigations including motor parameter identification from previous work, as well as static thrust and torque measurements have provided comprehensive data on motor–propeller performance across various configurations.

The results obtained from the motor–propeller characterization (Table 2) clearly indicate that selecting the optimal propeller for a UAV is a complicated task. It must account for maximum thrust, the torque-to-thrust ratio, propeller rotational speed, and the UAV's maneuvering capabilities.

Based on the results presented in Table 2, the 18×11 in propeller demonstrated the highest static thrust force and the most favorable thrust-to-torque ratio. These data indicate that it represents an optimal choice for UAVs that require special emphasis on the take-off flight phase. Furthermore, the results indicate that the AXI 4130/20 V3 BLDC motor, when equipped with the 16×10 in propeller, achieves the highest efficiency. This explains why this specific propeller is recommended as the optimal choice by the motor manufacturer.

Acknowledgments

This research was funded by the Military Technical Institute (VTI) Belgrade and partly by the Ministry of Science, Technological Development and Innovation of Republic of Serbia (Project number 451–03–34/2026–03/200325).

Abstract: *This paper describes and presents the essential technical knowledge and skills for future military and civilian pilots. The observations presented on this topic are based on current legal regulations, experience, training standards, as well as the assumed direction of aviation technology development and the approach to its operation. Special attention is dedicated to the similarities and differences in the types and levels of technical knowledge required for future military and civil pilots, and their potential harmonization, keeping in mind the modernization processes of both military and civil aviation with advanced aircraft technology in the Republic of Serbia.*

Keywords: *technical knowledge, skills, pilot, modernization process.*

1. INTRODUCTION

In the Republic of Serbia, aviation can be categorized into military and civil sectors, encompassing both military and civilian pilots. The civil aviation sector is further divided into commercial and non-commercial segments. A notable characteristic of aviation in Serbia today is the ongoing programs for extensive procurement and modernization of both military and civilian aircraft.

These programs are changing the requirements placed before the entire aviation personnel, especially pilots, both military and civil, who are required to master and operate these assets. In the initial phase of receiving aviation hardware, the focus is primarily on pilots who are completing conversion training and adapting to the operation of new aircraft. However, to complete conversion training high-quality, efficiently, and safely-especially when dealing with a significant technological leap-a high level of previously acquired technical knowledge and skills is required, gained through formal education, flight practice, or complex training programs. These requirements can be defined uniformly for both military and civil pilots in the Republic of Serbia, although the path to acquiring these knowledges and skills differs both chronologically and methodologically. Furthermore, the standards and regulations governing the attainment of the required level of core technical knowledge and skills for military and civil pilots in the Republic of Serbia also differ. This paper details specific aspects of the process of acquiring technical knowledge and skills for military and civil pilots, as well as the changes and needs expected in the upcoming period. It is precisely these changes and needs that will define the core technical knowledge and skills of future military and civil pilots in the Republic of Serbia. Predictions regarding specific knowledge and skills are also highlighted in this paper.

2. CATEGORIES OF MILITARY AND CIVIL PILOTS

When viewed as professional categories, military and civil pilots differ in numerous ways, although both are engaged in aircraft operation and air navigation. The philosophy and execution of their tasks usually differ significantly. The extent of these differences depends on the aviation subcategory. Simplified, military aircraft in the Republic of Serbia are divided into combat and non-combat platforms, as well as fixed-wing aircraft and helicopters. Generally, we can speak of fighters, fighter-bombers, transport aircraft, attack helicopters, multirole helicopters, and transport helicopters.

If we consider civil aviation in the Republic of Serbia, attention is focused on the national carrier, Air Serbia, along with several smaller companies and training centers engaged in commercial operations, aerial work (general aviation), and advanced pilot training. A significant aviation organization is also the Helicopter Unit of the Ministry of Internal Affairs of the Republic of Serbia (equipped with multirole and transport helicopters). For these exact reasons, we have categorized pilots by sector (*civilian*) rather than by primary purpose (*commercial*), because despite the designation of the license type (*Commercial Pilot License*), not all pilots or aviation organizations in the Republic of Serbia are engaged in commercial air transport.

From this, a wide diversity of aircraft and their

DOI: 10.5937/OTEH26015V

operational roles can be observed, implying different types of training and knowledge required for the pilots operating these platforms.

3. MODERNIZATION PROGRAMMES IN MILITARY AND CIVIL AVIATION IN THE REPUBLIC OF SERBIA

To define the core technical knowledge and skills of future military and civil pilots, it is necessary to identify the modernization processes in military and civil aviation over the past decade, as this reveals the technological shift from which the need for new knowledge and skills arises. The Serbian Air Force (SAF) practically initiated its modernization programs in 2012 with the introduction of the Lasta basic trainer aircraft, featuring a digital glass cockpit. The following year, in 2013, the national carrier Air Serbia commenced operations, opting from the start for European passenger aircraft manufactured by Airbus rather than American aircraft from Boeing. Following modernization trends in Serbia, the procurement package also initiated the modernization of the helicopter fleet of the Ministry of Internal Affairs (MoI) Helicopter Unit, which in the first phase received H145 helicopters identical to those of the SAF, followed by other specialized aircraft. An overview of aircraft procurements and modernizations for the SAF by year, role, and type is given in Table 1.

Table 1. Procurements and modernizations for the SAF

Airplane/ Helicopter	Role	Acquisition Year	Replace for:
Lasta	Basic Training	2012	Utva-75
MiG-29 SM	Multirole	2021	MiG-29 (izd.9-12)
C-295	Transport	2024	An-26
Dassault Rafale F4	Multirole	2028	MiG-29
Mi-17	Transport	2016	Mi-8
H145M	Multirole	2019	Sa-341/342
Mi-35M	Combat	2019	Sa-341/342 (Gama)
Mi-35P (Ex-Cypriot)	Combat	2023	Sa-341/342 (Gama)

An overview of aircraft procurements for Air Serbia by year and type is given in Table 2.

Table 2. Aircraft procurements for Air Serbia

Airplane	Operator	Acq.Year	Replace for:
Airbus A319	AirSerbia	2013	Boeing 737-300
Airbus A320	AirSerbia	2014	Boeing 737-300
Airbus A330-200	AirSerbia	2016	DC-10
ATR 72-600	AirSerbia	2023	ATR 72-500
Embraer E-195	AirSerbia	2024	-

An overview of helicopter procurements for the MoI Helicopter Unit by year and type is given in Table 3.

Table 3. Helicopter procurements for the MoI

Helicopter	Operator	Acq. Year	Replace for:
H145M	MoI	2019	Sa-341/342, Bell 206
H215/225 Super Puma	MoI	2022	Bell 212, S-76
Ka-32A11BC	MoI	2022	-

As another major operator, the ATO Air Academy in Vršac acquired a completely new fleet of Cessna 172S aircraft equipped with Garmin G1000 glass cockpit avionics in 2012.

What can be observed from the previously presented tables are the following:

- Virtually the entire civil and military fleet state-operated within the Republic of Serbia has been replaced with new or modernized aircraft, regardless of the specific user.
- All new aircraft feature digital glass cockpits, while modernized platforms and older types have been upgraded to semi-digital cockpits.
- The vast majority of new fixed-wing aircraft and helicopters were manufactured in Western countries.
- There is a clear strategic tendency toward relying on European manufacturers (Airbus and Dassault).
- Modernization of older Russian/Soviet-manufactured aircraft included Western/ICAO-standard avionics systems for navigation and air traffic control, including GPS/GNSS, civil ATC-compliant VHF radios, civilian-compatible transponders, and VOR/ILS capability.
- Newer Russian types, such as the Kamov Ka-32A11BC, were specifically designed to meet Western airworthiness standards. In 2009, it officially received its EASA Type Certificate. Considering these facts, technical knowledge and skills must be adapted more fully to this operating environment. Depending on the user and operator, education and training systems should be adjusted in line with directives issued by the regulatory bodies of the manufacturing countries. In this case, the relevant manufacturers are European, and their operations are largely governed by EASA (European Union Aviation Safety Agency) rules and regulations. Failure to recognize and apply these directives increases training costs, extends training duration, and may compromise flight safety.

4. THE WAY OF ACQUIRING PILOTS' KNOWLEDGE AND SKILLS

In the Republic of Serbia, there are generally three main educational and training streams through which individuals enter professional military and civil flight

duties as pilots.

The first and most complex pathway is the *Military Aviation* study program at the Military Academy, University of Defence in Belgrade [1]. This program is distinctive because it aligns with Bologna Process standards while also meeting Air Force operational requirements. It educates Military Academy cadets—undergraduate students in military terminology—for roles as fixed-wing or helicopter pilots, as well as mechanical engineers. The undergraduate Military Aviation program lasts four academic years and carries 240 ECTS credits. Upon completion, cadets earn a Bachelor of Science degree in Mechanical Engineering and receive a Diploma Supplement certifying their competencies as professional Air Force pilots.

The curriculum is divided into two main parts. The first phase, lasting six semesters, is conducted at the Military Academy headquarters in Belgrade. The primary goal of this phase is theoretical preparation for upcoming flight training in training squadrons. The first group of courses consists of theoretical, methodological, and general scientific subjects, while the second group comprises professional and engineering courses. Study of the second group occurs during the 3rd academic year (5th and 6th semesters) including subjects such as General Navigation, Radio Navigation, Communications, Principles of Flight (Aerodynamics/Flight Mechanics), Aircraft General Knowledge (Aircraft Construction), Meteorology, Powerplants (Aircraft Engines), Instrumentation (Flight Instruments and Systems), Mass and Balance, Human Performance and Limitations, Operational Procedures, and Air Law. A portion of these subjects is tailored specifically for future helicopter pilots. Due to international standardization, most listed courses are compatible in scope and content with similar courses taught at aviation universities or ATOs worldwide. Military-specific subjects are not evaluated in this paper. Flight training is executed in training squadrons during the final year of study.

The second stream, which has emerged over the last five years, is offered through the Aviation Academy (AA) in Belgrade and its ATO (Approved Training Organization) in Vršac. In close cooperation with the Academy of Applied Studies Polytechnic, AA educates pilots through the *Air Transport* study program over three academic years (180 ECTS). The main goal is to educate professional transport engineers with the knowledge, competencies, and practical skills required to perform engineering tasks in air transport, as well as to acquire the theoretical qualifications necessary for obtaining an Airline Transport Pilot License (ATPL) with an Instrument Rating (IR), in accordance with EASA Flight Crew Licensing regulations (Part-FCL) [2]. The program prepares professional engineers for professional pilot licenses, including the frozen Airline Transport Pilot Licence – Aeroplane (ATPL(A)). The curriculum, comprising compulsory and elective courses, aligns with requirements prescribed by EASA Part-FCL regulations. It includes 13 core theoretical subjects: Aircraft General Knowledge, Instrumentation, Performance, Mass and Balance, Flight Planning and Monitoring, General Navigation, Radio Navigation, Communications, Principles of Flight, Meteorology, Human Performance and Limitations, Operational Procedures, and Air Law. According to EASA requirements, the theoretical ground school scope comprises a minimum of 750 hours. Flight training is conducted at the ATO, commencing in the 4th semester.

The third stream for obtaining licenses and becoming a professional pilot in the Republic of Serbia is through independent ATO facilities approved for CPL/ATPL training. This process is fully grounded in EASA regulations and Part-FCL rules. Practically, the theoretical syllabus and flight training are identical to stream two, but without the academic degree components. This pathway can be shorter by at least a year, which is why many aspiring pilots opt for this route.

Although an informal industry view once favored requiring all commercial pilots to hold at least a Bachelor's degree, this requirement was never incorporated into aviation regulations. It remains mandatory only for military pilots and Ministry of Interior pilots, for whom a university degree is an employment prerequisite. Commercial airlines and flight training centers may employ pilots and instructors without a Bachelor's degree, although hiring practices differ between the United States and Europe. Major U.S. airlines often prefer candidates with a college degree during competitive recruitment periods, while European airlines place greater emphasis on demonstrated competencies and ATPL performance. A mandatory global degree requirement was never adopted, partly because of persistent pilot shortages. Nevertheless, when candidates have comparable flight competencies, a formal university degree can still provide a competitive advantage.

After obtaining their licenses, candidates from streams two and three are subject to a multi-stage selection process before entering an airline or operator, designed to test core competencies (such as those defined in ICAO and EASA frameworks). This process usually consists of:

- **Screening & Technical Assessment:** Evaluating theoretical knowledge and mental math capabilities.
- **Simulator Assessment:** Usually conducted in a Flight Synthetic Training Device (FSTD) / Flight Simulator. It serves as an operator's tool to evaluate manual hand-flying skills, instrument proficiency, raw-data navigation, and elements of Crew Resource Management (CRM).
- **HR & Competency Interview:** Assessing communication skills, adaptability, teamwork, and alignment with company culture.

Some of these core competencies are also evaluated in military pilots before initiating conversion training to a new aircraft type.

Considering the aforementioned points, all three entry streams feature a highly similar theoretical syllabus

defined by EASA regulations.[1] The detailed ATPL theoretical knowledge syllabus and its Learning Objectives (LOs) are defined in the Acceptable Means of Compliance (AMC) and Guidance Material (GM) to Part-FCL [3]. The syllabus is subject to periodic updates. The structural framework and core syllabus currently used across Europe—often referred to as the "2020 Syllabus"—was introduced by ED Decision 2018/001/R. This major regulatory decision was enacted eight years ago.

5. TECHNICAL KNOWLEDGE AND SKILLS

When analyzing the EASA ATPL theoretical syllabus followed by most aviation training organizations in Serbia, it becomes evident that technical knowledge serves as the underlying theoretical foundation explaining why aircraft systems function and how physical laws govern aircraft behavior.

In the EASA ATPL theoretical program, this technical knowledge is systematically developed across a 13-subject syllabus, which can be categorized into distinct subject areas:

1. **Aircraft Architecture & Physics:** Provides the fundamental engineering, mechanical, and physical concepts behind how an aircraft flies and operates. It comprises Principles of Flight, Aircraft General Knowledge (Airframe and Systems, Electrics, Powerplant), and Instrumentation.
2. **Navigation, Flight Planning & Operations:** Covers the quantitative, mathematical, and spatial knowledge required to navigate the aircraft safely and efficiently. This group includes General Navigation, Radio Navigation, Flight Planning and Monitoring, Mass and Balance, and Performance.

While technical knowledge represents theoretical understanding, technical skills reflect how a pilot executes tasks in the cockpit environment. Under internationally recognized standards, a pilot's technical skill set is divided into four main functional areas, as presented in Table 4.

Table 4. Pilot's technical skill set

Areas	Skills
Aircraft Handling & Control	Manual Precision Energy & Aerodynamic Management Upset Prevention and Recovery (UPRT)
Flight Path & Automation Management	FMS/Autopilot Operation Automation Mode Awareness Graceful Degradation
Systems Management & Troubleshooting	Aircraft System Operations Abnormal & Emergency Procedures Failure Diagnosis In-Flight Mental Calculations
Navigation & Environmental Execution	Chart Reading & PBN Weather Analysis Regulatory & SOP Compliance

Additionally, military authorities typically possess specialized knowledge and skills, which they express differently. An example of how this knowledge and these skills are integrated into military flight training, and the licensing process can be seen in the case of the Czech Air Force [4].

There are some of the skills that graduates of the study specialization of military pilots have to acquire:

- Aircraft or helicopter commanders have professional knowledge at the level of the requirements of the ATPL (air transport pilot – internationally recognized standard for military and civilian pilots) professional aviation course for aircraft or helicopters and other professional knowledge necessary to obtain the appropriate military license (Aircraft or Helicopter Commander).

Graduates will utilize the theoretical and professionally oriented knowledge gained during their studies to perform the duties of an operator within a relevant military aviation system. Graduates will also:

- apply knowledge of the requirements of standards, regulations, and laws in professional activities,

- use the assigned aeronautical equipment, technology, or system to the required professional standard, including maintaining the required level of efficiency and safety,

- use aeronautical radio communication in English,

- use aeronautical equipment in the performance of assigned tasks, observing the principles of safety and efficiency of air traffic,

- evaluate information, draw conclusions, and make decisions to accomplish the assigned tasks according to the type of air force to which they are assigned,

- assess the implications of the use of weapon systems of the airborne equipment operated.

According to military aviation regulations, every student pilot must first undergo theoretical type training, the so-called material part of the training process. In this course, they become familiar with the aircraft they will be flying. Subsequently, together with the flight instructors, they undergo special purpose training (specific emergency procedures, principles of piloting techniques, important landmarks in the vicinity of the aerodrome, radiotelephone procedures, and correspondence used at the home aerodrome).

Graduates with the appropriate professional knowledge and skills at the level of the internationally recognized standard for the air transport pilot (ATPL) professional flying course will meet the requirements for the relevant military license.

Previously mentioned technical knowledge and skills can be accepted in the case of Serbian military pilots, too.

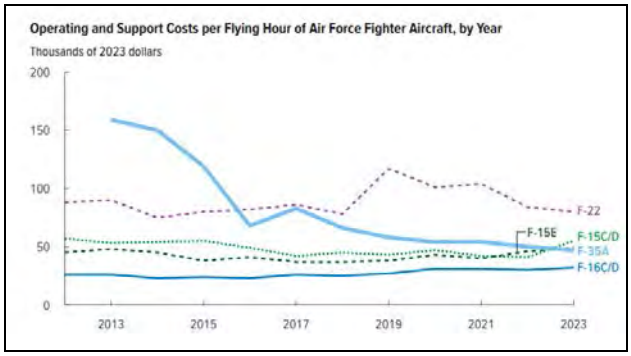
[1] The Republic of Serbia accepted EASA rules and incorporated them into its legal order since 2006 when Serbia signed the (ECAA Agreement) in Luxembourg.

But, the Serbian Air Force (SAF), however, has not yet adopted EASA standards to a sufficient extent, despite the fact that the majority of its recently acquired aircraft originate from European Union member states where EASA regulations are applied. This may create a need for additional costly conversion training and subsequent standardization, ultimately reducing personnel availability and operational readiness.

Also, when we consider the training of military pilots, it is necessary to take into account some other specificities.[2]

The specificity of military pilot training for operating modern multirole fighter aircraft is primarily reflected in the high operational and support costs (Operational & Support Costs). The cost per flight hour (CPFH) for this type of aviation can reach as much as USD 90,000. For example, during the 2023 fiscal year, the lowest cost per flight hour within the United States Air Force (USAF) was recorded for the F-16C/D, at approximately USD 30,000, while the highest was associated with the F-22, at approximately USD 90,000, as shown in Table 5. [5]

Table 5. Cost Per Flight Hour (CPFH) of Various Fighter Aircraft



When the total number of flight hours required by various military flight training programs -often reaching up to 200 flight hours - is taken into account, it becomes evident that the overall cost of training military fighter pilots is exceptionally high. Consequently, it is of paramount importance that pilot candidates for supersonic aviation possess a high level of technical knowledge and practical skills as a prerequisite for effective adaptation to the cockpit ergonomics of modern fourth and fifth-generation fighter aircraft.

Particular emphasis should be placed on mastering advanced Flight Control System/Fly-by-Wire (FCS/FBW) technologies integrated with the Hands-On Throttle and Stick (HOTAS) control concept. Training in configuring and managing the glass cockpit interface across multiple multifunction displays, depending on mission requirements, is conducted using Flight Simulation Training Devices (FSTDs) and Full Mission Simulators (FMSs). Such training significantly enhances pilots' situational awareness and decision-making capabilities in highly demanding tactical environments.

Furthermore, knowledge acquired in the field of Aviation Medicine, particularly the correct application of the Anti-G Straining Maneuver (AGSM), provides a solid foundation for developing the ability to withstand high positive vertical G-loads encountered during air combat maneuvering.

Equally important is comprehensive education in airpower doctrine, fighter tactics, and the employment of air units within modern operational environments characterized by advanced electronic warfare capabilities and the growing integration of artificial intelligence into the decision-making process. These developments represent a significant institutional challenge for military flight training organizations, requiring them to develop pilots capable of maintaining high levels of situational awareness in increasingly complex combat environments.

Counter-unmanned aircraft systems (C-UAS), including operations against remotely piloted aircraft and drones, constitute another critical area that should be incorporated into fighter pilot education and treated as a dedicated component of the training curriculum. Continuous modernization of training programs and instructional methodologies should therefore remain a permanent responsibility of organizations responsible for military flight education in order to ensure that pilots acquire the technical competencies required by the rapidly evolving nature of modern air warfare.

Although merely identifying categories of technical knowledge and skills presents little conceptual difficulty, the greater challenge lies in determining how to improve the process of acquiring those competencies in an effective manner, particularly considering the increasingly important role of technology in education and training [6].

Technological development in both military and civil aviation is progressing at a significantly faster pace than many existing training syllabi can accommodate. The intervals between revisions of EASA theoretical knowledge syllabi have proven to be excessively long. One example is the growing need for more modern approaches within subjects such as Radio Navigation, Aircraft General Knowledge, and Instrumentation, with increased emphasis on GNSS, RNP AR, GBAS, LPV, navigation integrity monitoring, ARINC 429, AFDX, More Electric Aircraft (MEA) systems, Threat and Error Management (TEM), cockpit automation, cybersecurity, and the operational use of Electronic Flight Bags (EFBs).

Rapid innovation in aviation technologies, such as advanced avionics systems, automation, and digital communication tools, necessitates updated and inventive training techniques to ensure professionals can effectively handle, maintain, and manage these systems [6].

The possible way for achieving higher level of technical knowledge and skills in the future is more comprehensive usage of immersive technologies, artificial intelligence and adaptable training systems, incorporation of game-based education and remote and cooperative instruction. A possible approach is given in [7].

[2] There is a saying „Where civilian pilot training ends, military pilot training begins."

6. CONCLUSION

This paper has identified the categories of military and civilian pilots in the Republic of Serbia, as well as the aircraft they currently operate or are expected to operate in the near future. It was observed that a significant portion of both the military and civilian aviation fleets has recently been modernized through state-funded procurement programs.

The paper has also outlined the institutions and organizations responsible for pilot education and training, with particular emphasis on the technical knowledge and practical skills that pilots are expected to acquire throughout their education and training process, or through specialized training alone in certain cases.

As an associated member of the European Union Aviation Safety Agency (EASA), the Republic of Serbia recognizes and applies the European Union's regulatory framework in the field of civil aviation. Civil aviation training organizations are therefore fully aligned with EASA standards regarding the acquisition of technical knowledge and practical competencies required of future pilots.

The Serbian Air Force (SAF), however, has not yet adopted EASA standards to a sufficient extent, despite the fact that the majority of its recently acquired aircraft originate from European Union member states where EASA regulations are applied. This may create a need for additional costly conversion training and subsequent standardization, ultimately reducing personnel availability and operational readiness.

Although the identified categories of technical knowledge and skills themselves are generally not subject to significant debate, the continuous evolution of aviation technologies will inevitably present new challenges regarding the methods by which these competencies are acquired. The intervals between revisions of the EASA theoretical knowledge syllabi have proven to be excessively long. Future research should therefore focus on identifying regulatory-compliant approaches for improving the acquisition of technical knowledge and practical skills among future pilots in the Republic of Serbian while remaining consistent with both national requirements and international aviation standards.

One of the recommended ways for achieving higher level of technical knowledge and skills in the future is more comprehensive usage of immersive technologies, artificial intelligence and adaptable training systems, incorporation of game-based education and remote and cooperative instruction.

Abstract: *This paper presents a ballistic module architecture developed for computing firing elements in mortar systems. The ballistic module application calculates firing elements within 5 seconds, significantly reducing engagement time compared to legacy manual procedures requiring 30–60 seconds. The computational engine implements six-degree-of-freedom trajectory modeling, solving the boundary value problem through an iterative shooting method. The system architecture is organized into three integrated modules, Configuration, Ballistic Module, and Communication supporting system setup, ballistic computation with real-time meteorological data, and forward observer data exchange. Beyond real-time computation, the module enables firing table generation, supports advanced engagement modes including Multiple Rounds Simultaneous Impact, and operates autonomously in both test and combat environments. Full system configuration is completed within 40 seconds, with the architecture adaptable to multiple weapon platforms without code modification. The results confirm its effectiveness as a decision-support tool for modern mortar fire control systems, combining computational speed with the flexibility required for integration into broader command and information architectures.*

Keywords: *Ballistic module architecture, Mortar systems, Fire control systems.*

1. INTRODUCTION

In modern artillery systems, ballistic modules must balance high accuracy with rapid response times [1]. Gacek and Leśnik validated 6-DOF models experimentally [2], while NATO STANAG 4355 recommends the MPMMT as a computationally efficient alternative [3]. This model enables faster calculations through yaw of repose simplifications, making it suitable for real-time FCS applications [4]. The trade-off between model fidelity and computational speed remains central to fire control system design, as engagement windows continue to shrink in modern combat scenarios. Mortar systems, with ranges up to 10–12 km, permit flexible model selection [4,5]. Chusilp et al. demonstrated 6-DOF iterative search achieving 10 m accuracy within 1-2 minutes [5,6]. However, longer-range systems require MPMMT for rapid computation [6,7], enabling firing element determination in seconds. NATO's NABK further exemplifies standardized ballistic software components [7,8]. The ability to switch between models based on operational requirements offers significant tactical advantages, allowing mortar units to maintain precision while adapting to dynamic battlefield conditions. Modern FCS integrate ballistic computation with configuration and communication [9]. Luković et al. highlight modular, hardware-independent ballistic modules [9,10], while FENIC'S supports multiple artillery platforms [10,11]. The Artillery FCS system likewise employs MPMMT over polynomial approximations [12]. These integrated environments reduce manual data entry errors and streamline targeting, enabling forward observers to transmit coordinates directly to the FCS.

This paper focuses on describing the operational environment, architecture, and functioning of a custom-developed ballistic software module intended for a FCS. Although the module is designed with particular attention to contemporary trends and the specific requirements of mortar fire with minimal modifications, adaptation and application across a broader spectrum of artillery systems, thereby achieving a high degree of universality. The architecture presented in this work builds upon established principles of ballistic computation while introducing a practical, platform-independent implementation that balances computational efficiency with operational flexibility.

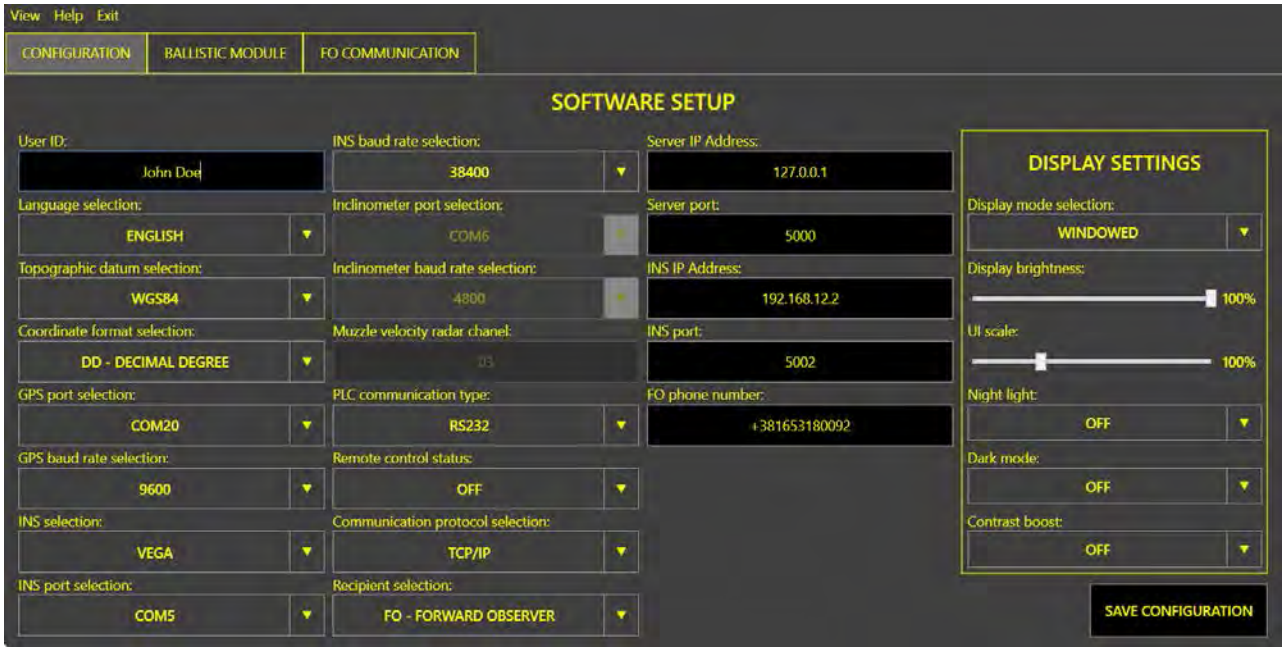

Figure 1. Configuration - Software Setup (example)

2. BALLISTIC MODULE FUNCTIONAL OVERVIEW

The process of calculating firing elements is implemented through an integrated ballistic computer algorithm, which begins with system initialization and the input of initial conditions such as firing position and target coordinates, internal ballistic parameters for the selected weapon, meteorological conditions, and environmental factors. The system then proceeds to solve the set of six-degree-of-freedom (6-DOF) differential equations of external ballistics, while optionally applying advanced correction models such as the Modified Point Mass Model (MPMMT) for enhanced computational efficiency in longer-range or rapid-response scenarios.

After each simulation, the system verifies whether the required range has been achieved by comparing the desired and actual impact point against the effective destruction radius of the munition. If a deviation is detected, the algorithm iteratively adjusts the initial condition vector primarily elevation and azimuth using predefined step sizes or optimization methods, and repeats the simulation until convergence is achieved. Once the target criteria are met, final refinements are applied, accounting for dynamic factors such as wind, projectile drift, and, if applicable, specialized engagement modes like Multiple Rounds Simultaneous Impact (MRSI) or linear target patterns.

In the concluding phase, the system outputs the complete firing solution, including quadrant elevation, azimuth, muzzle velocity, and any sequence-specific parameters, while simultaneously logging all computational steps and enabling real-time data exchange with higher-level command, control, and communication systems for seamless integration into the broader fire control architecture. A more detailed derivation of the computational algorithms is available in [1,3,6,13].

3. BALLISTIC MODULE ARCHITECTURE

The software environment of the ballistic module consists of three main tabs: Configuration, Ballistic Module, and Communication, as shown in Figure 1. Within the Ballistic Module section, there are two windows: Fire Preparation and Fire Elements Calculation, depicted in Figures 2 and 3, respectively, while Figure 4 presents the Communication tab.

3.1 Configuration – Software setup

The Configuration tab (Figure 1) enables initial setup of the FCS, allowing adaptation to specific operational scenarios, hardware configurations, and network architectures.

User Identification and Auxiliary Fields – The *User ID* field allows entry of a unique operator identifier (name, tactical designation, or internal code) used in network communications. The *FO Phone Number* field is used primarily during polygon testing and development phases for standard telephone communication with the forward observer.

System Configuration – Dropdown menus enable selection of language, topographic datum, and coordinate display format. Communication ports and baud rates are configurable for GPS, INS, and inclinometer devices. Additional selections include the inertial navigation system type (LYRA or VEGA), muzzle velocity radar channel, PLC communication type (RS232 or ETHERNET), and remote control status. For network

communication, the protocol (TCP or UDP), recipient, server IP address and port, as well as INS IP address and port, are defined. The *Save Configuration* button permanently stores all settings, enabling pre-adaptation to the platform and environment, thereby increasing efficiency and reducing firing data calculation time.

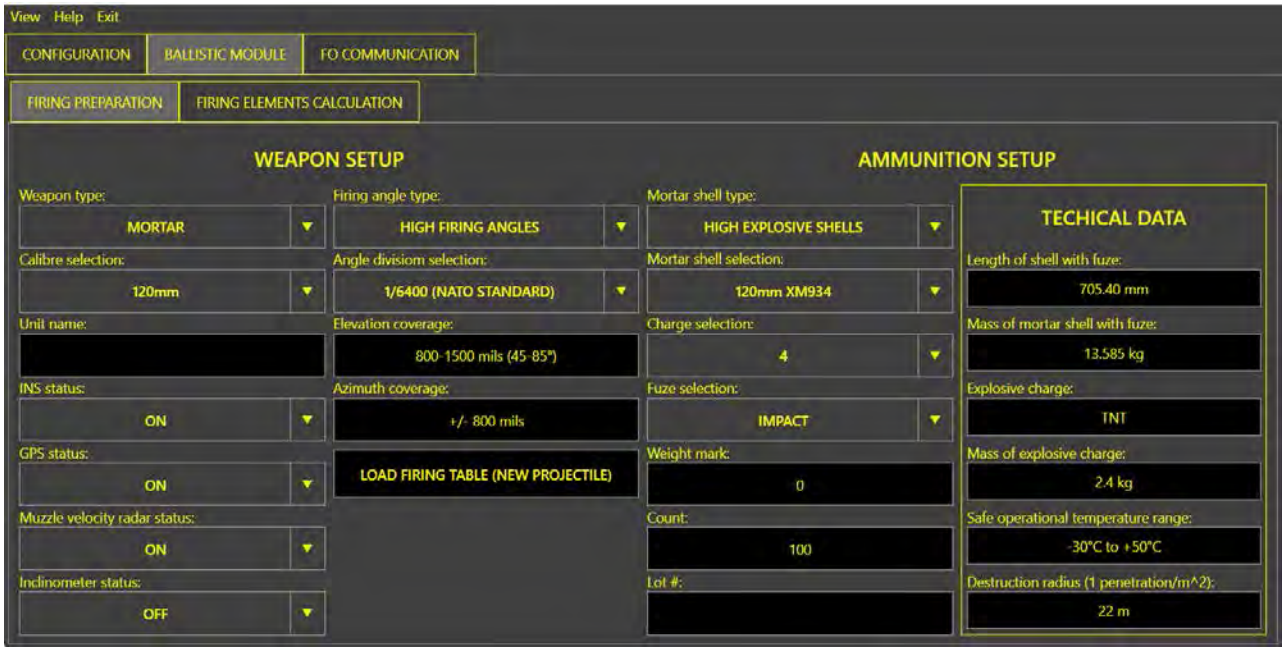

Figure 2. Ballistic Module - Firing Preparation (example)

3.2 Ballistic Module – Firing Preparation

The Ballistic Module tab, Figure 2, is the central computational component of the fire control system. It enables complete preparation and calculation of firing elements based on weapon type, ammunition type, firing position and target characteristics, and environmental conditions. The tab is divided into two logical sections: *Firing Preparation* and *Firing Elements Calculation*.

Firing Preparation – This section allows preparation (selection of weapon and ammunition) prior to calculating firing elements, enabling the software to support multiple weapon types and calibers.

Weapon and Ammunition Selection – The *Weapon Type* dropdown enables selection of the artillery system (howitzer, multiple rocket launcher, or mortar). The *Calibre Selection* dropdown is dynamically linked, displaying available calibers based on the selected weapon: Mortar (60 mm, 81 mm, 82 mm, 120 mm), Howitzer (155 mm), and MLRS (107 mm, 122 mm, 128 mm). The *Mortar Shell Type* dropdown (or *Projectile Type* / *Rocket Type*, depending on weapon) selects the ammunition category (HE, Smoke, Illuminating). The *Mortar Shell Selection* dropdown filters compatible ammunition based on the combination of weapon type, caliber, and ammunition category. The *Charge Selection* dropdown displays only propellant charges compatible with the selected ammunition (disabled for MLRS). The *Fuze Selection* dropdown allows selection of the fuze type (e.g., Impact, Super quick, Delay action, UT M39 P1, MRV-U). The *Weight Mark* field is used for ammunition weight designation.

Technical Data – This section provides a non-interactive informational display of the currently selected ammunition's technical characteristics, including length, weight, explosive weight and type, temperature range, and destruction radius.

System Status and Operational Fields – The *INS Status*, *GPS Status*, *MVR Status*, and *Inclinometer Status* dropdowns enable or disable the use of these sensors. The *Firing Angle Type* dropdown selects the firing regime (High Firing Angles or Low Firing Angles), which directly affects the elevation coverage display. The *Angle Division Selection* dropdown sets the angular conversion standard (360° = 6400 mils for NATO or 360° = 6000 mils for Russian standard). The *Azimuth Coverage* field displays the permissible traverse limits for the weapon. The *Unit Name* field allows entry of the organizational unit (e.g., battery, platoon), which can be combined with the previously defined *User ID* for network identification. The *Count* field specifies the number of available rounds, and the *Lot #* field records the production lot number for logistical tracking.

Load Firing Table – The *Load Firing Table* button allows uploading precomputed firing tables (.csv, .txt, .xlsx, or .xls format) for projectiles that are not part of the system's standard database and for which mass-inertial and aerodynamic data are unavailable for numerical trajectory simulation.

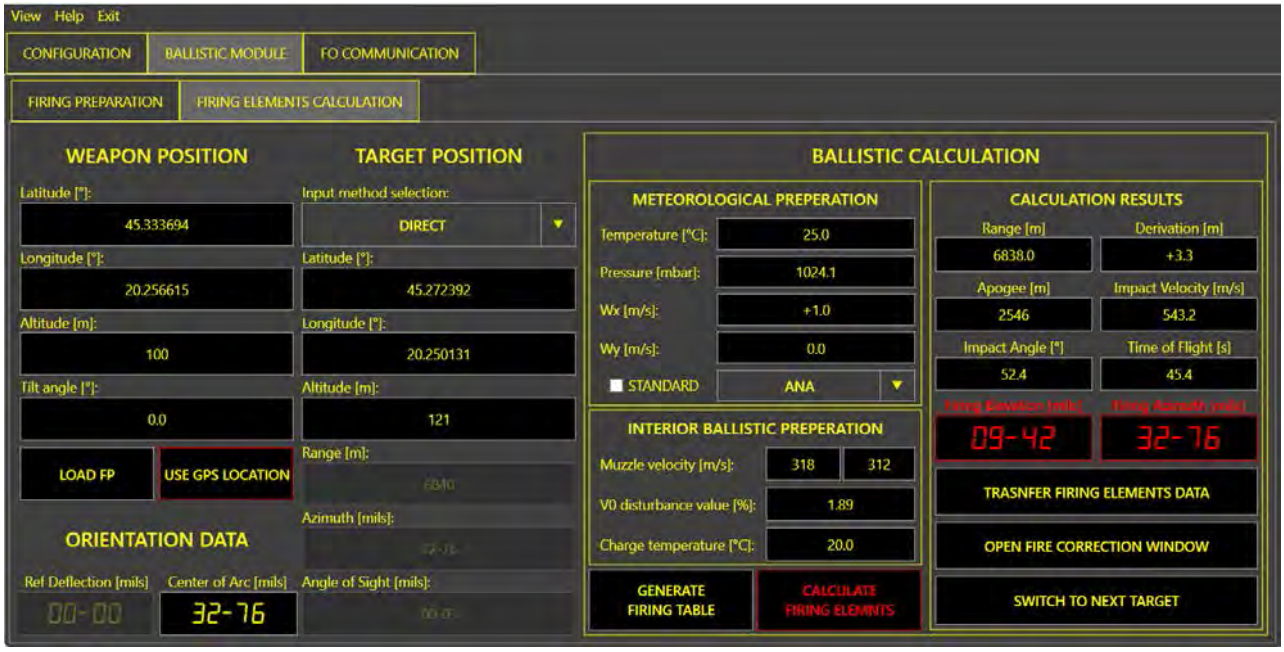

Figure 3. Ballistic Module - Firing Elements Calculation (example)

3.3 Ballistic Module – Firing Elements Calculation

The Firing Elements Calculation tab, shown in Figure 3, represents the core computational section of the ballistic module, where elevation and azimuth angles are determined based on predefined weapon and ammunition parameters combined with inputs entered within this section.

Weapon Position – This section defines the geographic location of the firing position, including latitude, longitude, altitude, and platform tilt angle. Accuracy of these inputs directly affects ballistic precision. Three input methods are available: manual entry, loading from a preconfigured firing position file (*Load FP* button), or reading from a GPS device (*Load GPS Location* button). Platform tilt angle can be entered manually or read from an inclinometer. Input formats depend on the topographic datum and coordinate format defined in the Software Setup tab.

Target Position – This section defines the geographic location of the target. Input accuracy directly impacts ballistic calculation precision. The *Input Method Selection* dropdown offers two modes:

- *Direct* – manual entry of latitude, longitude, and altitude.
- *Indirect* – target is defined relative to the firing position by entering range, azimuth, and site angle; the software then calculates geographic coordinates.

When the forward observer transmits target coordinates via the communication channel, the software automatically populates the relevant target information.

Meteorological Preparation – This section defines surface meteorological conditions affecting external ballistics, including temperature [°C], pressure [mbar], longitudinal wind (wx) [m/s], and crosswind (wy) [m/s]. The *Standard Atmosphere* checkbox allows selection of predefined standard conditions:

- *ANA (Artillery Normal Atmosphere)*
- *ICAO (International Civil Aviation Organization)*.

Interior Ballistic Preparation – This section defines parameters affecting interior ballistic calculations. Muzzle velocity is displayed with the prescribed nominal value on the left. If a muzzle velocity radar is used, the measured value appears on the right, along with the calculated percentage deviation, which is used to correct the firing elements (elevation angle). Propellant grain temperature is also defined, as it directly affects muzzle velocity through empirical coefficients, and together with barrel wear determines the total velocity deviation for fire control corrections

Calculation Execution – The *Generate Firing Table* button initiates a series of iterative ballistic calculations over a defined elevation range, producing a complete firing table in .pdf or .xlsx format for the selected weapon and ammunition combination. The *Calculate Firing Elements* button performs the final numerical calculation, verifying that all required inputs (weapon, ammunition, positions, meteorological parameters) are defined before computing the firing elements.

Figure 4. Forward Observer Communication

Calculation Results – This section displays the key outputs necessary for executing the fire mission. The primary calculated firing elements are *Firing Elevation* and *Firing Azimuth*, which represent the final angles to be transmitted to the weapon's executive system. Additional trajectory parameters are also displayed, including achieved range, deflection, maximum ordinate, impact velocity, impact angle, and time of flight.

The following auxiliary functions are available:

- *Transfer Firing Elements Data* – sends the calculated firing elements to the weapon's executive mechanisms.
- *Open Fire Correction Window* – opens a window for correcting firing elements, showing deviations from tabular values and allowing manual adjustment of elevation and azimuth based on forward observer reports of impact points.
- *Switch to Next Target* – resets current results and transitions to a new target for subsequent fire missions.

3.4 Forward Observer Communication

The FO Communication tab serves, Figure 4, as the communication interface between the weapon system and the forward observer. This section enables establishment, monitoring, and management of network connections, as well as real-time data exchange between connected entities. It is primarily designed to automatically process target data and projectile impact point data when transmitted by the forward observer. This functionality requires a radio device at both the observer and weapon locations.

Communication Service Management – The *Start Server* button initiates the communication service on the weapon system, assigning it the server role in the client-server architecture. The system opens the IP address and port defined in the Software Setup tab, initializes communication sessions, and enables forward observers to connect. Upon successful startup, the *Network Status* indicator turns green. The *Close Server* button safely terminates the communication service when needed.

Recipient Group – This section displays and enables selective communication with connected forward observers. The system supports up to four simultaneously connected observers, identified as FO1, FO2, etc. When an observer connects, the corresponding button becomes active and its status indicator turns green. These buttons allow selective message transmission to a specific observer.

Messaging – The *Formatted Messages* dropdown contains a list of predefined, standardized messages for rapid transmission to one or more connected observers, representing common operational commands or status information. The *Add/Remove Message* button allows modification of this list. The *Outgoing Message* field is a text area where the user composes messages to be sent selectively (via recipient group buttons) or to all connected observers simultaneously (via the *Send* button). The *Clear* button deletes the content of this field. All sent and received messages, along with connection status information, are displayed in the central panel of the tab.

4. PERFORMANCE EVALUATION

To assess the operational viability of the proposed ballistic module, two distinct scenarios were evaluated.

The first scenario represents full system configuration from a default state, encompassing all parameters within

the *Software Setup* tab, from user identification to communication protocols and display settings. The measured configuration time was approximately 40 seconds. While this duration is acceptable for initial integration and pre-deployment preparation, it does not reflect realistic tactical conditions, where systems are expected to be mission-ready with only mission-specific adjustments.

The second scenario reflects a realistic operational use case with predefined weapon type, caliber, and ammunition. Upon receiving target information (manually or via forward observer communication), the system performed ballistic calculations, including numerical trajectory integration and computation of firing elements and auxiliary trajectory parameters. The measured time from final input confirmation to displayed results was approximately 5 seconds.

The achieved 5 second calculation time aligns with real-time fire control requirements, where delays exceeding 10–15 seconds may compromise mission effectiveness, particularly against moving or time-sensitive targets. In comparison with legacy manual procedures using printed firing tables, which typically require 30–60 seconds depending on operator proficiency, the presented architecture provides a significant reduction in engagement time. The 40-second full configuration time, while not operationally critical, reflects the system's comprehensive configurability, enabling deployment across different weapon platforms (howitzers, mortars, MLRS) and hardware configurations without code modification. Together, these metrics demonstrate that the proposed architecture balances operational responsiveness with the flexibility required for multi-platform adaptability.

All measurements were performed on a hardware platform featuring an Intel Elkhart Lake Atom x6413E processor (quad-core, 1.50 GHz base frequency, up to 3.00 GHz boost), 8 GB of RAM, and 128 GB of internal storage.

5. CONCLUSION

The proposed custom-developed ballistic module architecture delivers a platform-independent fire control solution integrating configuration, ballistic computation, and forward observer communication into a unified software environment. With a full system configuration time of 40 seconds and a firing element calculation time of approximately 5 seconds compared to 30–60 seconds for legacy manual procedures the system meets real-time operational requirements while eliminating manual data entry errors. Its modular design supports seamless adaptation across howitzers, mortars, and multiple rocket launchers without code modification. With minor modifications, the system can also be integrated into a broader command and information system, enabling centralized fire control at the battery or battalion level. This architecture thus provides a universal solution compatible with existing artillery systems, combining speed, accuracy, flexibility, and interoperability as a foundation for next-generation fire control. The presented performance metrics were obtained under nominal conditions with optimal hardware resources and without network communication overhead. Future evaluation will include end-to-end latency with radio communication, performance under degraded hardware, simultaneous multi-observer connections, and live-fire validation against actual impact point accuracy.

Acknowledgment

The results presented here are the result of research supported by the Ministry of Science, Technological Development and Innovation of the Republic of Serbia under Contract 451-03-34/2026-03/200105 of 05.02.2026.

Abstract: *Impulse rocket motors are group of solid propellant rocket motors, which main characteristic is extremely short operating time. The application of these rocket motors is of particular importance for missile weapons as busters or control thrusters. The total operating time of such rocket motor is in order of ten milliseconds and that complex processes are highly non-stationary. In the anti-tank rockets the impulse motor role is to accelerate the rocket to a certain velocity in a very short time, during the rocket's motion through the launch tube, and to provide the necessary ballistic characteristics (dynamic stability, greater range, shorter flight time to the target and the less dispersion of hits). Reliability of this type of rocket motors is of crucial importance in terms of operation safety. This paper presents an experimental study of how fractured propellant charge affects rocket motor performances and safety.*

Keywords: *impulse rocket motor, propellant, fracture, propulsion, pressure.*

1. INTRODUCTION

Rocket missiles are launched by a rocket motor which is an integral part of the projectile. In order for a rocket to accelerate to a certain veocity and to be able to maintain that velocity, overcoming air drag and gravity, it is necessary to generate a force called thrust [1-11].

Thrust is the reaction force that occurs when a certain mass is ejected from the propulsion group. The separation of mass is most often realized through the outflow of gases (gaseous products of combustion) where the direction of the generated thrust force is opposite to the direction of outflow of gases [1-10].

In order to ensure the generation of gases, it is necessary to have a certain source of energy. Chemical energy contained in solid propellant is converted into thermal energy through a propulsion reaction which is accompanied by the release of energy. Propulsion is performed in the propulsion chamber where the chemical energy is transformed into heat, while the thermal energy is converted into kinetic energy through the rocket motor nozzle [1-10].

In the anti-tank weapons, all energy required to solve the ballistic problem is provided by the rocket motor propulsion. The projectile of such a weapon must have a basic impulse rocket motor, which achieves initial velocity at the muzzle. Rocket can also have an additional rocket propulsion system that is activated during flight on the trajectory and improves its ballistic characteristics [12].

This type of weapon is used for shooting at short ranges (200 m to 500 m) by launching from the rocket operator's shoulder, therefore the reliability and safety of such systems must be at a very high level.

As the most common form of propellant for man-portable anti-tank rocket launcher are multiple small diameter thin tubes with. Such a propellant geometry is the most favorable because of:

1. definition and reproducibility of manufacturing

Corresponding author: K. Nestorović;
E-mail: katarina.nestorovic993@gmail.com
DOI: 10.5937/OTEH26017N

technology,

2. combustion without significant slivers,
3. elegant solution of propellants integration inside the rocket motor chamber and
4. control benefits [1].

The basic internal – ballistics (IB) parameters of the rocket motor are maximum pressure, mean effective propulsion time and total impulse.

2. THEORETICAL BASIS

The rocket motor operating regime calculation can be conducted using IB coefficients that can be calculated theoretically, experimentally or semi-empirically (Figure 1) [1-2].

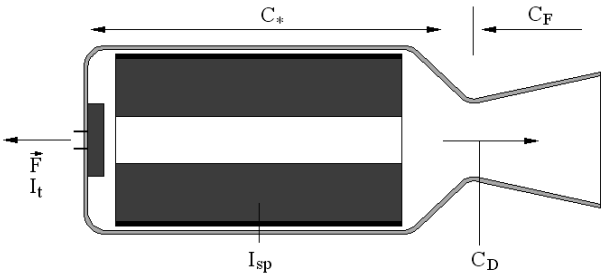

Figure 1. Basic model of propulsion product flow through the nozzle and characteristic process parameters [2].

Thrust of the rocket motor can be calculated based on the consideration of the motion of a body of variable mass (Mescherski's equation) and it is determined by the expression:

$$F = \dot{m}v_e + \left(p_e - p_a\right) A_e \tag{1}$$

where are:

$\dot{m}$ - mass flow rate,
v_e - nozzle exit velocity,
p_e – nozzle exit pressure,
p_a – atmospheric pressure and
A_e – nozzle exit area [1-2].

Nozzle exit pressure can be differentiated which depends on the difference (p_e - p_a):

- $p_e > p_a$ → under - expanded,
- $p_e = p_a$ → fully - expanded,
- $p_e < p_a$ → over – expanded [1-2].

Total impulse is the integral of thrust curve over the total operating time period τ and it can be calculated according to the equation:

$$I_t = \int_0^{\tau} F(t)dt \tag{2}$$

where is: τ – rocket motor operating time [1-2].

The specific impulse represents the thrust per unit propellants mass. Also, the specific impulse can be expressed as the ratio between the thrust coefficient c_F and the discharge coefficient c_D. It can be calculated according to the equation [1-2]:

$$I_{sp} = \frac{F}{\dot{m}} = \frac{I_t}{m} = \frac{C_F}{C_D} \tag{3}$$

The thrust coefficient represents efficiency of thrust generation, regarding nozzle flow efficiency and is dimensionless. It can be calculated according to the form:

$$c_F = \frac{F}{p_c A_t} \tag{4}$$

where are:
p_c – pressure of propulsion products,
A_t – specific nozzle throat area [1-2].

Discharge coefficient defines mass flow rate $\dot{m}$ trough throat area A_t, inducted with products pressure energy in chamber. It can be calculated according to the form:

$$c_D = \frac{\dot{m}}{p_c A_t} = \sqrt{\frac{\kappa}{RT_c}\left(\frac{2}{\kappa+1}\right)^{\frac{\kappa+1}{\kappa-1}}} \tag{5}$$

where are:
κ – heat capacity ratio,
R – gas constant,
T_c – chamber temperature [1-2].

The characteristic flow rate is a function of the propellant characteristics and propulsion chamber design, and it is independent of the nozzle characteristics. It can be calculated according to the equation [1-2]:

$$c^* = \frac{p_c \cdot A_t}{\dot{m}} = \frac{1}{c_D} \tag{6}$$

The output velocity of the propulsion product is calculated according to the equation [1-2]:

$$v_e = \sqrt{\frac{2\kappa}{\kappa-1} RT_c\left(1 - \bar{p}_e^{\frac{\kappa-1}{\kappa}}\right)} \tag{7}$$

Propulsion of the solid propellants takes place on the propulsion surface. Propulsion rate r is defined as a distance that crosses the flame front perpendicular to the free charging surface in a unit of time.

Pressure has a dominant influence on the value of propulsion rates and this dependence is expressed in form of Saint – Robert's law:

$$r = bp^n \tag{8}$$

where are: b – initial charge temperature function and n – the propulsion index which is a characteristic of rocket propellant and is always less than 1 [1-2].

Only in the case of propellant with frontal propulsion, the discharge of gases is carried out normally on the propulsion surface. In other cases, the gases move parallel to the propulsion surface, which affects the propulsion rate, which increases with increasing gas velocity along

the propulsion surface. This phenomenon is called erosive propulsion [1-2] [13].

The geometry of the nozzle (flow sections, number of nozzles and their position) is defined within the ballistic calculation of the rocket motor. During the flow of gaseous products through the nozzle, erosion of the nozzle neck can occur, which causes a reduction in the total impulse. Due to the expansion of the nozzle neck caused by erosion, the pressure drops and the operation of the rocket motor is prolonged. The erosion process occurs when the surface temperature of the nozzle neck reaches the melting temperature of the nozzle material. The most intense heat transfer from the propulsion surface to the flow cross-sectional surface is in the nozzle throat, so the melting temperature is reached closest there [1-2] [13].

The degree of expansion *(ε)* of the nozzle is a constant geometric characteristic that depends on the ratio of specific heats of the propellant and the ratio of pressures in the chamber and at the outlet of the nozzle. The calculation of the nozzle strives for the complete expansion of gases, with the aim of achieving the highest energy utilization. This is achieved if the pressure at the nozzle outlet is equal to the ambient pressure. The degree of expansion of the nozzle is determined by the equation [1-2]:

$$\varepsilon = \frac{A_e}{A_t} = \frac{\left(\frac{2}{\kappa+1}\right)^{\frac{1}{\kappa-1}} \cdot \left(\frac{p_c}{p_e}\right)^{\frac{1}{\kappa}}}{\left\{\frac{\kappa+1}{\kappa-1} \cdot \left[1-\left(\frac{p_c}{p_e}\right)^{\frac{1-\kappa}{\kappa}}\right]\right\}^{\frac{1}{2}}} \tag{9}$$

The chamber of the rocket motor is cylindrical shape, made of high-quality steel capable of withstanding the pressure of propulsion gases and their erosive action. The bottom of the rocket motor connects with a warhead over the thread. A stabilizer is set on the rear end of the rocket motor chamber.

3. EXPERIMENT

Since the man-portable anti-tank rocket is launched from the operators' shoulder, the rocket motor's operating time must be completed while the motor is in the tube. Such weapons are designed with a maximum rocket motor operation time of around $t_{max} \leq 18$ ms and the total impulse of around $I_t \approx 85$daNs [1]. For this type od weapons factor of safety must be maximum. The aim of this experiments was to show how fractured propellant influence on [5] [14]:

1. safety of the rocket operator,
2. performances of the impulse rocket motor, especially on pressure which is the most important rocket motor parameter in terms of safety.

The impulse rocket motor chamber is designed to have high mechanical properties. The high-strength aluminum alloy chambers usually can withstand pressure values of 1000 bar or more, which has been confirmed by experiments. The maximum pressure of the propulsion products in the rocket motor chamber is between 500 bar and 600 bar, and this is in case when propellant was previously exposed to extremely high temperatures (+50°C) for a period of time. In the case of ambient temperature (+20°C), the maximum pressure of combustion products is around 400 bar.

In this experiment two expected potentially critical failures are examined:

1. Due to the deterioration of the mechanical characteristics of the propellant and mechanical operational loads, different degree of fragmentation of certain number of tubes potentially may occur;
2. The bounded joint of the tubes to the grain holder may fail, which will lead to the ejection of certain number of the tubes through the nozzle.

For purposes of the experiments, two mentioned types of failure are simulated: some of propellant tubes were intentionally fractured or unbounded form the grain holder, in order to simulate propellant material deterioration, protentional damages of the rocket, bad exploitation conditions, etc. Since the propellant fractures cannot be easy detected, the aim of the experiment was to show whether such a flaw could cause a critical increase in pressure gradient [15] and the destruction of the rocket motor chamber, endangering the operator's safety.

Before realization of this experiment, propellant and the pyrotechnic mixture were tested by the method of vacuum stability and compatibility, described elsewhere [16].

The static tests of experimental rocket motors were realized on the test bench. First set of experiments were carried out at ambient temperature of +20°C, with intentionally fractured propellant. Propellant tubes are shredded to pieces 5×10 mm, and are shown in Figure 2. Shredded pieces of tubes are freely poured into chamber.

Figure 2. Intentionally fractured propellants tubes.

Second set of experiments are conducted with propellant grains with sertain percent of not bounded tubes, which are freely placed into the chamber as free-standing grains.

All static tests were carried out in experimental rocket motors, which free volume fully corresponds to a flight rocket motor. Changes in the pressure of the combustion products inside the chamber was measured during the

rocket motor operating time.

Experiment 1. Tube fracture.

In the first experiment, 4 of 37 or around 10% of the total number of propellant tubes were fractured. With such damage to the propellant, it was shown that the maximum pressure of the combustion products reaches over 350 bar, while operating time of the rocket motor is several milliseconds shorter than the projected operating time. Figure 3 shows diagram of the motor chamber pressure-time function.

Experiment 2. Tube fracture.

In the second experiment, 10 of 37 or around 27% of the total number of propellant tubes were fractured. Maximum pressure of the combustion products reaches 420 bar, while operating time of the rocket motor is similar like in the first experiment.

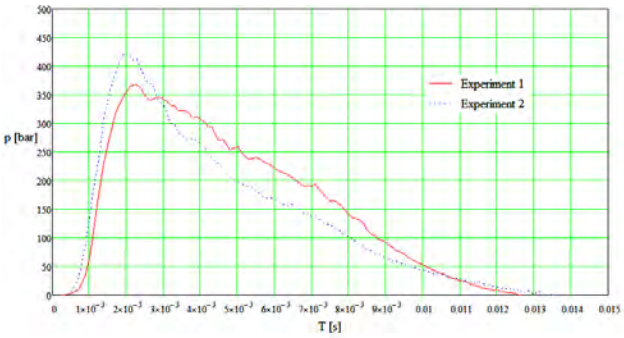

Figure 3. The rocket motor chamber pressure-time curves for experiments 1 and 2 with fracture tube.

The pressure-time curves are significantly changed compared to regular tests. The maximum pressure is increased, the pressure integral is reduced due to the ejection of unburned pieces of propellant, and the operating time is extended due to the pressure drop in the last stage.

Based on these two experiments, it can be concluded that a very significant fragmentation of the propellant grain is required in order to achieve a greater increase in pressure in the chamber. This type of propellant grain anomaly can lead to the motor failure only with tubes fragmentation in smaller pieces and a larger percentage of tubes.

Experiment 3. Joint failure.

In the third experiment, 8 of 37 or around 20% of the total number of propellant tubes were unbounded – free-standing. The maximum pressure of the combustion products reaches 340 bar, while operating time of the rocket motor is extended including significant secondary pressure peek. In this motor configuration complex internal ballistics phenomena are present, including movement of free-standing tubes. Free standing tubes are partially trapped in initial configuration, standing between chamber walls and bounded tubs. During the propellant combustion, products flow cause ejecting force on the free-standing tubes and they can randomly leave the motor partially burned. During the tube's passing through the nozzle, throat choking can occur, which can be explanation for secondary peek in pressure diagram.

Experiment 4. Joint failure.

In this experiment, 16 of 37 or around 37% of the total number of propellants tubes were unbounded. The maximum pressure of the combustion products reaches 380 bar, while operating time of the rocket motor is stilly extended. In this case two smaller secondary pressure peeks can be noticed. In this configuration free standing tubes are not rigidly confined like in previous experiment, so probably throat choking is less distinct.

Experiment 5. Joint failure.

In the last experiment, 22 of 37 or around 60% of the total number of propellants tubes were unbounded. The maximum pressure of the combustion products reaches 400 bar, while operating time of the rocket motor is also stilly extended, without secondary pressure peeks.

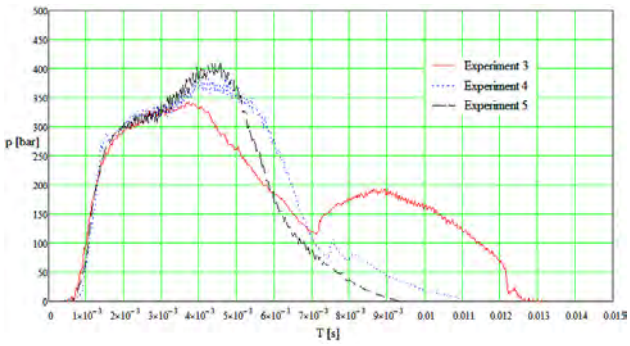

Figure 4. The rocket motor chamber pressure-time curves for experiments 3, 4 and 5.

The pressure-time curves are significantly changed in comparison to regular tests. The maximum pressure is increased, the pressure integral is reduced due to the unburned grains ejection. Assuming that every unburned grain ejection is causing some level of throat choking, configuration, type and percentage of ejecting tubes cause pressure increase which differ pressure diagram.

5. CONCLUSION

In this paper, an experimental study of fractured propellant influence on the impulse rocket motor safety was performed. From the IB parameters of the impulse rocket motor, the emphasis is placed on the maximum pressure of propulsion products inside the chamber as the most important safety parameter of the motor.

Five static tests were carried out with different amounts of fractured propellant tubes in order to check the safety impact on the rocket operator, as well as to check the changes in the pressure gradient depending of the increase in the propulsion surface.

In all of the five experiments, pressure gradient of the propulsion products was not significantly increased and did not exceed 415 bar (even in the case of severe damage to the propellant tubes - up to 60%), which corresponds to the nominal maximum pressure of the propulsion

products.

The operating regime of the rocket motor was not correct, which affects the operating time and which would potentially affect the flight parameters of the rocket, but the requirements during the desing of the weapon guarantee the safety of the rocket operator even in case of major damage to the propellant.

Nowadays, modern variants of man-portable anti-tank rocket launchers are in use in current warfares. An experimental study of this type provides a clear insight into the importance of safety over functionality in weapon systems that are launched by a rocket operator, in cases of unforeseen failures.

Abstract: *The presence of explosive remnants of war represents a long-term security and technical challenge, especially in urban areas and zones of exceptional cultural and historical importance. The paper presents the development of an integrated technical model for detection and risk management of explosive remnants of war, applied to the case study of the Smederevo Fortress site. The aim of the research is to establish a systemic approach that combines geophysical detection methods, an analytical risk assessment model and operational response procedures, with the aim of reducing the probability of an incident and its consequences for the population, infrastructure and cultural assets. The risk assessment was developed through a matrix that includes the probability of presence and activation of explosive remnants of war, population density, proximity to infrastructure and terrain specifics. By integrating technical data with operational security procedures, a phased model of risk management was defined, which includes initial assessment, technical reconnaissance, perimeter security, intervention and post-operative evaluation. A special contribution of the work is reflected in the adaptation of technical methods to the specifics of the protected cultural site, where the limitations regarding excavation and intervention are expressed. The proposed model can be applied to other locations with similar historical and infrastructural characteristics, thereby contributing to the development of a standardized technical-security approach to managing the risk of explosive remnants of war.*

Keywords: *explosive remnants of war, risk assessment, Smederevo fortress*

1. INTRODUCTION

Explosive remnants of war (EOR) represent one of the most significant long-term security challenges in post-conflict societies. Although armed conflicts often ended decades ago, their material remnants continue to threaten human life, infrastructure, cultural property and the environment. The presence of unexploded explosive devices can limit the development of certain areas, make it difficult to carry out construction and infrastructure works and represent a constant source of risk for the local population and visitors. Contemporary research indicates that effective EOR risk management requires a systematic approach that combines technical detection, risk assessment and response planning to potential incidents (Novik et al., 2023). According to the Law on Disaster Risk Reduction and Emergency Management, explosive remnants of war are explosive devices and unexploded ordnance, with or without detonators, prepared for use or used, i.e. fired, launched, ejected, launched or placed, and did not perform their function, i.e. unexploded, abandoned ordnance that was left behind or thrown away and assets left behind after the explosion of the ordnance warehouse, i.e. in the process of ordnance production (Law on Disaster Risk Reduction and Emergency Management, 2018).

A special challenge is presented by cultural and historical sites that had a military function during their history or were exposed to war. In such locations, there is often the possibility of the presence of residual explosive devices, while at the same time there are significant limitations in the application of invasive research methods due to the need to preserve cultural heritage. Therefore, it is necessary to apply modern detection methods that enable the identification of potentially dangerous objects without endangering the integrity of the site (Barone, 2019).

Smederevo Fortress is one of the most important medieval fortifications in the Republic of Serbia. A special place in the history of the Smederevo Fortress is occupied by the explosion of the ammunition warehouse on June 5, 1941, which represents one of the greatest tragedies in the history of Serbia. In addition to the large number of human casualties and the destruction of the city, the explosion left long-term consequences for the area of the fortress, including the possibility of unexploded ordnance

DOI: 10.5937/OTEH26018K

remaining in certain parts of the site. The historical circumstances of this event are documented in detail in the monograph by Miroslav P. Lazić, which represents a significant source for understanding the origin and development of security risks in the area of the Smederevo Fortress (Lazić, 2021). The historical circumstances of this locality point to the need for continuous consideration of potential security risks associated with the possible presence of explosive remnants of war.

The development of geophysical methods has significantly improved the possibilities of detecting explosive devices. Magnetometric, electromagnetic and other non-invasive surveys enable the identification of underground anomalies and potentially dangerous objects with minimal disturbance of the research area. The special importance of these methods is reflected in their application on cultural heritage sites, where preserving the authenticity of the space is one of the basic requirements (Ibraheem et al., 2021). In addition to technical detection, modern approaches emphasize the importance of spatial analysis and visualization of risk areas, which improves the process of decision-making and planning of protection measures (Lacroix et al., 2013).

Based on the above facts, the subject of this paper is the development of an integrated technical model of detection and risk of explosive remnants of war on the example of the Smederevo fortress. The aim of the work is to establish a model that combines technical methods of detection, risk assessment and operational procedures of risk management in order to increase the safety of people, infrastructure and cultural heritage. The scientific contribution of the work is reflected in the proposal of an integrated approach that can be applied to other cultural and historical sites with similar characteristics.

2. THEORETICAL AND CONCEPTUAL FRAMEWORK

Explosive remnants of war represent a residual explosive community that was not activated during use or was left abandoned after the end of armed conflicts. Their presence is a long-term security problem because they can remain active for decades after hostilities have ended. The risk of EOR is reflected in the possibility of causing human casualties, material damage and restrictions on the use of space for infrastructural, economic and social development (Novik et al., 2023). The presence of EOR is not only a technical problem of removing hazardous materials, but requires a systemic approach that includes hazard identification, risk assessment, prioritization of actions and implementation of appropriate protection measures. Modern approaches to risk management are based on the integration of technical, organizational and security measures in order to reduce the probability of an incident and mitigate its consequences (Novik et al., 2023). Technical detection is the basis for identifying and locating explosive remnants of war. The development of geophysical methods made it possible to significantly improve the field research process, especially in conditions where the application of invasive methods is not possible or desirable. One of the most commonly used methods is magnetometry, which is based on registering anomalies in the Earth's magnetic field caused by the presence of metal objects in the underground. This method enables a quick search of large areas and efficient identification of potential locations where explosive devices may be located (Butler, 2003). In addition to magnetometry, electromagnetic methods that enable more precise determination of the position and characteristics of underground metal objects are also widely used. The combined application of several geophysical methods contributes to increasing the reliability of results and reducing the possibility of misinterpretation of data (Pašteka et al., 2021). The use of georadar (Ground Penetrating Radar - GPR) is particularly important for the purposes of researching cultural and historical sites. This method enables non-invasive investigation of underground structures and anomaly identification without damaging archaeological layers and building structures. This is why georadar is often used in research on cultural heritage and protected sites (Martinho & Dionisio, 2014). Modern research indicates that the greatest efficiency is provided by the integration of several geophysical methods with the application of geographic information systems (GIS), which enable the processing, visualization and spatial analysis of collected data. Such an approach contributes to more accurate mapping of risk zones and more efficient planning of detection and remediation activities (Martorana et al., 2023).

Risk assessment is a key element of the security management system in areas suspected of containing explosive remnants of war. In a broader sense, risk can be viewed as a function of the probability of an unwanted event occurring and the consequences that event may produce. In EOR, risk assessment includes the identification of potential hazards, the analysis of the probability of their activation and the assessment of possible consequences for the population, infrastructure, environment and cultural assets. Based on the results of the assessment, action priorities and appropriate protection measures are defined (Novik et al., 2023).

Risk management involves planning and implementing organizational, technical and operational activities aimed at reducing the probability of an incident occurring or mitigating its consequences. This process includes continuous data collection, conducting technical research, establishing security procedures and making risk assessment decisions. With cultural and historical sites, risk management has additional complexity due to the need to preserve cultural heritage. Therefore, modern approaches are based on the integration of technical detection methods, spatial analysis and operational planning into a unique risk management system. Such an integrated approach enables more efficient use of available resources and a higher level of protection of people and cultural assets.

3. RESEARCH METHODOLOGY

The research is based on the case study method, which is

one of the most frequently applied qualitative research methods in social and technical sciences. This method enables a detailed study of a specific phenomenon in its real environment, while considering all the factors that influence its creation and development (Yin, 2018). A case study is particularly suitable for researching security problems, as it allows the connection of theoretical knowledge with empirical data collected in a specific location (Stake, 1995).

The Smederevo Fortress, one of the most important cultural and historical sites in the Republic of Serbia, was chosen as the subject of research. The choice of this locality is based on its historical significance, military function during different historical periods, as well as on the fact that in its area in previous years there have been cases of finding explosive remnants of war that required the intervention of competent services. The application of the case study enables the analysis of the existing situation, the identification of security risks and the development of an integrated technical model of risk detection and management that can be applied to other cultural and historical sites with similar characteristics. Primary and secondary sources of data were used in the research. Secondary sources consist of domestic and international scientific and professional literature in the field of explosive remnants of war, geophysical detection methods, risk assessment, security management and cultural heritage protection. Primary sources include data on the recorded interventions of competent services in the area of the Smederevo Fortress from 1994 to the present, including information on found explosive devices, the circumstances of their discovery and implemented security measures. For the purposes of the research, 38 recorded interventions were analyzed, which represent the basis of the empirical part of the work.

The work uses a combined research approach that combines qualitative and descriptive research methods. The analysis of scientific and professional literature was used to review modern approaches to the detection of explosive remnants of war and risk management models. The analysis of the documentation enabled the systematization of data on recorded interventions at the site of the Smederevo Fortress. The descriptive method was applied to show the characteristics of the explosive devices found, the frequency of interventions and their spatial distribution, while the comparative analysis enabled the comparison of existing approaches to risk management with the proposed integrated model. By combining different research methods, a more comprehensive overview of the investigated problem is achieved and the reliability of the conclusions drawn increases (Creswell, 2018).

The analytical framework is based on the assessment of the risk of explosive remnants of war using a qualitative analysis of the available data. Risk assessment includes hazard identification, analysis of the possibility of their occurrence and assessment of possible consequences for people, cultural heritage and infrastructure (Novik et al., 2023).

Within the scope of the research, the following were analyzed:

- the number of recorded interventions by competent services;
- types of explosives found;
- locations of finds within the fortress complex;
- the circumstances under which the funds were found;
- potential impact on the safety of visitors and employees i
- possibilities of applying modern technical detection methods.

Based on the results of the analysis, the elements of the integrated technical model of risk detection and management were defined, which represents the central contribution of this work

Also, we have to look at the limitations during the research. The limitations of the research refer to the availability of data on all historical interventions, as well as the fact that no direct geophysical surveys of the terrain were carried out within this work. Therefore, the analysis is based on the available documentation, recorded interventions of competent services and relevant scientific literature. Despite the mentioned limitations, the data used enable a reliable assessment of security challenges and the formulation of proposals for an integrated technical model of risk management

4. INTEGRATED TECHNICAL MODEL OF DETECTION AND RISK MANAGEMENT OF EXPLOSIVE REMNANTS OF WAR

Risk management is a set of measures and activities that are carried out with the aim of implementing disaster risk reduction policy as well as administrative operational and organizational skills and capacities for their implementation (Law on Disaster Risk Reduction and Emergency Management, 2018). Managing the risk of explosive remnants of war is a complex process that requires the integration of technical, organizational and security activities into a single system. Modern approaches indicate that individual measures, such as detection or removal of explosive devices, are not sufficient if they are not connected to systematic risk assessment and planning of preventive activities (Novik et al., 2023). Authors Nenad Komazec and Katarina Janković point out that integrated models of risk management enable more efficient planning of activities, more rational use of resources and improvement of safety during work with explosive remnants of war. Although their model was developed for EOR transport, the basic principles can also be applied to risk management at cultural and historical sites (Komazec & Janković, 2023). Starting from the mentioned approaches, in this work an integrated technical model was developed for risk assessment and management at the site of the Smederevo Fortress.

- The structure of the integrated model

The proposed model consists of six interconnected phases.

Phase 1 - Data collection and analysis

The first phase includes the collection of historical sources, archival documentation, data on previous interventions by the police and specialized teams, cartographic documentation and all available information that may indicate the presence of explosive remnants of war. At the Smederevo Fortress, historical data on the military name of the locality, the warehouse explosion in 1941, as well as data on subsequent discoveries of explosive devices are of particular importance.

Phase 2 - Technical detection

Based on the collected data, a technical survey is carried out using modern geophysical methods. The most important methods include:

- magnetometry;

- electromagnetic detection;

- georadar (GPR);

- GPS and GIS technologies.

Combining the mentioned methods increases the reliability of detection and reduces the possibility of misidentification of underground objects (Butler, 2003; Martinho & Dionisio, 2014).

Phase 3 - Risk assessment

After the identification of potential explosive devices, a risk assessment is carried out.

They are analyzed:

- type of explosive device;

- balance of assets;

- the depth of the find;

- activation probability;

- the frequency of the presence of people i

- cultural and historical value of the locality;

- possible consequences for people, infrastructure and cultural property.

As Vladimir M. Cvetković and colleagues point out, quality risk assessment is the basis for adopting adequate protection measures in the emergency management system (Cvetković et al., 2022).

Stage 4 - Making a decision

Based on the risk assessment, the procedure is determined. They may include more:

- continuous monitoring;

- additional geophysical research;

- restriction of access to the locality;

- engagement of specialized EOD teams;

- removal or destruction of an explosive device.

This approach enables decision-making based on risk assessment, and not exclusively on the assessment of an individual event (Komazec & Janković, 2023).

Phase 5 - Operational implementation

The operational phase implies the implementation of all planned activities by the competent services. Includes:

- location security;

- evacuation of the population if necessary;

- identification of funds;

- neutralization or transport;

- documenting the intervention.

All activities must be conducted in accordance with applicable safety procedures and standards.

Phase 6 – Evaluation and improvement of the system

The last phase of the model includes the analysis of the implemented intervention, updating the database and creating new risk maps. Based on experiences from previous interventions, procedures are improved, priority zones for future research are determined and preventive activities are planned. Such an approach enables the risk management system to be dynamic and to continuously adapt to new knowledge. The proposed model was applied to the case study of Smederevo Fortress. The starting point was historical data, documentation about the location and records of ten interventions by competent services due to the discovery of explosive remnants of war.

Based on the analysis of data collected from 1994 until today, it is possible to identify the zone of increased risk, determine priorities for technical research and propose preventive measures that contribute to the safety of visitors and the preservation of cultural property.

The advantage of the proposed model is reflected in the fact that it combines historical data, technical detection, risk assessment and operational decision-making in a single system that can be applied to other locations with similar characteristics.

5. CASE STUDY – SMEDEREVO FORTRESS

The construction of the Smedrevo fortress from 1428 to 1439 represented a unique construction undertaking, not only in terms of construction and organization, but also in cultural, historical and symbolic terms. Despot Đurađ Branković simultaneously built a strong military stronghold as the greatest achievement of medieval Serbian military architecture, but also a new capital city as a dynamic center of medieval Serbia. The undertaking stands out for its scale, short construction time and applied military-strategic concept

It was built in a period of dramatic historical events at the contact area between Europe and Asia during the decline

of the Byzantine Empire and the birth of the new Ottoman Empire on its ruins. The Smederevo fortress, created at the intersection of space, epochs and historical breaks, experienced its fall in 1459, ending the historical course of the medieval Serbian state, and beginning the epic life of Smederevo in the traditions, as a unifying symbol of the heroism and tragedy of the Serbian people. The life of the city of Smederevo continued in the following centuries within the framework of the Ottoman and Austrian states, and in 1805, during the restoration of Serbian statehood, as the first freed city and seat of the Governing Soviet, it became the thread that connects medieval and modern Serbia in a broad historical arc.

The 20th century brought catastrophic destruction to the Smederevo fortress in the world wars. First in the fall of 1915, during the second attack on Serbia, and then in the large explosion of stored military assets on June 5, 1941 (Lazić, 2021) and during the Allied bombings in 1944. These destructions left permanent consequences for the cultural property itself, but also for the entire city, which, in addition to great material suffering, suffered great human sacrifices. After the Second World War, extensive research and restoration of the Smedrevo fortress followed, and at the same time, its new evaluation as an important part of the national monumental heritage when it was designated as a cultural monument of exceptional importance. The process of proving its universal values as a basis for becoming part of the UNESCO world heritage is underway. The historical development of the Smederevo Fortress and its wartime sufferings represent an important context for understanding contemporary security risks at this location. During various infrastructural works, archaeological research and conservation interventions, a large number of unexploded ordnance was found. These facts confirm the importance of a systematic approach to risk detection and management in the area of cultural property.

The historical development of the Smederevo Fortress and the events of the Second World War represent an important context for understanding the contemporary security risks at this site. The explosion of the ammunition warehouse on June 5, 1941 caused large-scale destruction and left permanent consequences, which is why even today, during various works and interventions, unexploded ordnance is found. These facts confirm the importance of a systematic approach to risk detection and management in the area of cultural property (Lazić, 2021).

Source: Lazić, M. P. (2021). The explosion in Smederevo on June 5, 1941/80 years later. Museum in Smederevo.

The Smederevo fortress was a military facility until 1947, when the army handed it over to the city administration, and since then research, restoration, and its arrangement and infrastructural equipment have continued successively. After the Second World War, large damages as a result of war destruction were largely repaired, the craters caused by the big explosion directly near the main entrance and many smaller craters from the bombing were buried. During these works, the systematic removal of unexploded ordnance was carried out, as well as those encountered during the works, but for the period up to 1994, there is no reliable record of them.

The Regional Institute for the Protection of Cultural Monuments Smederevo keeps records from 1994 to 2026 for all unexploded hand grenades, mortar mines and artillery shells of various calibers, which were found in the area of the Smederevo Fortress and its immediate surroundings. A large amount of lighters, shrapnel, mining cables, slow-burning sticks, paraffin, rifle ammunition and other non-lethal war equipment, which was not precisely recorded, was also found. The largest amount of these findings was discovered in the period from 2019 to 2024, when extensive archaeological excavations were carried out in the Varoška Gate 1 zone (in table VK1), which was located directly in the direction of the main shock wave of the explosion on June 5, 1941. That is, on the rim of the crater that was created on that occasion, and which was filled with water for a long time after the Second World War, only to be buried in the early fifties.

12 hand grenades, 5 mortar shells and 13 artillery shells were found in the area of Varoška Gate 1, while 3 more hand grenades and 5 artillery shells were found in other locations. The largest grenade was found in 1998 (caliber 305mm) during infrastructure works in the wider area of Varoška kapija 1. All unexploded ordnance discovered were taken over by members of the emergency department, and since 2019, archaeological research has been carried out under pyrotechnic supervision.

During the analyzed period in the area of the Smederevo Fortress, starting from 1994 until today, 38 interventions by the competent services were recorded due to the discovery of explosive remnants of war, as shown in Table 1. The collected data indicate that the finds occur in

different parts of the complex, which confirms the need for continuous monitoring of the site and the application of preventive measures.

Source: Overview of registered EORs in the period from 1994 to 2026 from the documentation of the Regional Institute for the Protection of Cultural Monuments Smederevo, 2026.

Based on the data, the frequency of finding explosive remnants of war in the area of the Smederevo Fortress can be observed. By analyzing the place of discovery, the type of means and the circumstances of their discovery, it is possible to identify the zone of increased risk and set priorities for future technical research.

Based on the analyzed interventions, it can be concluded that the Smederevo Fortress is a site where there is still a risk of finding explosive remnants of war. The frequency of interventions confirms the justification of the application of an integrated technical model of risk detection and management, especially when performing construction, archaeological and conservation works.

7. DISCUSSION

The results of the research indicate that the Smederevo Fortress is a cultural and historical site where there is a continuous security risk from the discovery of explosive remnants of war. The analysis of 38 recorded interventions confirms that the presence of explosive remnants of war is not only a historical problem, but a

current security challenge that requires a systemic approach. The proposed integrated technical model enables the unification of historical data, results of technical detection, risk assessment and operational decision-making into a single management system. Such an approach is in line with modern tendencies in the development of risk management systems, which emphasize the need for an interdisciplinary approach and evidence-based decision-making (Novik et al., 2023). The application of modern geophysical methods, such as magnetometry, electromagnetic detection and georadar, enables non-invasive exploration of space, which is of particular importance for cultural heritage sites (Martinho & Dionísio, 2014). At the same time, the analysis of the case study shows that technical detection must be complemented by quality risk assessment, organizational measures and coordination of all competent institutions.

A special contribution of this work is reflected in the development of an integrated model that can serve as a basis for improving the risk management system not only in the area of the Smederevo Fortress, but also in other cultural and historical sites in the Republic of Serbia and the region where there is a possibility of the presence of explosive remnants of war.

8. CONCLUSION

Explosive remnants of war pose a long-term security problem that can threaten human lives, cultural property and infrastructure even decades after armed conflicts have ended. Localities that had a military function during history or were exposed to war activities are of particular importance, among which the Smederevo Fortress stands out. Based on the analysis of scientific literature and a case study, it was determined that existing approaches to risk management can be improved through the application of an integrated technical model that combines data collection, technical detection, risk assessment, decision-making, operational procedures and continuous evaluation. The analysis of recorded interventions in the area of the Smederevo Fortress confirms that the risk of finding explosive remnants of war still exists, which is why it is necessary to carry out preventive activities continuously, especially when carrying out archaeological research, conservation works and infrastructural interventions.

The proposed model can contribute to the improvement of people's safety, preservation of cultural heritage and more efficient planning and management of the activities of competent services. It is also important as part of the nomination process for entering the Smederevo Fortress on the UNESCO World Heritage List. In the complex and demanding process of nomination of the Smederevo Fortress for the UNESCO World Heritage List, which takes place in an extremely competitive environment, returning to the models and values from the beginning of the journey could decisively contribute to its successful completion. This would open a completely new chapter of preservation of established value systems, necessary for our future uniqueness and duration (Radovanović, 2023). Its application is not limited exclusively to the Smederevo Fortress, but can represent the basis for risk management in other cultural and historical sites with similar characteristics.

Future research should be directed towards the development of GIS databases, the application of drones, artificial intelligence and advanced geophysical methods to improve the process of detection and risk assessment of explosive remnants of war.

Abstract: *The case study presents a comparison of the calculated muzzle velocity using the well-known internal ballistics Drozdov analytical mathematical model results and the experimental muzzle velocities obtained using a Doppler radar for the 30 x 165 mm AP-T projectile. The experiment was conducted during a field testing using three 30 mm barrels at the center for testing military equipment and weapons NIKINCI with the objective to determine their barrel wear. Therefore, the comparison of the measured and calculated muzzle velocities of the projectiles are the crucial parameters of relevance whether the barrels are in usable condition or not, which is analyzed and presented.*

Keywords: *Internal ballistics, Drozdov method, Doppler radar, muzzle velocity, 30mm barrel.*

1. INTRODUCTION

The case study examined the comparation of experimentally obtained muzzle velocities of three 30 mm barrels with characteristic shown in Table 1, with mathematically calculated muzzle velocities obtained using the internal ballistics Drozdov analytical mathematical model and tactical technical characteristics of the manufacturer for Ammunition Fig. 1, Table 2 and gunpowder in Table 3.

Table 1. Technical characteristics of the 30 mm barrel

Barrel Characteristic	Value
Caliber, d [mm]	30
Barrel length, l [mm]	2400

Table 2. 30 x 165 mm, AP-T Medium caliber ammunition technical characteristics [2]

Ammunition Characteristic	Value
Caliber, d [mm]	30
Muzzle velocity, v_0 [m/s]	970 ± 15
Max pressure of powder gasses, p_{max} [MPa]	360
Round mass, m_r [g]	853
Projectile mass, m [g]	400 ± 6
Tracer burning time, t [s]	Min. 3.5
Operating temperature [°C]	-40 to +50

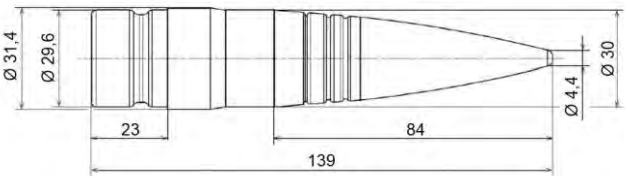

Figure 1. Projectile 30 x 165 mm [3]

The powder charge that was used for the 30 x 165 mm ammunition was the NC-48-7 perforated powder that is regulated by the standard SORS 8665 [10], the characteristics of the powder that are defined by the manufacturer [4].

Table 3. Technical data of the NC-48-7 powder charge [4]

Powder charge	Weight	Velocity	Pressure
NC-48-7	124 [g]	970 [m/s]	≤ 355 [MP_a]

2. MATHEMATICAL MODEL

To determine the projectiles muzzle velocity that is expected in the experiment, the muzzle velocity must firstly be calculated mathematically using classic theory of interior ballistics. For this case study the analytical model by Drozdov [1] was applied which is one of the classic theories of internal ballistics. Internal ballistics has the primary task of determining the relationship between the gunpowder pressure P [MPa] and the position of the projectile in the barrel. Also establishing the relation between the gunpowder pressure in the function of time respectively. Therefore, the Drozdov analytical model determines the internal ballistic parameters in the function of an independent variable such as time and displacement.

Corresponding author: V. Garčević;
E-mail: vuk.garcevic@mod.gov.rs

DOI: 10.5937/OTEH26019G

For this case study the parameter of analysis were the muzzle velocities. Therefore, it is the significant value that derives from the Drozdov analytical model. The ballistic property calculated using the Drozdov analytical model - maximum pressure in the barrel, is beneficial because it will also be compared with the projectiles manufacturing declaration [2].

The following are the fundamental equations that are used to solve the system of internal ballistics, determined by the Drozdov analytical method. [5].
Equation of energy balance:

$$pS_C\left(X_\psi + X\right) = f_b m_b \psi - \frac{k-1}{2}\varphi m \nu^2 \quad (1)$$

Equation of motion:

$$\varphi m \frac{d\nu}{dt} = pS_C \quad (2)$$

Projectile velocity:

$$\nu = \frac{dX}{dt} \quad (3)$$

Burning rate equation:

$$u_z = u_{z0} p \quad (4a)$$

with

$$\frac{dy}{dt} = \frac{u_{z0}}{r_0} p \quad (4b)$$

The burned propellant mass rate:

$$\psi = ky\left(1 + \lambda y + \mu y^2\right) \quad (5)$$

Grain surface burning rate:

$$\sigma = 1 + 2\lambda y + 3\mu y^2 \quad (6)$$

The approximate free volume length of the combustion chamber:

$$X_\psi = W_0 - \frac{m_b}{\rho_b}\left(1 - \psi\right) - \alpha m_b \psi \quad (7)$$

The essential values for determining the system of equations are grouped as:

- Barrel characteristics: S_C, W_0 and X_u,
- Projectile characteristics: m, p_0 and φ,
- Propellant characteristics: m_b, f_b, α, u_{z0}, ρ_b, k, $2r_0$, λ and μ.

The following assumptions are adopted based according to the Drozdov analytical method:

- The propellant grains burn according to the geometry hypothesis,
- The combustion takes place at medium pressure (Although in reality it changes from the bottom of the barrel to the bottom of the projectile),
- The combustion rate of the grain varies linearly with the pressure,
- Composition of the combustion products during the firing process does not change, so that the specific work and co-volume are constant, and
- During the firing process, the resistance of the air, the deformations of the exterior bullet surface and the interior walls of the barrel are neglected.

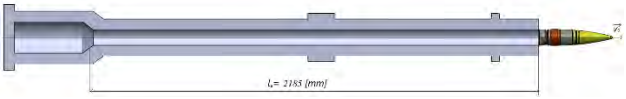

Figure 2. Graphic representation of the 30 mm grooved barrel length.

The results obtained using the Drozdov analytical model are presented in table 4 and are also presented in figures 3 and 4 respectively.

Table 4. Specific output values obtained using the Drozdov analytical method

Time [*ms*]	Projectile position [*m*]	Pressure [MP_a]	Velocity [*m/s*]
0.0	0.000	30.0	0
0.5	0.009	95.3	45.3
1.0	0.062	238.4	181.3
1.5	0.2094	346.9	430.5
1.73	0.3185	359.2	566.5
2.0	0.5052	227.0	694.3
2.5	0.8785	124.7	819.3
3.0	1.2891	80.5	892.0
3.5	1.7744	55.4	945.5
3.946	2.185	43.2	977.2

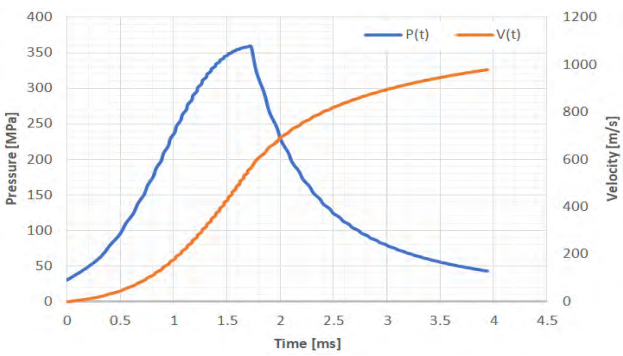

Figure 3. Pressure – Velocity – of the projectile as a function of time.

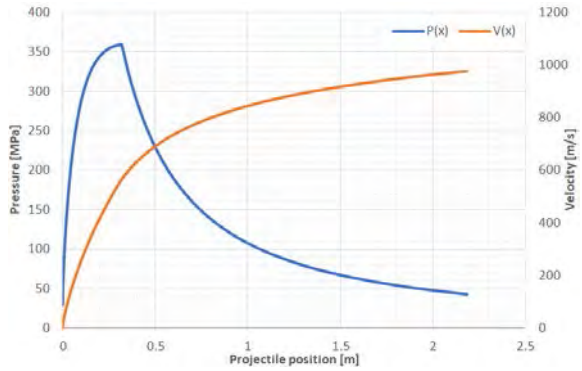

Figure 4. Pressure – Velocity – of the projectile as a function of the position of the projectile in the barrel.

The results obtained using the Drozdov analytical model show that the maximum pressure and muzzle velocity that can be expected are 359.2 MP_a and 977.2 m/s, respectively. The time that is needed for the projectile to leave the barrel is 3.946 ms.

3. FIELD TESTING

The field testing was conducted at the center for testing military equipment and weapons NIKINCI. Three 30 mm barrels were tested by measuring their muzzle velocities. The ammunition used to conduct the experiment was the 30 x 165 mm AP-T M90. The characteristics of the ammunition and the barrel are as shown in tables 1 and 2. Before the testing started, each barrel fired two rounds for conditioning.

The barrels were aligned at a horizontal elevation (0 deg). The first barrel fired eight rounds, second barrel fired thirteen rounds and the third barrel fired nine rounds. Each rounds muzzle velocity was measured using a Doppler radar that was placed adjacent to the muzzle of the barrel. This radar type works on the basis of the well-known Doppler effect [3], [4].

The testing was conducted in such a manner that the main objective was to measure the interior ballistic properties of the barrel without damaging the barrel itself. Since the only way to measure the pressure inside the barrel would be to use a piezoelectric pressure sensor or crusher-gauge [5],[6], by having to drill a hole in the side of the barrel and the cartridge of the ammunition round itself and therefore preventing further exploitation of the barrel. The resolution for this issue was to obtain the muzzle velocity of the projectile.
The obtained experimental results of the fired rounds for each barrel are shown in tables 5, 6 and 7 and graphically in figure 5, 6 and 7.

4. RESULT COMPARISON

Firstly, a comparison between the manufacturer specified muzzle velocity defined in table no.2 and the muzzle velocity calculated in chapter 2 defined in table no.4 reveals a high degree of correlation, with negligible deviation from the nominal velocity.

Second, to compare the muzzle velocity with the values obtained through the mathematical model, the average experimental muzzle velocity for each barrel was utilized.

It is observed that for each barrel, the muzzle velocity falls below the lower limit defined by the manufacturer, as well as below the velocity calculated by the mathematical model. The differences between the analytical and experimentally obtained values range from 2.34% to 2.85%.

Given that these values are below the manufacturer's lower threshold, it is concluded that the three examined barrels do not meet the required criteria. Specifically, these barrels have entered the wear zone from an internal ballistics perspective.

Table 8. Difference of the analytical and experimental results for barrels no.1, no.2 and no.3

Average experimental results	Barrel no.1	Barrel no.2	Barrel no.3
Muzzle velocity [*m/s*]	952.6	954.9	950.1
Range max-min [*m/s*]	12.7	20.2	13.1
Difference of the analytical and experimental results. [%]	2.58	2.34	2.85

5. CONCLUSION

The comparison of the applied mathematical model obtained by the well-known method Drozdov for calculating internal ballistics parameters and experimentally gained muzzle velocities for three 30 mm barrels were performed in this case study. The field test was conducted using the 30 x 165 mm AP-T M90 ammunition. The objective of the experiment was to measure the interior ballistic properties of the barrel without damaging the barrel itself. Therefore, only the muzzle velocities were obtained using a Doppler radar.
Hence the obtained average experimental muzzle velocities for each barrel were compared to the analytical muzzle velocity.

The comparison concluded that each barrel muzzle velocity was below the analytically obtained muzzle velocity and the manufacturer's lower characteristic threshold.

The percentage difference for which the velocities are below the threshold that are defined by the analytical model are between 2.34% to 2.85%.

This concludes that from the internal ballistic aspect the barrels have entered the barrel wear zone. This conclusion could be better analyzed in future experiments using a piezoelectric pressure sensor or crusher-gauge. This would give an improved representation of the worthiness of the barrels from an internal ballistics aspect.

It would be useful to use a different type of known ammunition in further experiments to eliminate the possible suspicion of the used ammunition.

The results obtained in this case study encourage further experimental investigations in terms of internal ballistic parameters and barrel wear.

Abstract: *The paper presents a comparative analysis of the ballistic performance of subsonic weapons of small caliber, which are suitable for use in urban conditions. The use of small-caliber subsonic weapons with shot suppressors is very effective for close range of 50 to 150 meters. The weapon suppressors enable operations that take place with reduced gunfire noise level and reduce the detection of the position of the shooters. Proper selection of ammunition systems is important for the effectiveness of subsonic weapons at close range. Automatic pistols, submachine guns and special subsonic rifles are used for such operations. The paper presents an analysis of significant ballistic parameters during the use of small-caliber firearms with silencers. The analysis includes a comparison of gunfire noise level, muzzle velocity and statistical indicators of precision and accuracy. The paper shows the experimental measurement of the gunfire noise level and the muzzle velocity. In addition to the reduction of gunfire noise level, the energy of the projectile that interacts with the target is also important. Based on the characteristics of the projectile, an estimate of the energy of the projectile during interaction with the target at different distances is presented.*

Keywords: *Muzzle Velocity, Sound Pressure Level, Energy of Projectile, Energy Density.*

1. INTRODUCTION

Special subsonic small caliber weapons for use in urban conditions are silenced personal weapons of small dimensions and mass intended primarily for tactical units. Standard rifle ammunition creates a localized gunshot noise during firing because of breaking the sound wall with the supersonic flight of the projectile on the trajectory, which easily detects the position of the shooter. By using subsonic projectiles with a weapon silencer, the sound of the gunshot is eliminated, which optimizes stealth and tactical advantage for operations at short distances in urban conditions. Among other things, weapons that use subsonic ammunition have lower recoil forces, which allows for more accurate hits, even in multiple bursts of fire. Weapon silencers (mounted or integrated) on this type of small arms, in addition to reducing sound, eliminate flash during firing, which increases the camouflage characteristics of tactical units. Among other things, short-barreled rifles (SBR) with folding stocks allow users to move freely in urban and difficult-to-access conditions, as well as facilitate the transportation of units during operations. Typical special subsonic ammunition is .300 Blackout (Figure 1a for SIG MCX Rattler Figure 2a), 9x19 mm (Figure 1b for Daewoo K7 Figure 2b), 9x39mm (Figure 1c for AS Val Figure 2c) and others similar. The mass of the projectile of the listed ammunition is generally in the range of 8 to 16 grams.

a) b) c)

Figure 1. Special subsonic ammunition: a) .300 Blackout, b) 9x19 mm, c) 9x39mm SP5

Generally, this type of special subsonic small caliber weapon is intended for effective action at distances of up to 200 meters, or rather, it provides the best results at distances of 50 to 100 meters.

The paper analyzes the performance efficiency of four representatives of weapons and ammunitions. The analysis considers the mass of the projectile, the muzzle velocity and the kinetic energy of the projectile in interaction with the obstacle at distances of 50 and 100 meters. The intensity of the gunshot sound is also analyzed as an important characteristic.

2. EXPERIMENTAL PERFORMANCE TESTING

Experimental tests were carried out on the automatic pistol M84 in 7.65x17 mm caliber, the HK MP5SD in 9x19 mm caliber, the VSS Vintorez in 9x39 mm caliber, and on the modified modular platform AM 20 in caliber 7.62/6.5x39 mm, for which a 9x39 mm caliber barrel was manufactured. During the experimental tests, the muzzle velocity of the projectile and the sound pressure level on the corresponding sample were recorded.

The sound level test of a firearm shot is complex due to the very short duration of the peak of the sound pressure level (SPL) function. The Bruel & Kjaer model 2250 shown in Figure 3 was used to register the SPL according to the MIL-STD-1474D testing standard. The device is equipped with software for sound level measurement, frequency analysis, and appropriate filters for measured signals (FFT analysis and vibration and frequency analysis). The sound level meter sensor is a 1/2" condenser microphone 4189, with a sensitivity of 50mV/Pa (corresponding to: 26dB equivalent to 1V/Pa) ± 1.5dB, a capacitance of 14pF (at 250Hz), which is connected to a ZC-0032 preamplifier with a nominal attenuation of 0.25dB [22].

Figure 3. Bruel & Kjaer model 2250 [22]

The MIL-STD-1474D specifies the position of the sound level meter, which is placed at a 90-degree angle, 100 centimeters to the left of the silencer tube outlet. Both the silencer and the sound level meter should be 160 centimeters above the short-cut grass. The SPL of the gunshot is recorded at this position, as shown in Figure 4. [20].

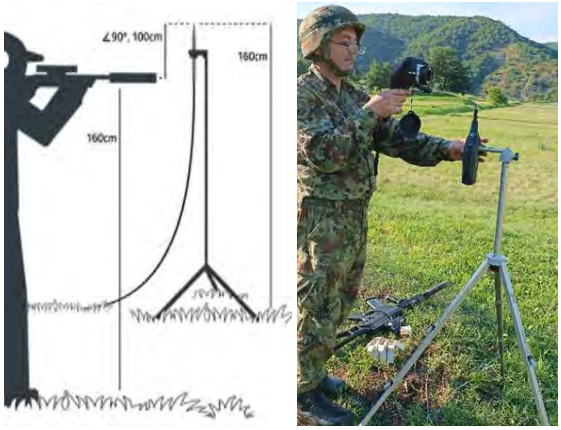

Figure 4. The noise meter position for measuring SPL [22]

To measure the muzzle velocity of the projectile, the GARMIN Xero C1 Pro Doppler ballistic chronograph shown in Figure 5, with the characteristics in Table 1, was used.

Figure 5. Chronograph GARMIN Xero C1 Pro

Table 1. Characteristics of Chronograph GARMIN Xero C1 Pro

Period	Production per period (pcs)
Measuring range	30 to 1600 m/s
Dimension	77 mm x 60.5 mm x 34.44 mm
Weight	105.6 g
Water rating	IPX7
Display type	Sunlight-visible, monochrome
Display size	133 mm x 44 mm, diagonal 55 mm
Battery type	Internal rechargeable lithium-ion battery; non replaceable
Battery life	Up to 2,000 shots or up to 6 hours
Operating range	-10° C to 55° C (14° F to 131° F)
Memory/history	50 sessions at max 100 shots per round before a Xero Core app sync is required to save data to phone
Interface	USB-C

During noise level measurements, for a detailed analysis of efficiency, in addition to *LCpeak* (the absolute maximum sound pressure level currently achieved, with a flatter frequency response that includes more low-frequency sounds), *LAeq* (the average sound level over the period, weighted to reflect typical human hearing) was also recorded.

As the first sample, the performance of the M84 automatic pistol, caliber 7.65x17 mm, with a silencer was measured (Figure 6).

The results of the parameter measurements are shown in Table 2.

For this research, in the fourth case, the AM 20 modular assault rifle platform was used, for which a 9x39 mm caliber barrel was made (Figure 9). Given that the rear cross-section of the case is identical for the 7.62x39 mm, 6.5x39 mm and 9x39 mm calibers, no additional changes to the locking and firing mechanism are required. The idea of the research itself was to examine the possibility of improving the existing AM 20 platform with minimal changes.

The recoil spring was replaced, which is less powerful, but is long enough to safely return and lock the bolt. The powder chamber was modified, which was reduced to fully utilize the pressure of the borrowed powder gunpowder gases, and the percussion spring was replaced. These changes did not affect the functions of the other mechanisms of the rifle.

The existing gunpowder is unknown, so the energy characteristics and dimensions were examined. It was determined that the energy potential is about 3900 J/g and that the shape is a seven-channel cylinder, with a thickness of about 0.176 mm.

Based on the experimental results obtained, it can be concluded that the gunpowder is probably double base. To improve the function of the test rifle, thicker gunpowder with similar energy characteristics was used. Optimal results were achieved using the double-base plate gunpowder NGB-09.

For smooth functional operation, in addition to structural changes to the rifle, the propellant was also replaced, which resulted in higher muzzle velocities, but the maximum pressure is lower than with the original ammunition. The test results are shown in Table 5.

Figure 9. Test Rifle 9×39mm based at the AM 20 modular assault rifle platform

The weapon's silencer is designed by modifying the silencer for the M76 sniper rifle by changing the chambers. In terms of dimensions and volume, it corresponds to the silencer for the VSS Vintorez.

Silencer type 1 is standard silencer for sniper rifle M76 adapted to test rifle caliber. Silencer type 2 is new design of silencer consisting of standard casing (cylinder of M76 silencer) and inner parts that compose four chambers.

Table 5. Measured performance for the Test rifle, caliber 9x39 mm, silencer type1.

3. MODEL OF PROJECTILE FLIGHT

Based on the measured results of muzzle velocities, projectile velocities were calculated for all shot cases at distances of 50 and 100 meters. The calculation of the velocities of the projectile was realized according to the modified material point flight model. The governing equations of the model are,

$$m\frac{d\vec{V}_k}{dt} = m\vec{g} + \vec{D} + \vec{L} \tag{1}$$

and,

$$\frac{d\vec{K}}{dt} = I_x\frac{dp}{dt}\vec{x}_0 + I_x p\dot{\vec{x}}_0 + I_y(\vec{x}_0 \times \ddot{\vec{x}}_0) \tag{2}$$

where are aerodynamic forces are,

$$D = \frac{\rho V^2}{2} S C_D(Ma) \tag{3}$$

$$L = \frac{\rho V^2}{2} S C_L(\sigma, Ma) \tag{4}$$

Velocity is defined as,

$$\vec{V}_K = \vec{V}_W + \vec{V} \tag{5}$$

$$V = \sqrt{(u_k - u_w)^2 + {v_k}^2 + (w_k - w_w)^2} \tag{6}$$

where are,

u_k, v_k, w_k components of velocities and

u_w, w_w horizontal components of wind velocities,

$\vec{g}$ gravitational acceleration,

S projectile cross-section surface and,

C_D, C_L aerodynamic coefficients of drag and lift forces.

Angular momentum is defined as,

$$\vec{K} = I_x p\vec{x}_0 + I_y(\vec{x}_0 \times \dot{\vec{x}}_0) \tag{7}$$

where are

I_x, I_y are projectile's moment of inertia,

$\vec{x}_0$ is axial axis of projectile,

$\dot{\vec{x}}_0$ is axial spin of projectile and,

p spin rate of projectile.

Calculated values of the velocities are initial data to determine the terminal parameters (energy and energy density) of the different projectiles at distances of 50 and 100 meters.

4. RESULTS ANALYSIS

Based on the mass of the projectile and the cross-section, the values of kinetic energy and energy density during the interaction with the obstacle were calculated. The values of the quantities mentioned (velocity and energy) are shown in table 7.

Table 7. Performance of the projectiles during interaction

	Velocity [m/s]		Projectile energy [J]		Energy density [J/mm^2]	
	distance [m]					
	50	100	50	100	50	100
AP M84	290	276	193	175	4,03	3,65
HK MP5 SD	281	270	316	292	4,77	4,40
VSS Vinto-rez	273	265	578	544	8,70	8,19
Test rifle	309	299	740	673	11,14	10,43

Projectile energy and projectile's energy density during interaction with an obstacle at 50m and 100m are determined, in relation to velocities, mass and caliber. These parameters are key performances of the presented small arms weapon system.

Figure 10 shows the comparative values of projectile energy at 50m and 100m for the analyzed weapons.

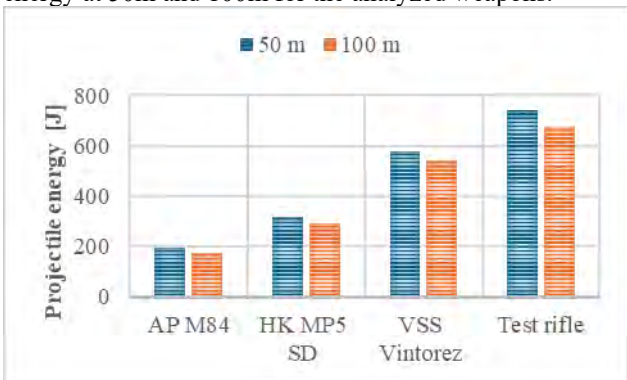

Figure 10. Comparative values of projectile energy at 50 and 100 m

Figure 11 shows the comparative values of the projectile's energy density during interaction with an obstacle at 50m and 100m.

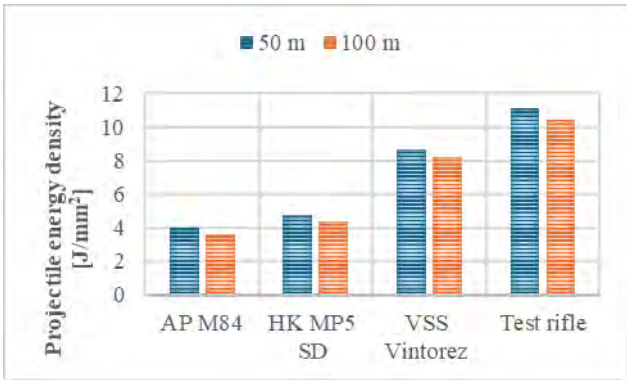

Figure 11. Comparative values of projectile energy density at 50 and 100 m.

Figure 12 shows the comparative values of sound pressure levels for different weapon systems.

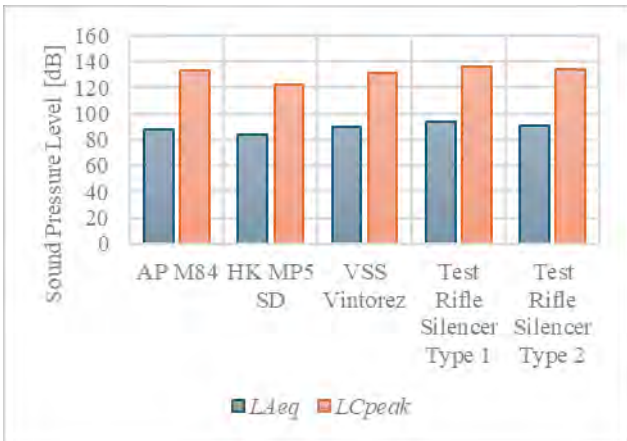

Figure 12. Comparative values of SPL.

The analysis is performed due to verification of the performances of the small arms weapon systems for tactical application in urban conditions and it's evaluating the quality of performance.

The most common representative of this weapon system in most of the world's armed forces is the SMG 9 mm HK MP5 SD, which was selected as a reference system for comparing characteristics.

The characteristics of different weapon models were compared in relation to the reference representative, namely: (a) sound pressure level (SPL) registered with two scales $LAeq$ and $LCpeak$, (b) muzzle velocity level and (c) energy of projectile interaction with an obstacle at the two stated distances.

Automatic pistol 7.65x17 mm M84 showed to have higher SPL on both scales (higher $LAeq$ by 4.82% and higher $LCpeak$ by 9.14%) with higher muzzle velocity by 5.5%. Although the muzzle velocity is higher, due to the significantly lower mass of the bullet (4.6 g vs. 8 g), the energy of the projectile at referential distances is about 40% lower.

The VSS 9x39mm Vintorez rifle was shown to have higher SPL on both scales (higher $LAeq$ by 7.44% and higher $LCpeak$ by 7.92%) with lower muzzle velocity by 4%. Although the muzzle velocity is lower, due to the significantly greater mass of the bullet (15.5 g vs. 8 g), the energy of the projectile at referential distances is about 85% higher.

The Test rifle 9x39 mm with Silencer Type 1 showed that having SPL on both scales (higher $LAeq$ by 12.3% and higher $LCpeak$ by 11.4%) with higher muzzle velocity by 5%. Due to the significantly greater mass of the bullet, the energy of the projectile at referential distances is about 132% higher.

The Test rifle 9x39 mm with Silencer Type 2 showed that it has higher SPL on both scales (higher $LAeq$ by 8.75% and higher $LCpeak$ by 9.64%) with higher muzzle velocity by 4%. Due to the significantly greater mass of the bullet, the energy of the projectile at referential distances is about 131% higher.

To evaluate the new weapon system Test rifles with two types of silencers, a comparison was made in relation to the special sniper rifle VSS of the same ammunition system. The results of the comparison in relation to the VSS rifle are given below.

The Test rifle 9x39 mm with Silencer Type 1 showed that it has higher SPL on both scales (higher $LAeq$ by 4.5% and higher $LCpeak$ by 3.3%) with higher muzzle velocity by 9.4%. The energy of the projectile at referential distances is about 26% higher.

The Test rifle 9x39 mm with Silencer Type 2 showed that it has higher SPL on both scales (higher $LAeq$ by 1.2% and higher $LCpeak$ by 1.6%) with higher muzzle velocity by 8.2%. The energy of the projectile at referential distances is about 25% higher.

To evaluate the performance of different types of silencers, the characteristics of the Test rifle with both silencers were compared. The comparison was made with the newly constructed silencer system Type 2 in relation to Type 1, which represents the existing modified silencer model.

The Test rifle with the new Type 2 silencer showed lower SPL values on both scales. Lower $LAeq$ values by 3.2% and lower $LCpeak$ values by 1.6%. The level of the muzzle velocity was lower by about 1%, as well as the energy of the projectile at referential distances by about 0.6%.

CONCLUSION

The paper presents an analysis of the performance of subsonic weapons for use in urban conditions. Comparisons were made of four types of weapons equipped with silencers. The aim of the research was to present the performance of the Test rifle with two types of silencers and to compare the performance in relation to existing systems. As a reference system, the SMG 9 mm HK MP5 SD was taken, which is the most common and is considered the standard for use in urban conditions.

Based on the presented results, it can be concluded that the weapon systems with the 9x39 mm ammunition system have significantly better performance compared to other representatives. The comparative analysis showed

significant improvements in the performance of the Test rifle in relation to the VSS Vintorez in relation to the muzzle velocity and the energy during the interaction.

If we compare the performance of the two silencer configurations for the Test rifle, it can be concluded that the concept with four chambers showed better results.

Selection of the optimal configuration demands additional tests and analysis of several possible structural solutions of the shot silencer.

Acknowledgment

The paper is a part of the research done within the project of the University of Defence in Belgrade, No. VA-TT/1/24-26.

Abstract: *Pioneer machines, such as diggers, are particularly challenging to test, especially under real operating conditions. This paper presents a practical approach to quality testing of pioneer machines, using a digger as a representative case study, based on procedures applied at the Technical Test Center.*
The study in this manuscript focuses on the implementation of testing procedures required to verify compliance with specified technical characteristics and manufacturer requirements for a digger as a representative machine for the case study. Emphasis is placed on practical testing methods used at the Technical Test Center, including measurement techniques and testing conditions that ensure reliable and repeatable results in real operating environments. The results obtained were based on precise measurements within different testing frameworks and were evaluated against relevant standards and regulatory requirements.
Following the completion of all testing procedures, an overall assessment of the level of compliance with the required characteristics was conducted. In addition, the usability and future potential of the machine were evaluated from the perspective of its design and the analyzed performance characteristics.

Key words: *pioneer machine, testing, digger, exploitation.*

1. INTRODUCTION

The highest hierarchical principle of equipping and developing the Defence system is “creating maximum combat readiness”. That principle is realized with quality means at the level of competitiveness on the world market of armament and military equipment [1]. The degree of quality of an asset intended for the Defence system is evaluated by testing at the Technical Test Center (TTC).

The Technical Test Center is a scientific research institution established by the Serbian Ministry of Defence for testing different parts of armament and other equipment that is going to be part of the official armament of the Serbian Army. The Technical Test Center is testing various parts of regular classic armaments (classical infantry and artillery, missile, aviation, naval, etc.), ballistic protection equipment, different types of electronic equipment and systems, vehicles (combat, non-combat, special), pioneer machines, aircraft, etc. Tests are performed in laboratory, testing ground, and field conditions. All the measurements and tests performed and being conducted at the TTC are defined by both international and domestic standards. Likewise, the TTC is making some new standards and new test methods based on experience and modern achievements in measurement techniques and new measurement equipment. The measured values are being analyzed and compared both with the required characteristics specified in the standard and with the declared characteristics of the manufacturer, after which a decision is made on official use in the Serbian Army [2].

The pioneer machines are machines made for hard work in the construction industry, road construction, snow cleaning, and all other work that needs a lot of energy and force to be used in it [3]. One of the pioneer machines that is commonly used in the Serbian Army units for various heavy works is the digger. It is a self-propelled combined excavator-loader, which is being used for heavy land working and loading of material, material excavation, and heavy material moving with an integrated loader bucket as a working tool [4]. The machine has a lot of different additional equipment that gives us different possibilities: to break materials, dig holes in different ground types with a diameter depending on the used drilling tool, strip different layers of land, asphalt, and concrete, and meet

Corresponding author: D. Stojadinović
E-mail: dragan.stojadinovic@vs.rs

DOI: 10.5937/OTEH26021S

various other demands as it is stated in [4] and [5].

Within the framework of pioneer machine testing at the TTC, a comprehensive evaluation is conducted with the aim of determining the level of compliance with all required technical characteristics and tactical/technical requirements defined by the customer (in this case, the Serbian Army). The testing includes an assessment of the machine`s usability under real exploitation conditions, taking into account specific operational requirements imposed by the user, as well as an evaluation of the modernity and future viability of the applied technical solutions, both at the level of individual subsystems and the system as a whole [4]. The majority of the tests are carried out with a focus on determining the exploitation and maneuvering capabilities of the machine.

The object of examination in this manuscript is a digger which is now in use in the Serbian Army, model JCB 4CX (Figure 1), with the following tools:
- loading bucket,
- digging spoon,
- soil drill,
- fork,
- hydraulic breaker.

Figure 1. Test object, digger JCB 4CX

2. PIONEER MACHINE TESTING

For this tested pioneer machine, first the Test Program is prepared in order to determine all parameters and characteristics that will be checked. The basis for the Testing Program is the declared characteristics of the manufacturer, the tactical/technical requirements of the institution that orders the testing (the Serbian Army in our case), as well as new standards and methods for testing. All tests will be performed according to the adopted Test Program.

The purpose of the test is to assess:
- Satisfaction of the tactical-technical requirements of users,
- Compliance of the declared characteristics with the tactical/technical requirements,
- Usability of the asset in real conditions,
- Modernity and perspective of the applied solutions,
- Ease of handling and maintenance.

Generally, mechanical testing of excavators consists of four stages, as shown in the block diagram in Figure 2.

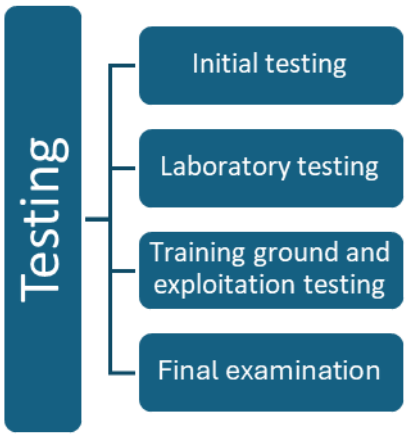

Figure 2. Test phases

2.1. Initial testing

Initial testing is carried out with the aim of determining whether there are basic prerequisites for conducting the test. First, the completeness of the construction documentation and identification data of the asset and basic subassemblies are determined, as well as a comparison of basic parameters with available documentation. The validity of attestations and certificates is checked. The general condition and proper functioning of the device are visually determined.

The intention of this part of testing the pioneer machine is as follows:
- recognition and identification of all constituting parts of the digger, machine sets and assemblies according to the technical documentation of the machine provided by the manufacturer,
- checking of the engine and engine systems, including the parts they are made of, specifically measurement of some engine and engine system parameters (air suction system, engine fuel supply system, system for engine lubrication, exhaust system, engine cooling system, checking the level of all working fluids in the engine, heating and ventilating system of a digger, etc.),
- transducer installation for some engine parameters (temperature of oil, cooling fluid etc.),
- checking the built-in parts of the digger transmission, tyres, measuring tyre pressure, all fluids and fluid levels in transmission sets, and checking the functionality of the digger transmission, etc,
- identification of the parts of the digger's braking, steering, and hydraulic systems (hoses, pumps and motors, small additional tools attachment set, etc.), fluid levels in all mentioned systems, etc.;
- Electromagnetic compatibility (EMC) characteristics (in documentation);
- basic checking of the functionality of all digger systems and simulation of work with machine tools.

Following the completion of all initial tests, it is necessary to conduct, at the end of the initial tests, a trial run of approximately 20 km on an asphalt road, in order to evaluate the performance and functional behavior of all components, assemblies, and the machine under

operational conditions [4].

2.2. Laboratory testing

Laboratory testing is customized for each individual machine and performed with respect to the specific characteristics of the test object. It generally consists of several stages and associated measurements, including:

- Geometric parameters of the machine [6],
- Digger mass characteristics – total mass of the machine, machine weight distribution by wheels and axles, machine center of gravity [7],
- Backward movement,
- Ergonomic noise characteristics – internal noise level in the cabin, external machine noise level, siren noise level [8],
- Ergonomic temperature characteristics in extreme environmental conditions – at temperature levels from -30ºC to +50ºC, checking the engine start at low (-12ºC) and high (+46ºC) ambient temperatures [9], [10],
- Determining Predicted Mean Vote (PMV – seven-point thermal scale that shows to what extent the comfort temperature is achieved in the real environment, namely: -3 (icy), -2 (cold), -1 (moderately cold), 0 (comfortable), 1 (moderately warm), 2 (warm), 3 (hot)) and Predicted Percentage of Dissatisfied (PPD - predicts the percentage of people dissatisfied with the thermal environment, that is, the percentage of people who will feel thermal discomfort in a certain real environment) index at low external temperature (-16ºC) and normal external temperature [11], [12],
- Characteristics of all electrical wiring systems and electrical equipment, voltage levels, current intensity, short circuit protection, insulation, alternator voltage level [13], [14],
- EMC characteristics [15],
- Corrosion protection [16],
- Safety features,
- Features related to environmental protection.

2.3. Training ground and exploitation testing

Training ground and exploitation tests include the examination of functional and other characteristics in real conditions of exploitation, which derive from the name of the means being tested, as well as the set requirements. The main goal of this test phase is to get as close as possible to the realistic working conditions of the machine. Polygon and exploitation tests involve some of the most intensive testing conditions we can put on a single machine. These tests include:

- Dynamic characteristics testing [17], [18], [19],
- Intensive driving testing of the machine in a few specific road conditions [20],
- Reliability, efficiency and durability of work tools,
- Accuracy, precision and life expectancy, etc.,
- Safety and resilience.

Testing the mechanical durability by driving on different types of roads is a mandatory part of this test phase, and when it comes to machines, it is also mandatory to test the work with all the tools that are mounted on it, also in different conditions.

The most important dynamic characteristics of the machine are:

- Stability and passability (overcoming longitudinal and lateral slope, clearance) [21],
- Handling performance (turning radius, steering sensitivity),
- Braking performance (stopping distance),
- Startability (acceleration and maximum speed).

Within the mentioned object of testing, dynamic characteristics according to [17] are being determined:

- Evaluation of the machine's capability to overcome longitudinal and lateral inclinations (gradients), including stability and mobility performance under such conditions,
- Wheel radius (static, dynamic);
- Evaluation of the machine's handling characteristics, including minimum turning radius and steering response sensitivity under defined operating conditions [22],
- Testing the braking system, braking distance measurement in driving testing [23],
- Highest and lowest velocity in manual and automatic mode in all gears,
- Acceleration in manual and automatic mode in all gears and acceleration from minimum to maximum velocity,
- Vehicle resistance using the coast method, etc.

Intensive driving testing of the machine in a few specific road conditions is a very important part. This is specific for a vehicle and/or machine by itself. For this object of testing - a digger, it includes driving of the machine for around 500 km, under a few different road conditions: about 250 km on plain and hill ground road and about 250 km under heavy off-road conditions.

While driving, some basic indicators are being monitored, where the most important are:

- Test road conditions, ground and meteorological conditions while driving for every day of testing,
- Total distance driven in kilometers per day and in total,
- Driving time, per day/total, time of standing (non-work time),
- Failures, fractures, and possible crushed parts of the machine construction that occur while testing is being done, with the number of kilometers at which the failure occurs being recorded,
- Regular maintenance, adjustment, and servicing while testing, with the number of kilometers being recorded,
- Durability of parts and sets in transport.

Reliability and efficiency of digger working tools are a special phase of testing. In this phase, work with the digging spoon is performed for a total of 25 engine working hours, while excavating, laying-off, and loading land, and working with the loading spoon is performed for a total of 25 engine working hours [4].

The objective of this testing is to verify and evaluate the following parameters:
- maximum excavation depth,
- ground reach of the excavator arm,
- kinematic and functional characteristics of the bucket, including digging speed, bucket width, and load-carrying capacity, as well as the operating speed of the loading shovel,
- functionality of the hydraulic control system, maximum working pressure within the hydraulic installation, condition of hydraulic hoses, and integrity of the system with respect to leakage and overall operational reliability.

Parallel with testing, the quality of oils is being checked, together with digger fuel consumption (in all different road and working conditions) and engine characteristics when working under maximum load, high external temperature levels, etc.

If auxiliary attachments are integrated into the machine (e.g., hydraulic hammer, concrete saw, drilling, etc.), additional testing procedures are required, including:
- verification of functional performance over a continuous operating period of 5 hours during the processing and fragmentation of various materials,
- assessment of drilling capability for boreholes with diameters up to 950 mm,
- evaluation of performance in the removal of asphalt and concrete layers with widths up to 400 mm and depths up to 120 mm,
- testing of cutting efficiency and the capability for demolition of concrete structures,
- evaluation of performance in auxiliary operations such as snow removal, etc.

2.4. Final examination

Final tests are carried out with the aim of determining whether there are any major failures or major deviations from the initial machine characteristics. Usually, all the parts of initial testing are performed again, but this time with the goal of determining major differences between the start and the end of the machine testing and deviations from the machine construction documentation.

3. ANALISE OF TEST RESULTS

3.1. Results of initial testing

At initial testing of a digger the conclusions were:
- All parts and sets are made according to the documentation of the machine provided by the machine manufacturer;
- All parts and sets are working correctly,
- All the fluids in assemblies are at proper levels that are set by the manufacturer. Also, the working fluids in the machine are filled according to technical documentation and maintenance manual, provided by manufacturer of the machine,
- Digger start-up is smooth and continuous, without abrupt or irregular dynamic responses,
- Transmission is working properly in manual and automatic mode and when moving forward and in reverse, in every gear, etc;
- The braking system is working, as well as the steering system,
- All digger sets are working without irregular responses,
- Additional tools are working properly,
- Digger is equipped with appropriate safety systems, including rollover and falling object protection, an adjustable steering mechanism, adequate ventilation, a safety belt, an audible warning device, and other relevant operator safety features, etc.

3.2. Conclusions of laboratory testing

The measured dimensions (including transport height, width, length, bucket width, etc.) comply with the required specifications, with negligible deviations of less than 5%, which are considered acceptable within the measurement tolerance limits, as stated in [4].

According to [4], the angles of the rear wheel turning are from 15° to 18°, which is acceptable. Also, the total mass and axle mass distribution are according to the documentation provided by the manufacturer.

The results of the digger cabin noise level measurements are given in Table 1.

Table 1. Digger cabin noise level

Noise level	Digger cabin	Directive 2003/10 [24]
Close windows	79,5 dB	Above 72 dB
Open windows	84 dB	Below 86 dB

The low and high temperature testing is performed according to [9] and [10], with all the required test preparations and conditions. The engine has successfully started both at high external temperature (+46ºC) and low external temperature (-12ºC) in the cooling and heating test chambers.

Together with high and low external temperature digger testing in cooling and heating chambers, the efficacy of the cabin heating system has been tested [11], [12], as shown in Table 2.

Table 2. Digger cabin heating system efficiency

Digger cabin	PMV	PPD
Measured	-0,5	10%
Criteria	$-0{,}5 \leq PMV \geq +0{,}5$	$\leq 10\%$

The electrical installation of the machine was characterized as follows:
- the conductors are adequately protected against mechanical influence,
- the alternator provides stable and reliable power supply, ensuring proper battery charging and maintenance,

- the minimum measured insulation resistance was 400 MΩ. Narrow-band interference at high frequencies slightly exceeded 400 MHz, with a maximum permissible deviation of 5 dB,
- prior to operation, the measured voltage drop ranged from ΔU = 0.30 V to ΔU = 1.25 V. After a 500 km test drive and 50 engine operating hours under working conditions (earth excavation), the voltage drop increased to a range of ΔU = 0.70 V to ΔU = 2.25 V, indicating a significant increase compared to the initial measurements. The system maintained a constant voltage of 14.4 V across an engine speed range from 500 rpm to 3000 rpm, with regulation provided by the alternator voltage controller.

3.3. Conclusions of training ground and exploitation testing

Dynamic characteristics of the machine were:

- Equal digger velocity at all gears, both in forward or reverse, except 4th gear, 38.9 km/h in reverse/ 40 km/h in forward motion (digger meets the demand for a maximum velocity of 40 km/h/or in the range of 40 km/h to 50 km/h),
- Satisfactory tire rolling radius according to the technical documentation provided by the manufacturer;
- The braking performance of the machine was assessed as satisfactory. Type "0" brakes with engage/disengage clutch demonstrated adequate efficiency, as the measured maximum stopping distance was below the permissible limit. The performance of Type "I" service brakes was also evaluated as satisfactory. The parking (hand) brake was capable of holding the machine stationary on the maximum tested gradient of 30%.

Testing of the machine in intensive driving conditions was performed similarly to [4] on plain-ground roads and under heavy off-road conditions. The average velocity of 14 km/h on plain roads and an average velocity of 15,5 km/h under heavy off-road conditions was rated as positive for this type of machine.

Functional performance and operational safety under working conditions were evaluated during excavation operations using both the backhoe bucket and the loader bucket over 50.6 engine operating hours, also similarly to [4]. The backhoe bucket was utilized for earthworks in soil of category II, while the loader bucket was also operated under category II soil conditions. During the test, the temperature of the engine fluids was monitored. The results obtained were within acceptable limits and were assessed as satisfactory.

Some characteristics of the digger, measured within exploitation tests, are given in Table 3:

Table 3. Some digger characteristics

Digger	Measured	Demand
Max. digging depth with spoon	5970 mm, fulfill	More than 5800 mm
Digging spoon velocity	0,24 m^3	-
Lifting Force of digging spoon, extracted telescope	1200 kg	
Lifting Force of digging spoon, sucked telescope	1550 kg	
Loading spoon velocity	1,22 m^3	
Lifting Force of forks integrated with spoon	1000 kg	
Total rate of flow	152 l/min	
Max. working presure	226 bar	

4. CONCLUSION

The combination of a backhoe and loader on the same engineering machine is the most optimal solution for the needs of the army. This model has a multi-purpose loading hydraulic opening bucket, according to the 6-in-1 system, with bucket blade protection and an additional fork. The machine has a power shift transmission and a high level of comfort. The construction of the digger ensures quick assembly of all additional tools (hydraulic hammer, spiral drill, fork, hydraulic breaker, concrete grinder, etc.), which is of particular importance for the purpose of the army pioneer units.

However, in terms of construction and workmanship, minor defects were observed. The measured turning angle of the wheels is less than required. The noise in the cabin is higher than allowed and a voltage drop was also found in some parts of the electrical installation, which directly affects the driving and working conditions in operational conditions.

Based on the comparison of the obtained results with other solutions of this type of pioneer machines, as well as based on the previous experience of researchers at the Technical Test Center, the summary view is that the digger meets the set requirements and is a promising product in terms of intended use.

This paper presents one approach of the TTC when testing a pioneer machine. With the results obtained by precise measurements, the customer can come to a conclusion as to whether a certain product meets the conditions for use and procurement or not. In this specific case - testing of the digger, the results are mostly positive, with minor defects, which do not significantly affect its operational use. We believe that this approach is expedient and recommended when purchasing this type of machine. Certainly, there is always the possibility of additional tests and checks, all in accordance with the needs of the client.

Abstract: *In this paper, a methodology for the implementation of an environmental safety sensor device as part of a fuzing system for aerial bombs will be presented. Complete hardware and software for this system architecture will be described herein.*
Environmental sensors have a wide range of applications in industry, military technologies, IoT, and many more. These are usually devices that can measure various physical parameters of the environment and convert data into electrical signals suitable for use with electronic devices. In military applications, in weapon systems, the most important factor is safety during the handling and use of explosive products. In this particular case, the application of the environmental sensors in the fuzing systems for aerial bombs is crucial for the safety of pilots and aircrafts.
The test results of the implemented device will be shown as proof of functionality under the given conditions. Software is written in C language as the operating system of a microcontroller used as the main control unit of the entire system.
The core contribution of this work is the analysis of safety features of a device that generates the appropriate signals as conditions for the aerial bomb fuze's performance of its arming process.

Keywords: *safety sensor, environmental conditions, electronics, aerial bomb, C language.*

1. INTRODUCTION

Aerial bombs detonation is controlled by the action of a fuze. A fuze is a device that causes the detonation of an explosive charge at the proper time after certain conditions are met. Part of the fuzing system is also a product called initiator mounted in the middle of the bomb between lugs as shown in Figure 1. [1]

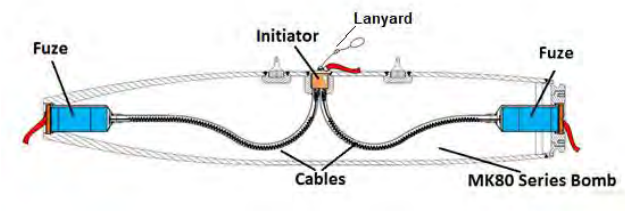

Figure 1. Position of the fuzes and initiators in aerial bomb

The initiator is a cylindrically shaped metal component that is installed in the bomb charging well.
The initiator contains two essential components:

- ***Launch sensor,*** MP1 (switch): which in the active position (closed) connects the battery to the electronic block of the fuze and to the initiator;
- ***Environmental sensor*** with appropriate comparator. This component provides data, designated as MP2, about the pressure of the air stream, indicating that the aircraft has released the bomb and the bomb is flying to the target.

A dedicated hardware-software architecture has been developed for the realization of the proposed sensor device for safety in air-bomb fuzing systems.
The system relies on the integration of a microcontroller unit (MCU) and a differential pressure sensor to ensure that the arming signal is generated only after meeting the given environmental conditions.

Environmental sensor does not serve to activate the bomb on the target, but as a safety device that prevents the fuze from operating until the bomb has safely left the vicinity of the aircraft. [1], [2]

Safety role means that the sensor will generate arming signal when the pressure of air stream is greater than 0.2 psi. This signal is monitored by MCU in the electronic block of the fuze during the bomb flying.

Advantage of this integrated software in a relation with pressure sensor is in the following: when we are comparing system used in AUFK M-91 fuze, with system presented in this paper, we can see that AUFK M-91 fuze

Corresponding author: S. Pelemiš;
E-mail: slobodan.pelemis@vlatacom.com
DOI: 10.5937/OTEH26022P

in order to be armed, must meet the electrical condition, i.e. to receive a certain electric pulse of nominal value of 24V from the plane. It represents a safety requirement and as such would not be acceptable to the modern 1316 safety standard used today. [3]

In this paper, by introducing an initiator based on the differential pressure sensor, we have two safety conditions instead of one. First one represents the opening of the switches when dropping the bomb in form of MP1 signal. Second one is a physical component, i.e. the measurement of differential pressure, which is directly proportional to the speed of the air flow, in real time conditions shown as MP2 signal.

This creates two independent safety conditions that form the basis for the fulfillment of standard 1316.

2. HARDWARE DESIGN AND SIGNAL CONDITIONING

Environmental pressure sensor is located inside the steel housing of the initiator and is activated during the flight of the aerial bomb.

Electronic assembly of complete system which includes mentioned sensor is shown in **Figure 2**.
Characteristics of sensor are given in **Table 1**.

Table 1. Pressure sensor characteristics

Characteristic	Symbol	Min	Typ	Max	Unit
Pressure Range	P_{OP}	0	-	50	kPa
Supply Voltage	V_S	4.75	5.0	5.25	V_{dc}
Supply Current	I_O	-	7.0	10	mAdc
Min. Pressure Offset (0 °C to 85 °C), Vs=5 V	V_{off}	0.088	0.2	0.313	Vdc
Full Scale Output (0 °C to 85 °C), Vs=5 V	V_{FSO}	4.587	4.7	4.813	Vdc
Full Scale Span (0 °C to 85 °C), Vs=5 V	V_{FSS}	-	4.5	-	Vdc
Accuracy (0 °C to 85 °C)	-	-	-	±2.5	$\%V_{FSS}$
Sensitivity	V/P	-	90	-	mV/kPa
Response Time	t_R	-	1.0	-	ms
Output Source Current at Full Scale Output	I_{o+}	-	0.1	-	mAdc
Warm-up Time	-	-	20	-	ms
Offset Stability	-	-	±0.5	-	$\%V_{FSS}$

Upper PCB contains differential pressure sensor and ESD protection diodes.

Lower PCB contains pressure switches which are responsible for providing battery power supply to the fuze electronic block.

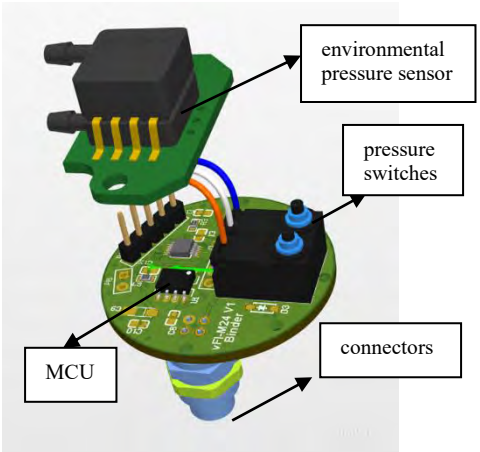

Figure 2. Electronic PCBs of the initiator

The system relies on the integration of a microcontroller unit (MCU) [4] and a differential pressure sensor to ensure that the arming signal is generated only after meeting the given environmental conditions.
Electrical block scheme of complete system is shown in Figure 3**.** [5]

The main purpose of the system is to measure differential pressure, process the sensor signal inside the MCU, and generate a digital output signal when the measured pressure exceeds a predefined Threshold. [6]

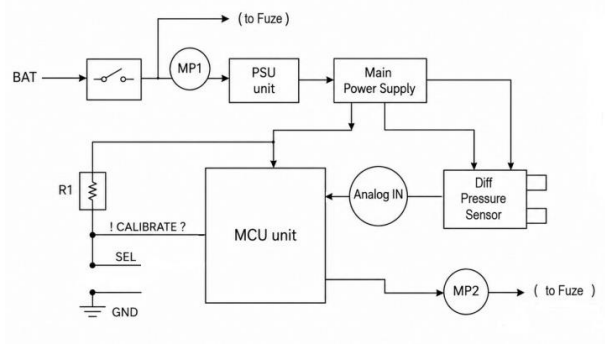

Figure 3. Electrical block scheme of complete system

The system is powered by the battery input (**BAT**). After passing through the main power switch, the supply voltage is available at signal **MP1** which is first signal to be achieved. **PSU Unit** represents preliminary power conditioning stage. Main Power Supply generates the regulated voltages required by the MCU and the differential pressure sensor.

The regulated outputs from the Main Power Supply provide stable operating voltages for the MCU unit and the differential pressure sensor. This arrangement ensures reliable operation regardless of battery voltage variations.

The Differential Pressure Sensor measures the pressure difference between its two pressure ports.

The sensor produces an analog voltage proportional to the measured differential pressure. This analog signal is routed to the MCU through the Analog IN interface.

The MCU continuously samples this signal using its internal Analog-to-Digital Converter (ADC), converts the analog voltage into a digital value, and evaluates the measured pressure against predefined limits.

The calibration circuitry consists of:

- R1 pull-up resistor;
- CALIBRATE input;
- SEL input;
- Ground reference.

These signals allow the system to enter a calibration mode during startup.

When the CALIBRATE line is active, the MCU performs a sensor offset calibration procedure and stores the calculated offset values into non-volatile memory. This compensates for sensor tolerances, temperature effects, and manufacturing variations. [7]

Regarding the output section, it is important to note that the **MCU** generates a digital output signal that is available at MP2, which indicates wheather the measured pressure exceeds the programmed Threshold.

3. SOFTWARE DESIGN AND IMPLEMENTATION

The software support, implemented in the C language, directly controls the states of the hardware components shown in the schematic on **Figure 3**. [8]

Sensor expected measurement range indicated in the experimental results equates to the value of V_{off} + 620.7 mV ± 5% of measurement inaccuracy. The value of 620.7 mV is derived from the formula presented by the device vendor:

$$V_p = V_{off} + \frac{90}{0.145} \cdot P\ [mV] \qquad (1)$$

where V_p is the output voltage in [mV], V_{off} is voltage offset in [mV], and P is pressure (difference) in [psi] which produces the output voltage V_p.

3.1 SOFTWARE CODE WRITTEN IN C LANGUAGE

Following lines show the code written for check of the 0.2 psi pressure value of the sensor. [9], [10]

```
/*
 * Pressure sensor equation: Vp-Voff = (90/0.145)*P [mV]; P is in Psi units
 * for 0.2Psi Vp-Voff = 124mV
 * if using 12bit A/D conversions 1LSB is 1.22mV so threshold is equal to 102
 */

#define MP2_THRESHOLD12b  102

//Functions prototypes
unsigned char MP2_Read2B (void);
void writeOffsetToMem2B (unsigned char tempHigh, unsigned char tempLow);
void MP2_Calibrate2B (unsigned char*memLow, unsigned char *memHigh);

//Main program
void main (void)
{
   unsigned char  memLow=0, memHigh=0;
   int i=0, j=0;
   P04_PUSHPULL_MODE   //P0.4 output push pull  -- MP2
   P01_INPUT_MODE;        //P0.1 input mode -- CALIBRATE
  P06_PUSHPULL_MODE;          //led on initiator board

   P04=0;
   P06=0;
   if(P01)
   {
            while(1)
            {
                     if (MP2_Read2B())
                     {
                              P04=1;
                     }
                     else
                     {
                              P04=0;
                     }
            }
   }
   else
   {
            P06=1;
            MP2_Calibrate2B(&memLow, &memHigh);
            writeOffsetToMem2B(memHigh, memLow);
            P06=0;
            while(1);
   }
}
```

Software support, implemented in C language, directly manages the states of the hardware components shown in the diagram in **Figure 3**.
At the very beginning of the execution of the *main()* function, the input-output pins of the microcontroller is initialized as follows:

- *Port P0.4* is configured in push-pull operation mode. According to the scheme on **Figure 3**, this pin directly controls the MP2 output signal to the fuze.
- *Port P0.1* is set to input mode of operation and corresponds to the line *!CALIBRATE?* from the electrical diagram.
- *Port P0.6* is configured as a push-pull output to control the LED on the initiator board, which serves as a visual status indicator during calibration.

After initialization, the software checks the state of pin *P0.1(if(P01))* to determine the branching of the algorithm:

- **Detection and assurance mode (Normal operation)**: If pin *P0.1* is at a high logic level (calibration switch is open), the system enters an infinite *while(1)* loop where the *MP2_Read2B()* function is continuously called. This function reads the value from the Analog IN position

(pressure sensor output). In the code, the safety threshold *MP2_THRESHOLD12b* is defined with a value of 102. This value directly corresponds to a physical pressure of 0.2 psi (that is, a voltage shift of 124 mV above the offset, taking into account the 12-bit resolution of the ADC where 1 LSB is 1.22mV). If the differential pressure read exceeds the defined threshold, the software sets pin P0.4 to a high logic level *(P04=1)*, which activates the output to the igniter via MP2. Otherwise, the output remains inactive *(P04=0)*, ensuring system security.

- **Calibration mode**: If pin *P0.1* is low at startup *(else branch)*, the LED is activated (*P06=1*). The software then calls the function *MP2_Calibrate2B (&memLow, &memHigh)* to measure the current offset of the pressure sensor at rest, and then writes these values permanently to memory via the function *writeOffsetToMem2B(memHigh, me*mLow). Upon completion of the calibration, the LED turns off (*P06=0*), and the microcontroller enters a waiting state (*while(1)*), blocking further operation of the igniter until the system is restarted in normal mode.

With this synergy of hardware lines and software conditions, a high resistance to unwanted activation of the aerial bomb was achieved, because the arming signal cannot be generated without an adequate change in the environmental pressure that follows the specific flight trajectory of the aircraft.

4. EXPERIMENTAL TESTS WITH RESULTS AND FUNCTIONALITY PROOF

In order to verify developed software which is implemented on MCU, experimental tests are performed. [11]

Equipment necessary for these tests is:

- pneumatic calibration pump with connected digital pressure gauge;
- initiator electronics test box;
- power supply 10.8 V DC;
- voltage meter.

Pneumatic calibration pump with digital pressure gauge shown in **Figure 4** is necessary for simulating air stream pressure which will occur in real-time working conditions during air bomb flight.

Figure 4. Pneumatic calibration pump with digital gauge

By using the appropriate adaptor and a hose, pressure port of the sensor of UUT and the output of pneumatic calibration pump must be connected as shown in Figure 5. UUT in this case is pressure sensor located inside of the initiator housing.

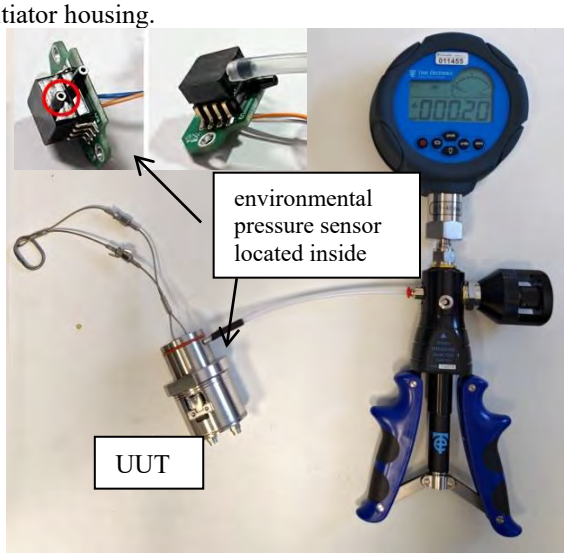

Figure 5. Pump connected with UUT sensor

First part of the test setup is shown on Figure 5. To complete test, we must have also connected power supply, voltage meter and initiator test box. Initiator test box is used to show when MP1 and MP2 signals are activated. Rest of the setup we can see on Figure 6.

Figure 6. MP1 signals activated

In above Figure, it is demonstrated that with air stream pressure lower than 0.2 psi (see display on calibration pump), we have only MP1 signals active (MP1 diodes

glows red, and MP2 diodes don't). This means that when air bomb is released on active mode, switch MP1 is closed, the battery connects to electronic block and arming process started. Environmental sensor still didn't detect air stream and didn't produce any analogue output signal. This is implemented through the C language written code.

Next step is to produce pressure of 0.2 psi or bigger which happens during bomb flight. [11]

We can see pressure value manually defined on pump on **Figure 7**.

Figure 7. MP2 signals activated

When the pressure of the air stream reaches 0.2 psi or above, pressure sensor produce signal MP2=TRUE. This signal is monitored by the microcontroller in the electronic block of the fuze during the bomb moving. The microcontroller starts monitoring this signal when 0.9 of the arming time has elapsed, i.e. at the beginning of the last 10% of the arming time. The sensor will generate an MP2 signal TRUE only if the pressure of air stream is greater than 0.2 psi. (for example if the arming time is preset at 10 seconds, in order for the fuze to arm, this presure must be greater than 0.2psi after 9 and before 10 seconds of arming time have elapsed). **Figure 7** shows that, with the appropriate pressure applied, beside the MP1 diodes, the MP2 diodes on the test box also glow, which indicates the start of the arming process. [11]
In order to prevent influence of noise and interference the microcontroller checks signal MP2 three times after the completion of the 90% of arming time. In case the signal is present during all of these checks, microcontroler concludes that the bomb is moving away and distance from the aircraft is safe enough for the arming process of the fuze to be completed.. Conversely, if the MP2 signal is not TRUE during the last 10% of arming time (3 consecutive readings), arming process will be stopped and arming time resets. The fuze will not be armed.

5. CONCLUSION

This paper has presented the implementation and experimental verification of an environmental safety sensor device designed for aerial bomb fuzing systems. By integrating a microcontroller unit with a differential pressure sensor, the developed hardware-software architecture successfully addresses the strict safety demands critical to military applications.

The embedded software, written in C language, provides reliable signal processing and introduces a dedicated calibration routine that effectively compensates for sensor tolerances and environmental variations.

Through the experimental laboratory setup which includes a pneumatic calibration pump and a dedicated test box, we successfully validated the system's functionality under simulated flight conditions. The testing confirmed that the crucial arming signal (MP2) triggers only when the airflow pressure safely crosses the 0.2 psi threshold.

It is shown that comparing to other similar products used in military, we have two safety conditions ensured (explained through MP1 and MP2 signals) which is advantage regarding the modern military standard 1316. Other fuzes such as for example AUFK type has one condition in form of electrical impulse variable.

Ultimately, the core value of this design lies in its contribution to pilot and aircraft safety. By tying the arming sequence directly to a precise, verifiable change in environmental pressure along the flight trajectory, the system achieves excellent resistance to accidental or premature activation.

Abstract: *The paper presents a preliminary assessment of the precision measures on the conceptual design of a long-range artillery projectile. The precision measures were calculated using the Monte Carlo method based on the projectile trajectory elements obtained using the flight model. The precision testing procedure is based on numerous simulations of projectile flight with six degrees of freedom, adjusted with selected perturbations of the initial firing conditions. Monte Carlo simulations consisted of 200 virtual firings with standard deviations of initial conditions. The initial conditions consisted of the standard deviation of the: muzzle velocity for different propellant charges, mass of the projectile, initial elevation and azimuth angles and estimated values of the angular velocities around transverse axes. The results of the precision expressed through probable deviations showed good agreement with referenced data of related artillery systems.*

Keywords: *Monte Carlo Method, Long-Range Artillery Projectile, Precision, Probable Deviation, Standard Deviation.*

1. INTRODUCTION

Contemporary artillery systems demand continuous evolution due to extend range, maintain and improve precision and accuracy and enhance operational effectiveness [1, 2]. The global trend is the standardization of mail caliber systems for tactical artillery support, particularly the 155 mm caliber, which has become widely adopted across many countries due to its favorable balance between range, payload, and system compatibility [1]. The artillery system 152 mm as artillery system with similar ballistics characteristics, also depends on technological and standardization design progress.

The research investigates the precision of the conceptual design of velocity enhanced long-range artillery projectile (V-LAP) 155 mm, as part of the ballistic performance.

The objective of this work is to provide a solid assessment of flight performance and precision to identify concurrent design directions for novel long-range artillery projectiles, based on reliable methods.

2. METHODOLOGY

The research consists of the flight model, Monte Carlo model for assessment of the deviations and determination of the precision measures, performed on the conceptual design of V-LAP 155 mm.

2.1. Conceptual Design of Projectile

The final phase of the projectile trajectory analysis is the determination of the precision and efficiency metrics of the projectile model using Monte Carlo simulations [3,4,5], Fig. 1. Due to determination of the trajectory parameters, it is necessary to employ the flight model.

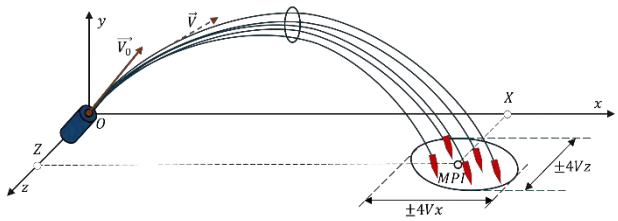

Figure 1. Exterior Ballistics Range Firing

This procedure simulates exterior ballistic range testing, during which the trajectory elements of an unguided projectile are measured [3]. Exterior ballistics firing in these tests varies depending on the type of equipment and the objective of the testing. Range firing is conducted

Corresponding author: D. Jerković;
E-mail: damir.jerkovic@va.mod.gov.rs
DOI: 10.5937/OTEH26023J

using high-explosive projectiles, like the one proposed in this model; their impact can then be monitored and recorded from a safe distance [3,4,5].

The study was performed on the conceptual design of long-range projectile, developed to improve the maximal ranges for artillery system with top propellant charges, Fig. 2.

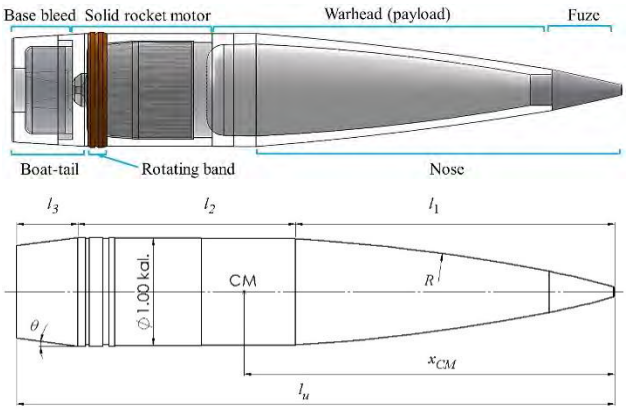

Figure 2. Conceptual design of long-range projectile

2.2. Flight Model

Flight model incorporates model of six degrees of freedom (6-DOF) [3,4,6] to determine projectile trajectory elements and the deviations of the elements.

Governing equations of the 6-DOF model:

$$\frac{d\overrightarrow{r_{CG}}}{dt} = \overrightarrow{V_r} \tag{1}$$

$$\frac{d(m\overrightarrow{V_r})}{dt} = \vec{R} + m\vec{g} + m\overrightarrow{a_c} \tag{2}$$

$$\frac{d(I\vec{\Omega})}{dt} = \overrightarrow{M_R} \tag{3}$$

$$\vec{\Omega} = \overrightarrow{\Omega_E} + \dot{\vec{\lambda}} + \dot{\vec{\varphi}} + \dot{\vec{\psi}} + \dot{\vec{\theta}} + \dot{\vec{\phi}} \tag{4}$$

Equations are applied on the model of long-range projectile, Fig. 1, with determined aerodynamic properties, [7, 8, 9,10].

Parameters in governing equations are:

$\overrightarrow{r_{CG}}$, vector of the center of gravity of projectile,

m, mass of projectile,

I, inertia tensor of projectile,

$\overrightarrow{V_r}$, velocity of the center of gravity of projectile,

$\vec{\Omega}$, angular velocity of projectile,

$\overrightarrow{\Omega_E}$, angular velocity of Earth coordinate frame,

λ, φ, geographic longitude and latitude,

ψ, θ, ϕ, angles of projectile,

$m\vec{g}$, gravity force,

$m\vec{a_c}$, Coriolis force,

$\vec{R}$, aerodynamic force on projectile and

$\overrightarrow{M_R}$, aerodynamic moment on projectile.

2.3. Precision measures

The standard deviation (σ), [11, 12] is a summary measure of the differences of each observation from the mean, i.e. each shot from the mean point of impact (MPI).

$$\sigma_x = \sqrt{\frac{\sum_{i=1}^{n}(x_i - \bar{x})^2}{n-1}} \tag{3}$$

$$\sigma_z = \sqrt{\frac{\sum_{i=1}^{n}(z_i - \bar{z})^2}{n-1}} \tag{4}$$

Based on the observer's position, it is possible to determine the coordinates of the projectile impact point (X, Z), and then, relative to the position of the firing asset and the direction of fire, calculate the probable deviation of the projectile in range and cross range (Vx, Vz) [3,4,5]. Fig. 1 shows an example of range firing [3].

Parameters Vx and Vz represent the limits of the interval containing 50% of the hits and are determined based on the standard deviation σ_x and σ_z as follows [3,4,5]:

$$V_x = 0.6745\,\sigma_x = 0.6745\sqrt{\frac{\sum_{i=1}^{n}(x_i - \bar{x})^2}{n-1}} \tag{5}$$

$$V_z = 0.6745\,\sigma_z = 0.6745\sqrt{\frac{\sum_{i=1}^{n}(z_i - \bar{z})^2}{n-1}} \tag{6}$$

Where are (x_i, z_i), coordinates of the i-th hit, ($\bar{x}$, $\bar{z}$), coordinates of the mean point of impact (MPI), and n is number of hits.

Circular error probable (CEP) [9-12] or circle of equal probability is measure of the precision that represents the radius of the circle, centered on the MPI, such that 50% of the impact points lie within it, Fig. 3. CEP is based on circular bivariate normal distribution (CBN), analog to normal (Gaussian) distribution.

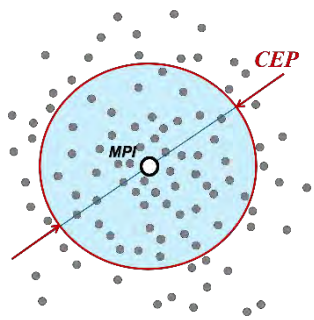

Figure 3. CEP

$$CEP = \begin{cases} \sigma_L(0{,}67 + 0{,}8w^2), & 0 < w < 0{,}5 \\ 0{,}59\sigma_L(1 + w), & 0{,}5 \le w \le 1 \end{cases} \tag{7}$$

$$\sigma_L = max(\sigma_x, \sigma_y), \sigma_S = min(\sigma_x, \sigma_y), w = \frac{\sigma_S}{\sigma_L} \quad (8)$$

3. RESULTS

Monte Carlo simulations consist of applying disturbances to the initial firing conditions, as defined in Table 1. These include the muzzle velocity, azimuth and elevation angle of the barrel, the initial mass of the projectile, and the angular velocities q and r. Each Monte Carlo simulation comprised 200 firings, with pre-defined standard deviations for the analyzed disturbances. As a result, the disturbances varied randomly from one firing to another according to normal (Gaussian) distributions. The standard deviations considered were assumed based on available literature data for similar 155 mm projectiles [13,14].

Table 1. Initial conditions and standard deviations for the Monte Carlo simulation

Initial Condition		Unit	Mean value	Standard deviation
Muzzle velocity	V_{01}	[m/s]	830	2
	V_{02}		950	
Initial mass	m_0	[kg]	43.3	0.1
Elevation angle (barrel elevation)	θ_0	[mils]	996	1
Yaw angle (barrel azimuth)	ψ_0		0	1.25
Pitch angular velocity	q	[s^{-1}]	0	1
Yaw angular velocity	r		0	1

In real firing conditions, disturbances in initial velocity and projectile mass are generally considered systematic deviations. These are corrected using adjustments provided in firing tables. For example, the deviation given in the tables for initial velocity is ±10 m/s, while for the projectile mass, the deviation is related to the number of markings on the ammunition (the so-called weight zones). These systematic deviations also include the following initial conditions: wind speed (longitudinal and lateral), air temperature, atmospheric pressure, and propellant charge temperature. However, the measurement of these quantities during ballistic firing is also subject to random deviations due to the measurement uncertainties of the instruments used. Therefore, the Monte Carlo simulations in this analysis also include disturbances in initial velocity and projectile mass. Disturbances in the azimuth and elevation angle of the barrel are also considered random deviations, as they arise from mechanical factors (vibrations, recoil, etc.) or improper operator handling. Finally, disturbances in the angular velocities q and r are viewed as dynamic, random deviations that cannot be controlled and vary from one firing to another.

In this part of the study, the precision assessment was done to obtain a result of the probable deviation for hybrid model of long-range artillery projectile 155 mm. The initial set of disturbances was performed to muzzle velocity, mass, initial angles of the barrel and initial angular velocities.

4.1. Results of simulation for probable deviation

The Monte Carlo simulation results are shown in Figs. 4 through 13 for an elevation angle of 56° and muzzle velocities V_{01} (830 m/s) and V_{02} (950 m/s), corresponding to maximum ranges of 42 km and 57 km, respectively. Five firing scenarios were considered for each muzzle velocity. Muzzle velocity disturbances were accounted for in the first scenario (Figs. 4 and 6), while projectile mass disturbances were included in the second (Figs. 6 and 7).

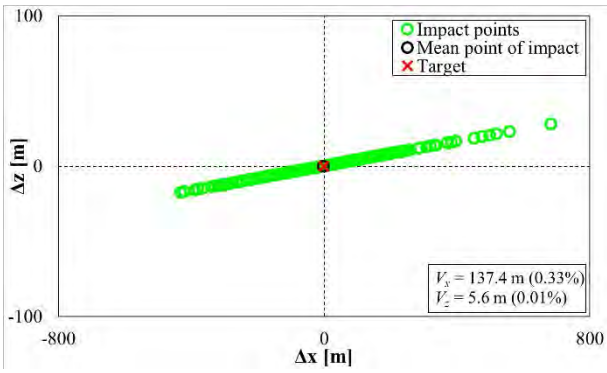

Figure 4. Probable deviation of hits due to deviation of muzzle velocity at 830 m/s

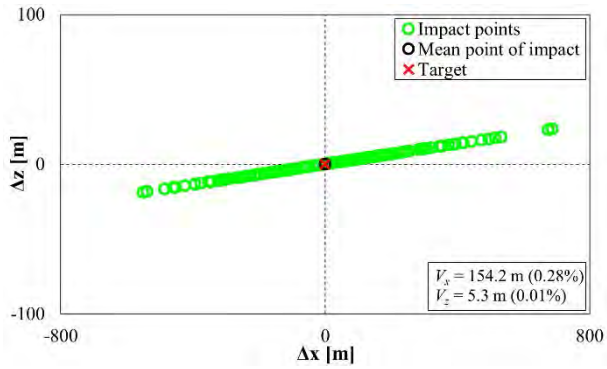

Figure 4. Probable deviation of hits due to deviation of muzzle velocity at 950 m/s

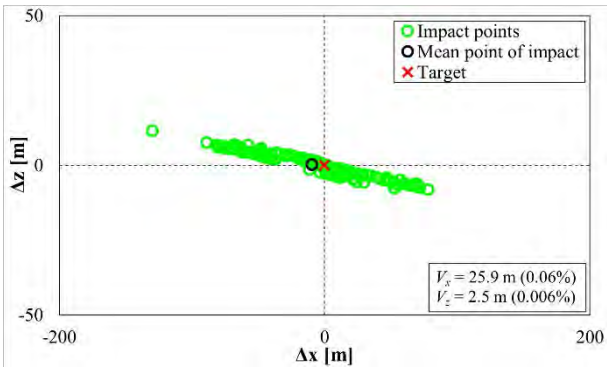

Figure 6. Probable deviation of hits due to deviation of projectile mass at 830 m/s

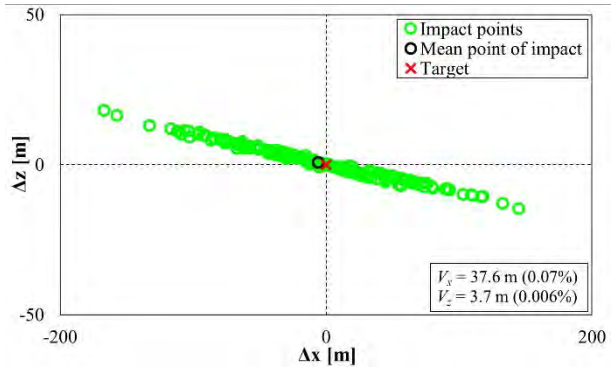

Figure 7. Probable deviation of hits due to deviation of projectile mass at 950 m/s

Azimuth and barrel elevation angle disturbances were examined together in the third scenario (Figs. 8 and 9).

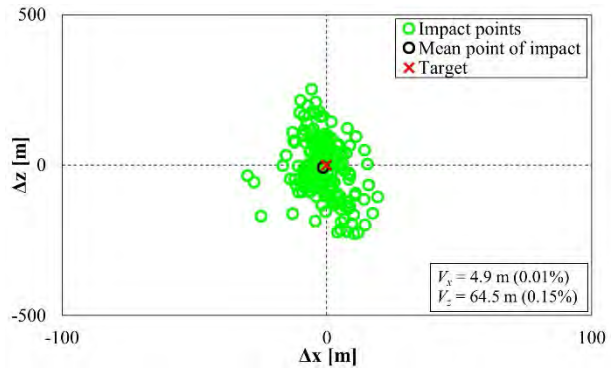

Figure 8. Probable deviation of hits due to deviation of elevation and yaw angles at 830 m/s

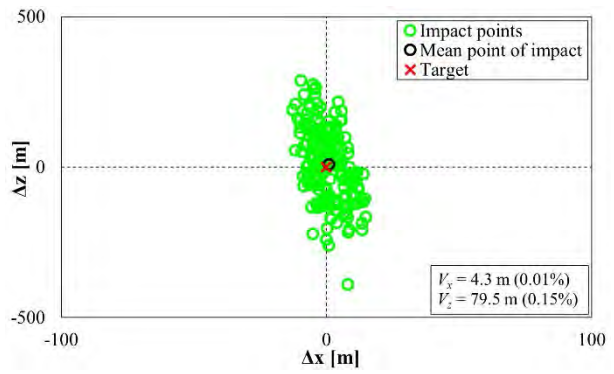

Figure 9. Probable deviation of hits due to deviation of elevation and yaw angles at 950 m/s

Similarly, disturbances in the angular velocities *q* and *r* were introduced in the fourth scenario (Figs. 10 and 11).

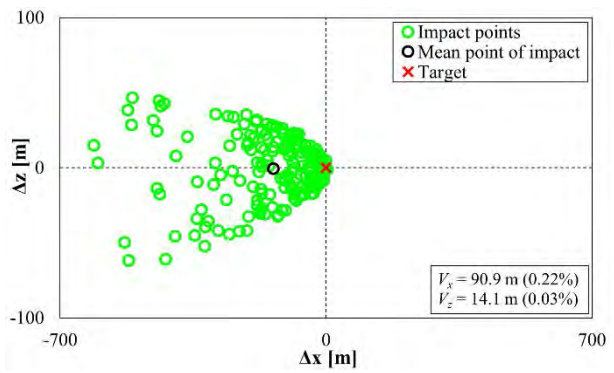

Figure 10. Probable deviation of hits due to deviation of pitch and yaw angular velocities at 830 m/s

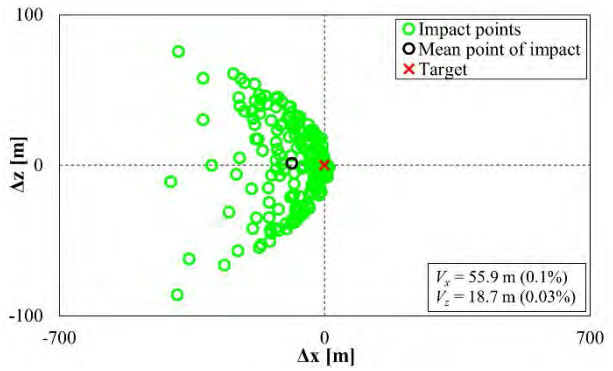

Figure 11. Probable deviation of hits due to deviation of pitch and yaw angular velocities at 950 m/s

Finally, the fifth scenario includes disturbances of all initial conditions considered in the first four scenarios (Figs. 12 and 13).

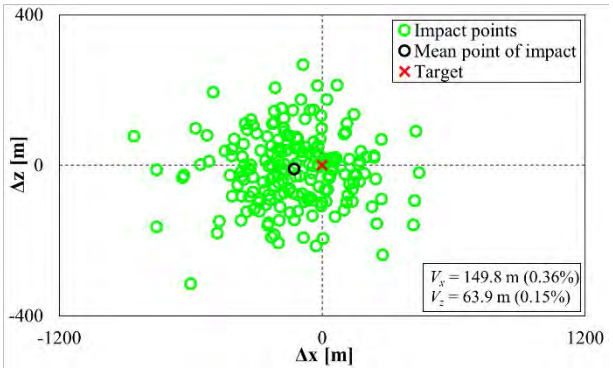

Figure 12. Probable deviation of hits due to deviation of all considered integral factors at 830 m/s

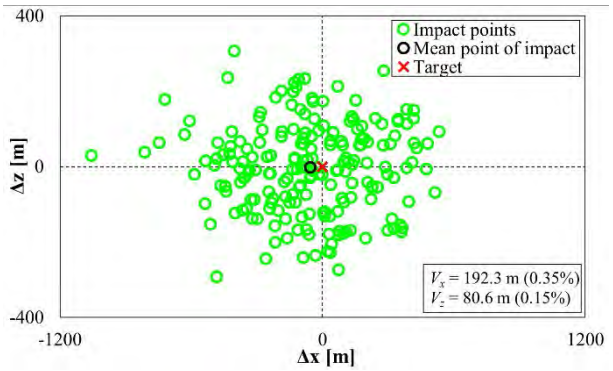

Figure 13. Probable deviation of hits due to deviation of all considered integral factors at 950 m/s

The target is located at point (0, 0) in each figure, and the projectile moves in the positive direction of the *x*-axis, from left to right. The probable deviation of the projectile across the range Vx and deflection Vz for each scenario is also illustrated in the figures. The percentages are calculated relative to the mean range.

The results in Figs. 4, 5, 6 and 7 show that disturbances of muzzle velocity and projectile mass have a significantly greater impact on range than on projectile deflection, with the mean points of impact nearly all centered on the target.

The results of the third scenario in Figs. 8 and 9 demonstrate that disturbances of the elevation angle cause minimal changes in range, whereas disturbances in the

barrel azimuth angle significantly affect projectile deflection. Although the considered standard deviations for both angles are nearly identical, their effects differ substantially. Furthermore, for this scenario, the mean point of impact coincides with the target point.

The hit plot for the fourth scenario shows that disturbances in the angular velocities q and r affect both the range and the projectile deflection (Figs. 10 and 11). All hits are located at distances less than or equal to the target range. The distribution of hits is nearly symmetrical with respect to the x-axis, with a boundary in the shape of an arc directed toward the target, which corresponds to the zone of highest hit density. The mean point of impact deviates from the target point, particularly for the initial velocity V_{01} (Fig. 10).

4.2. Results of simulation for CEP

The dimensions of the CEP metrics are presented in Table 3 under all disturbances.

Table 3. Results of CEP

Velocity [m/s]	CEP [m]	Vx [m]	Vz [m]
830	121.8	149.8	63.9
950	156.3	192.3	80.6

4.3. Analysis

The impact of all considered disturbances on the hit pattern is shown in Fig. 1. In the case of muzzle velocity V_{01}, the hit density is higher in the zone in front of the target, which is why the mean point of impact is at a greater distance from the target compared to the one obtained with velocity V_{02}, which is very close to the target. The hits for velocity V_{02} are more evenly distributed around the target than those associated with velocity V_{01}. This is a direct result of the stronger influence of disturbances in the angular velocities q and r in the case of velocity V_{01}. The probable deviation, as a measure of precision, amounts to 0.35% in range (Vx) and 0.15% in deflection (Vz) relative to the mean range for both velocity cases V_{01} and V_{02}, meaning that the projectile maintains the same precision even at a longer range. Based on the study presented in [9], which refers to 155 mm artillery system with 39 caliber barrel length and 52 caliber barrel length, the probable deviations Vx and Vz should not exceed 0.75% and 0.14%, respectively. Available data [15] on similar existing projectile models show that the probable error of the hybrid V-LAP projectile, which is currently in use, is 0.6% in range (Vx) and 0.13% in deflection (Vz) relative to the firing range. The probable error must remain within these limits to enable the successful application of potential 1D and 2D Course Correction Fuzes [4].

Available literature data show that the proposed projectile model has satisfactory precision, and even better in range. However, this comparative analysis is more indicative than fully objective, as the Monte Carlo simulations performed do not include all possible disturbances that can occur in real firing conditions. Furthermore, the standard deviations used were taken from similar studies available in the literature [13,14], which state that they are appropriate and representative for the analyzed model. However, it is not explained how these deviations were determined, nor are reference studies cited that would confirm this.

5. CONCLUSION

The study presents an investigation into ballistic performance of the long-rang artillery projectile 155 mm through precision assessment. The analysis showed that the considered disturbances of the initial conditions proportionally affect the trajectory parameters. The external ballistics model confirmed that the proposed projectile concept can achieve a substantial increase in range.

The results also demonstrated that range growth can be further improved through complementary approaches, including higher muzzle velocity, aerodynamic optimization, base-drag reduction, and rocket propulsion. The proposed approach provides a solid basis for future design optimization and experimental validation, particularly in relation to precision, flight performance, and range extension capability.

SHEAR STRESS-BASED FORCE MODELING FOR M-84 TRACKED VEHICLE ON DEFORMABLE TERRAIN

MOMIR DRAKULIĆ
University of Defence in Belgrade, Military Academy, Belgrade, momir.drakulic@va.mod.gov.rs

ALEKSANDAR ĐURIĆ
University of Defence in Belgrade, Military Academy, Belgrade, aleksandar.djuric@va.mod.gov.rs

Abstract: *This paper presents a methodology for calculating interaction forces acting on the tracked armoured vehicle M-84 during motion on deformable terrain. The research is based on a previously developed and experimentally validated track-terrain interaction model, which is extended toward application at the vehicle level. The proposed approach applies a shear stress model within the framework of terramechanics theory to estimate the distribution of stresses along the track-soil contact area. Based on this model, the resultant interaction forces are numerically evaluated under different operating conditions, including straight motion and steering. The calculated force outputs are structured for integration into a complete dynamic vehicle model. They also provide a consistent input set for driveline analysis and transmission studies, especially for optimization of the gear shifting process in a power-shift transmission system, aiming to achieve smooth gear transitions without interruption of power flow. The presented methodology contributes to improved prediction of mobility performance and supports further development of control-oriented models of tracked armoured vehicles.*

Keywords: *Tracked vehicle, terramechanics, shear stress model, track-soil interaction, vehicle dynamics.*

1. INTRODUCTION

Tracked vehicles are designed to maintain mobility across terrains that vary significantly in stiffness, strength, and surface conditions [1,2]. Their operational performance depends not only on propulsion and suspension systems but also on the complex mechanics of track–terrain interaction [3,4]. During high-speed steering manoeuvres, nonlinear distributions of contact forces emerge, which strongly affect vehicle stability, controllability, and energy consumption [5]. These effects become especially pronounced in heavy platforms such as main battle tanks, where large inertial loads amplify slip, lateral displacement, and uneven load distribution along the track [6].

Accurate prediction of track–terrain interaction forces is essential for reliable assessment of vehicle behaviour under demanding operating conditions [7]. Empirical models provide simplified estimates but often fail to capture the coupled effects of soil deformation and slip dynamics [8]. On the other hand, high-fidelity numerical methods, such as discrete element or finite element approaches, offer improved physical realism but are typically computationally expensive for system-level simulations. Therefore, a balanced modelling approach that combines physical consistency with computational efficiency is required for engineering analysis and design purposes.

The simulation framework used in this study is based on terramechanics principles and the shear stress theory of soil deformation, enabling the prediction of longitudinal and lateral contact forces generated during track–terrain interaction [9]. The model has previously been developed and validated for the infantry fighting vehicle BVP M80, with results reported in [10], where good agreement with experimental data was demonstrated in terms of contact force distribution and vehicle trajectory prediction.

In this work, the same validated modelling framework is applied to the M84 main battle tank. The objective is to investigate how changes in vehicle mass, geometry, and inertial properties influence the predicted track–terrain interaction forces during steering manoeuvres. By introducing vehicle-specific parameters, the study evaluates the adaptability of the model to a heavier and dynamically different tracked platform, while maintaining the same underlying physical formulation.

The contribution of this paper lies in demonstrating the transferability of a previously validated terramechanics-based simulation model to a different class of tracked vehicle and in analysing the resulting differences in contact force distribution under identical maneuver conditions. The results provide additional insight into the influence of vehicle configuration on track–terrain interaction and support the use of such models in comparative studies, system design, and further development of control-oriented simulation tools.

2. MODELING

Considering the variety of approaches used in the analysis of track–terrain interaction, a systematic overview of modern terramechanics methods is given in [8,11]. To achieve a balance between physical realism, numerical stability, and computational efficiency, the Janosi–Hanamoto semi-empirical model is adopted as the basis for

Corresponding author: M. Drakulić;
E-mail: momir.drakulic@va.mod.gov.rs

DOI: 10.5937/OTEH26024D

describing the shear behaviour of deformable terrain. This choice is consistent with the modelling framework previously developed and validated in [10], where the same approach was successfully applied to the infantry fighting vehicle BVP M80.

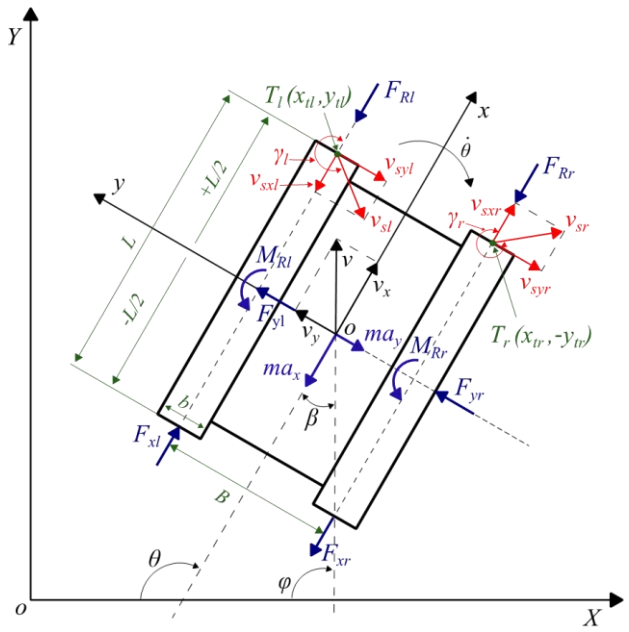

Figure 1. Tracked vehicle during the steering [10].

Starting from the established modelling framework, a consistent vehicle dynamics formulation is required to enable coupling with the terramechanics model [8,12,13]. The vehicle is considered as a rigid body performing planar motion during steering, where the interaction between the left and right track systems generates longitudinal and lateral motion as well as yaw dynamics. A detailed derivation of the governing equations of motion is provided in [10] and is directly utilized in the present study without modification of the underlying structure.

Within the Janosi–Hanamoto formulation, the key coupling variable between vehicle kinematics and soil response is the shear displacement, which arises due to the relative motion between the track and the deformable soil [14,15]. This quantity governs the development of shear stress within the contact patch and provides a direct link between slip conditions and traction generation. The shear stress is described by the exponential relationship:

$$\tau = (c + \sigma tan\phi)\left(1 - e^{-\frac{j}{K}}\right) \quad (1)$$

where c is the soil cohesion, σ is the normal stress, φ is the internal friction angle, j is the shear displacement, and K is the shear deformation modulus.

Based on the obtained shear stress distribution, the interaction forces between the track and the terrain are determined by integrating the local stresses over the contact length. In this way, the longitudinal and lateral force components acting on the right and left track are obtained as functions of vehicle motion, soil properties, and local pressure distribution [16–18].

Based on Figure 1, F_{xr} and F_{xl} represent the components of the shear force exerted by the right and left tracks, respectively, on the terrain in the x-direction. F_{yr} and F_{yl} are the corresponding components of the shear force in the y-direction. M_{Rr} and M_{Rl} denote the steering resistance torques for the right and left tracks, respectively, while F_{Rr} and F_{Rl} represent the rolling resistances for the tracks on both sides.

$$F_{xr} = \int_{-\frac{L}{2}}^{\frac{L}{2}} (c + p_r \tan\phi)\left(1 - e^{-\frac{j_r}{K}}\right) b\cos(\gamma_r + \pi)dx \quad (2)$$

$$F_{xl} = \int_{-\frac{L}{2}}^{\frac{L}{2}} (c + p_l tan\phi)\left(1 - e^{-\frac{j_l}{K}}\right) b\cos(\gamma_l + \pi)dx \quad (3)$$

$$F_{yr} = \int_{-\frac{L}{2}}^{\frac{L}{2}} (c + p_r tan\phi)\left(1 - e^{-\frac{j_r}{K}}\right) b\sin(\gamma_r + \pi)dx \quad (4)$$

$$F_{yl} = \int_{-\frac{L}{2}}^{\frac{L}{2}} (c + p_l tan\phi)\left(1 - e^{-\frac{j_l}{K}}\right) b\sin(\gamma_l + \pi)dx \quad (5)$$

In addition to traction forces, the model accounts for rolling resistance effects through a load-dependent formulation that includes lateral load transfer during steering manoeuvres. The normal load distribution between the left and right tracks is influenced by vehicle mass, lateral acceleration, centre of mass height, and track gauge, which leads to asymmetric resistance forces on the two sides of the vehicle [19]. This effect is incorporated in the form of equivalent resistance forces acting at the track level, ensuring compatibility with the overall dynamic equilibrium.

$$F_{Rr} = f\left(\frac{mg}{2} + \frac{ma_y h}{B}\right) \quad (6)$$

$$F_{Rl} = f\left(\frac{mg}{2} - \frac{ma_y h}{B}\right) \quad (7)$$

$$M_{Rr} = \int_{-\frac{L}{2}}^{\frac{L}{2}} (c + p_r tan\phi)\left(1 - e^{-\frac{j_r}{K}}\right) b\sin(\gamma_r + \pi)xdx \quad (8)$$

$$M_{Rl} = \int_{-\frac{L}{2}}^{\frac{L}{2}} (c + p_l tan\phi)\left(1 - e^{-\frac{j_l}{K}}\right) b\sin(\gamma_l + \pi)xdx \quad (9)$$

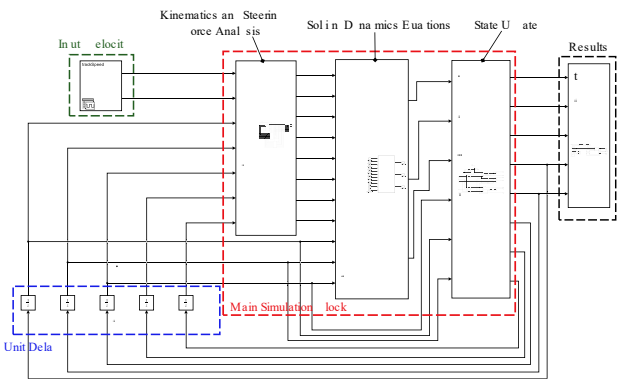

Figure 2. Simulation model [10].

The developed force and moment model is implemented in a MATLAB/Simulink environment, where it is coupled with the previously established vehicle dynamics model. The simulation structure enables numerical evaluation of high-speed steering manoeuvres by computing

instantaneous track–terrain interaction forces and vehicle response in a time-domain framework. Compared to the previously published model in [10], the present implementation retains the same mathematical structure while extending its application to a different vehicle class by introducing the geometric and inertial parameters of the M84 main battle tank, shown in table 1.

3. RESULTS

For the purposes of simulation, a Gault clay soil was selected as the terrain type (Table 2), as it is representative of cohesive soil conditions commonly associated with the operational environments of the M84 tracked vehicle. The reference trajectory to be followed by the vehicle was predefined [20,21], and a closed-loop control structure based on a PID controller was implemented to ensure accurate trajectory tracking. The controller continuously minimizes the position error between the desired and actual vehicle path, thereby enabling the system to follow the prescribed trajectory while maintaining stable dynamic response throughout the maneuver. The simulated trajectory, shown in Figure 3, closely follows the prescribed reference path throughout the entire manoeuvre.

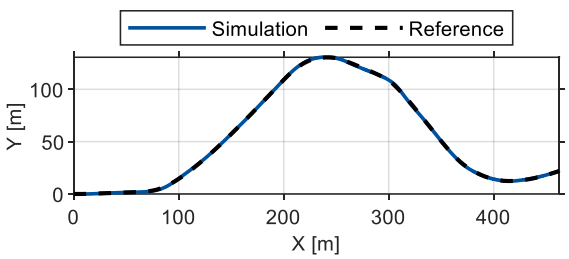

Figure 3. Vehicle trajectory.

This confirms that the PID-based closed-loop control structure maintains adequate path-tracking accuracy despite the combined influence of nonlinear shear-stress traction forces and lateral load transfer acting on the vehicle.

The corresponding sideslip angle, presented in Figure 4, remains within a narrow ran e of a roximatel −0.4° to +0.2°, with the most pronounced excursions coinciding with the steepest curvature segments of the trajectory (aroun t ≈ 10 s an t ≈ 40–55 s). This behaviour confirms the expected coupling between path curvature and lateral slip and indicates that lateral instability effects remain limited for the considered manoeuvre and terrain conditions.

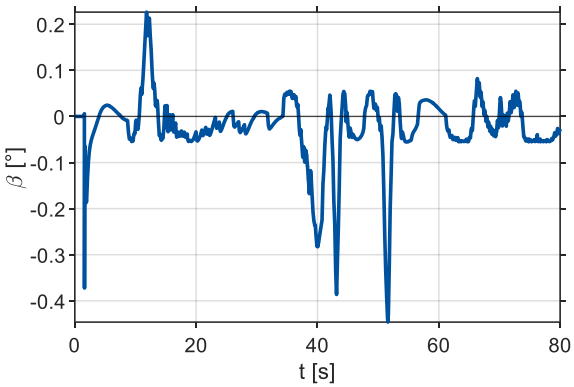

Figure 4. Sideslip angle.

This kinematic response is governed by the underlying track–terrain interaction forces. The longitudinal forces on the right and left track, shown in Figures 5 and 6 respectively.

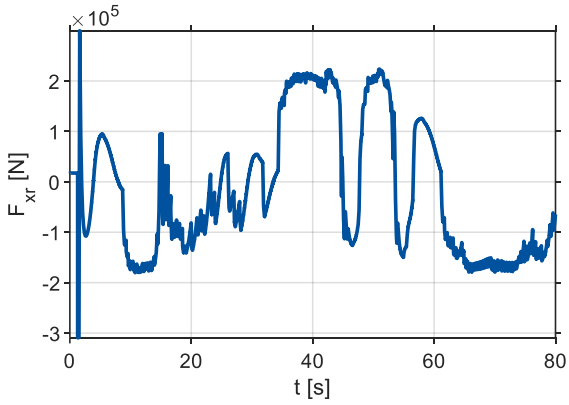

Figure 5. Longitudinal force on the right track.

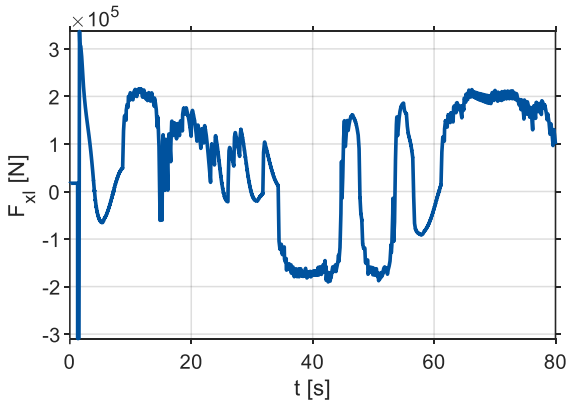

Figure 6. Longitudinal force on the left track.

This asymmetry between Fxr and Fxl is consistent with the

differential traction and braking distribution required for skid-steering and represents the primary mechanism generating the yaw moment needed to execute the prescribed turn; the pronounced plateau visible between t ≈ 30–55 s corresponds to the sustained turning phase, during which the outer track is required to sustain a higher traction level than the inner track.

A similar coupling is observed in the lateral force components, presented in Figures 7 and 8, which remain close to zero during straight-line motion and develop pronounced peaks of up to approximately 3.5×10^4 N urin the steering phase.

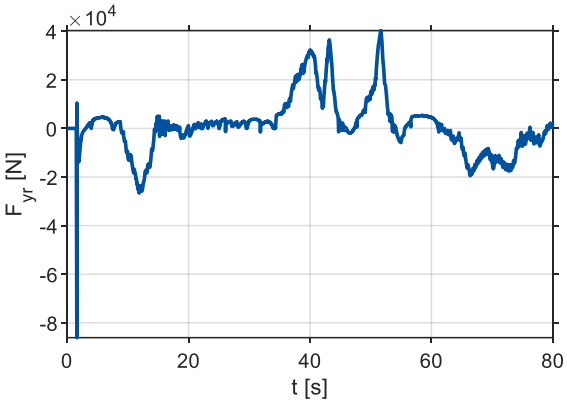

Figure 7. Lateral force on the right track.

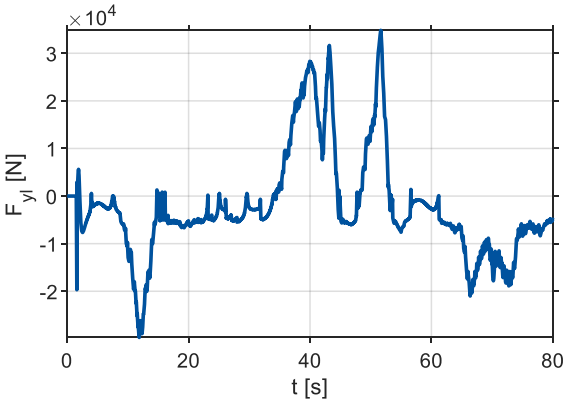

Figure 8. Lateral force on the left track.

The magnitude and timing of these lateral force peaks correlate well with the sideslip angle response discussed above, confirming the physical consistency of the shear-stress-based lateral force formulation across both tracks. The combined effect of these longitudinal and lateral force asymmetries is reflected in the turning resistance moment shown in Figure 9, which varies between approximately -5×10^5 Nm an 5×10^5 Nm and reaches its largest sustained values during the central turning segment of the manoeuvre; the relatively high magnitude of this moment, compared with the values previously reported for the lighter BVP M80 platform in [10], illustrates the influence of the M-84's larger mass and track gauge on rolling and turning resistance.

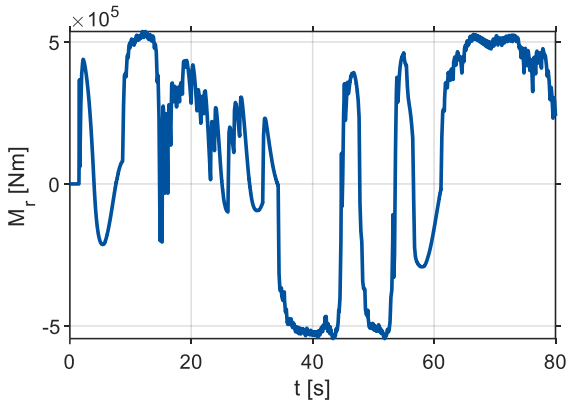

Figure 9. Turning resistance moment.

Despite these substantial variations in track forces and moments, the vehicle's speed response remains well-regulated. Following an initial transient associated with the start of the manoeuvre, the total vehicle speed, shown in Figure 10, stabilises around 25 km/h with only minor fluctuations of approximately ±1 km/h during the steering phase.

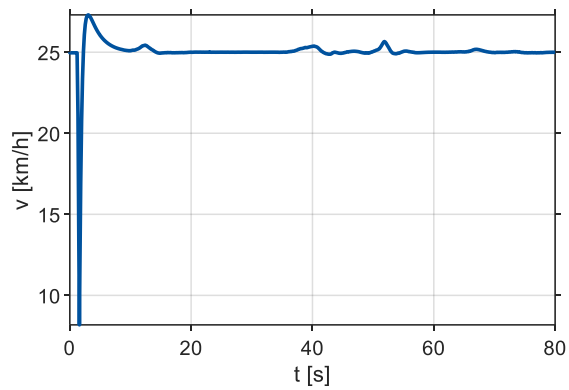

Figure 10. Total vehicle speed.

The longitudinal velocity component, presented in Figure 11, closely tracks this overall speed profile, confirming that the lateral velocity contribution remains small throughout the manoeuvre.

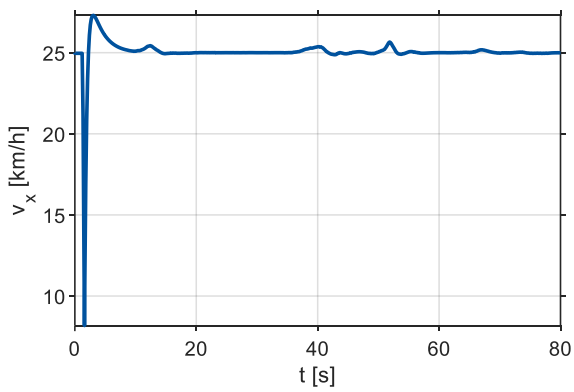

Figure 11. Longitudinal vehicle speed.

This is corroborated by the lateral velocity response in Figure 12, which stays within a narrow band of approximately ±0.15 km/h; although small in absolute terms, the visible oscillations during the steering phase are

directly linked to the lateral force and sideslip behaviour discussed above and represent the residual lateral dynamics not fully suppressed by the trajectory controller.

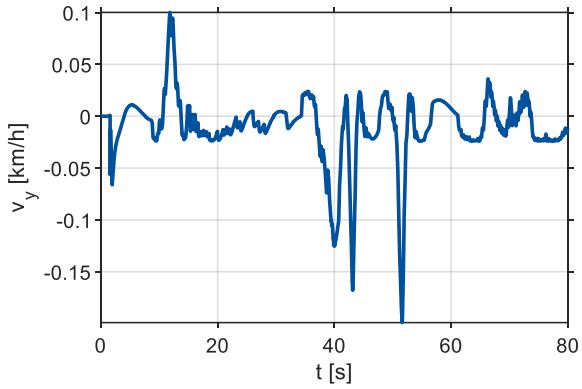

Figure 12. Lateral vehicle speed.

The corresponding acceleration responses further support this picture of stable, well-controlled vehicle behaviour. Apart from an initial transient peak of approximately 1.5 m/s² associated with the vehicle's start-up phase, the longitudinal acceleration in Figure 13 remains close to zero, with only minor oscillations occurring during the steering segment as the controller works to maintain constant forward speed under varying traction demand.

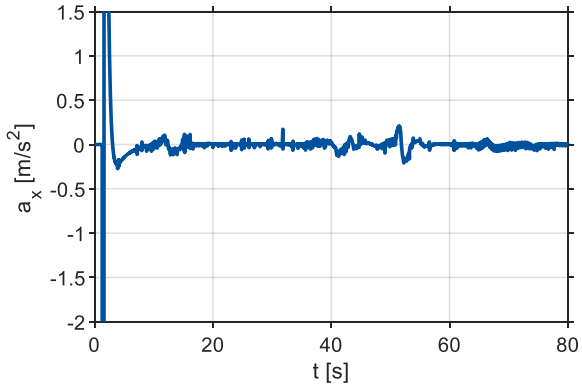

Figure 13. Longitudinal vehicle acceleration.

The lateral acceleration, shown in Figure 14, reaches peak values of approximately ±1.1 m/s² during the sharpest turning segments, in direct correspondence with the lateral force peaks discussed for Figures 7 and 8, these values remain within a range that does not indicate critical lateral instability, further supporting the conclusion that the controller and the underlying force model produce physically consistent vehicle behaviour.

Finally, the trajectory tracking error, presented in Figure 15, oscillates within approximately ±0.6 m, with the largest transient excursions occurring during the most demanding curvature changes of the manoeu re (t ≈ 15 s, 40 s an 50 s). While these peaks indicate a temporary degradation of tracking accuracy under high lateral force demand, the error consistently returns toward zero, confirming the overall stability and adequacy of the PID control structure for the considered class of high-speed steering manoeuvres.

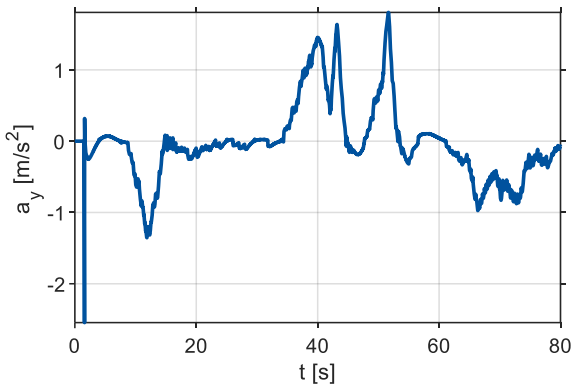

Figure 14. Lateral vehicle acceleration.

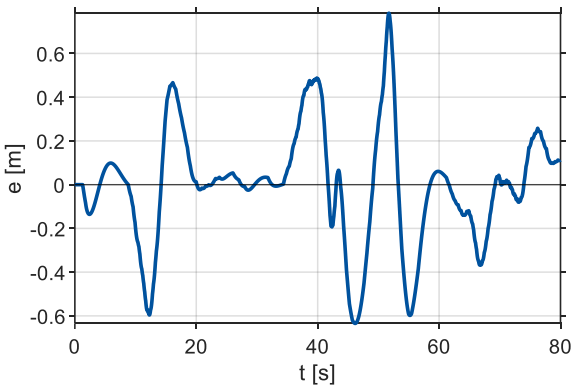

Figure 15. Trajectory tracking error.

4. CONCLUSION

This paper presented a shear stress-based methodology for calculating track–terrain interaction forces acting on the M-84 main battle tank during steering manoeuvres on deformable terrain. The approach extends a previously developed and experimentally validated terramechanics model, originally established for the infantry fighting vehicle BVP M80, to a heavier and dynamically different tracked platform by introducing the M-84's specific geometric and inertial parameters.

The simulation results, obtained for a representative cohesive soil (Gault clay) and a closed-loop PID-controlled steering manoeuvre, demonstrate that the model produces physically consistent and well-correlated force, moment, velocity and acceleration responses. The vehicle maintained accurate trajectory tracking, with sideslip angle and lateral acceleration remaining within bounded, stable ranges throughout the manoeuvre, while the trajectory tracking error remained limited even during the most demanding curvature transitions. The obtained results confirm the model's transferability across vehicle classes while preserving the same underlying physical formulation validated in [10].

The calculated force and moment outputs provide a consistent and structured data set suitable for integration into a complete vehicle dynamics model, and for driveline and transmission studies, including the optimisation of gear-shifting strategies in power-shift transmission

systems. Future work will focus on the experimental validation of the model for the M-84 platform, the extension of the analysis to additional terrain types and manoeuvre conditions, and a direct quantitative comparison between the M-84 and BVP M80 force responses to further characterise the influence of vehicle mass and geometry on track–terrain interaction.

Abstract: *A new algorithm is developed to interpolate the thrust curve for a given propellant temperature based on the known thrust functions for one higher and one lower temperature than the given one. The algorithm is based on the fact that the impulse of thrust as a function of the burnt mass of propellant changes very little depending on the temperature of the propellant compared to the change in thrust and operating time depending on the temperature of the propellant. Examples of calculations for several rocket motors of different purposes are given, which demonstrate the high efficiency of the algorithm.*

Keywords: *solid propellant rocket motor, thrust interpolation, propellant temperature, impulse..*

List of Symbols

F , F_k	thrust at any time and its discrete value [N, daN, kN]
$\bar{F}$	scaled thrust to the mean value of total impulse
I_t	impulse of thrust at time t , [Ns, daNs, kNs]
$\bar{I}_t$	scaled impulse to the mean value of total impulse
I_{tot}	total impulse
$I_{\text{tot}.m}$	mean value of total impulse for plus and minus temperature
T_p	temperature of rocket motor propellant, [°C]
$T_{p.\max}$, $T_{p.\min}$	maximal and minimal temperature for which thrust is known (measured)
t , t_i	time and its discrete value, [s, ms]
t_b	total burning time, [s, ms]
$\bar{t}$	scaled time to the mean value of total impulse
$\bar{\sigma}_m$	coefficient of interpolation quality

1. INTRODUCTION

It is well known that propellant temperature influences operation of solid propellant rocket motor. With increase of propellant temperature level of thrust increases and the operation time decreases, and vice verse - with decrease of propellant temperature level of thrust decreases and the operation time increases [1]. Depending mostly on type of propellant, than on the grain shape and motor construction the influence can vary from small to large amount.

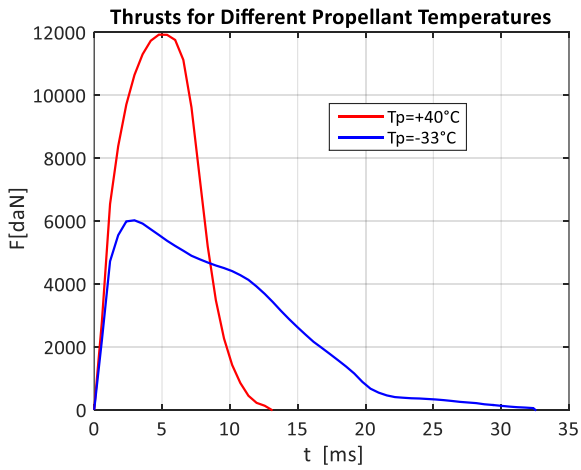

Figure 1. Thrust vs time for two different temperatures for AT rocket M79 OSA.

In figure 1 the thrust for the two propellant temperatures +40°C (red line) and -33°C (blue line) for the anti-tank shoulder launch rocket 90 mm M79 OSA [2] are shown. It can be clearly seen that maximum thrust for the +40°C propellant temperature is two times greater than for -33°C and that operation time for +40°C propellant temperature is two times less than for the -33°C propellant temperature. Note that curves are obtained after filtering and averaging ([3]) of the set of measurements of thrust (seven runs, fig. 2), which is not subject of this work.

Corresponding author: M. Ćurčin;
E-mail: miodragcurcin@gmail.com

DOI: 10.5937/OTEH26025C

In operational usage propellant temperature can be any between minimum and maximum specified for the rocket, and we need thrust function in time for that temperature to calculate trajectory.

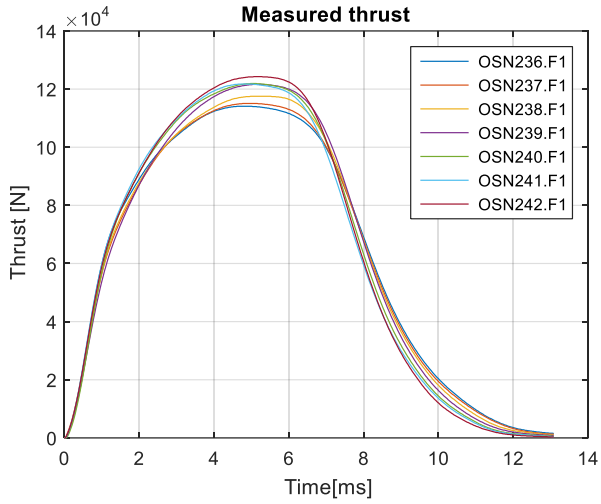

Figure 2. Filtered thrust vs time for 40°C propellant temperature – seven measurements.

The difference of the operation time of rocket motor between the two temperatures can be large while at the same time the difference between the total impulses for the two temperatures are relatively small. For example, for the considered rocket for the +40°C propellant temperature the total impulse is 833 Ns and for the -33°C propellant temperature the value is 795 Ns, the difference being 4.78 %. Total impulse with respect to propellant temperature $I_{\text{tot}}(T_p)$ for rocket motor is shown in figure 3. We can see huge influence at lower propellant temperature and small influence of the propellant temperature at high propellant temperature to the total impulse.

In serial production we usually measure thrust characteristics at extreme temperatures – plus maximum $T_{p.\max}$ and minus maximum operation temperature $T_{p.\min}$, and sometimes also at standard temperature (20°C). But in real combat situation the propellant temperature can be any value in the interval from minimum to maximum and we need the thrust function in time for the actual propellant temperature for many reasons, the main being calculation of trajectory. The question is whether we can determine the thrust in time for any other propellant temperature than the two extremes, for example for $T_p = 20\,°\text{C}$ for the rocket 90 mm M79 OSA based on two known curves as shown in figure 1.

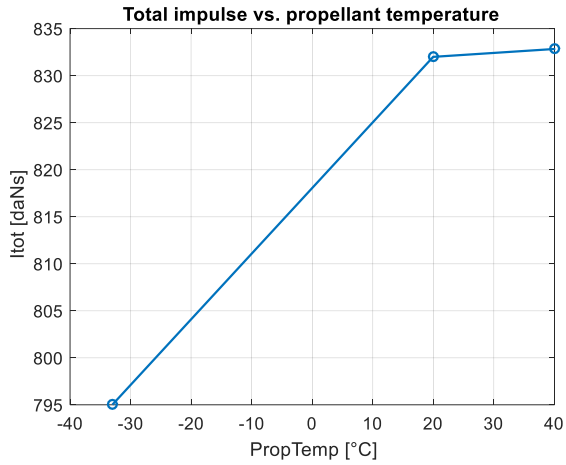

Figure 3. Total impulse with respect to propellant temperature for AT rocket M79 OSA.

Even if we have measured the thrust in time for three or four propellant temperatures the actual propellant may differ from those measured and we have to estimate thrust for the required propellant temperature.

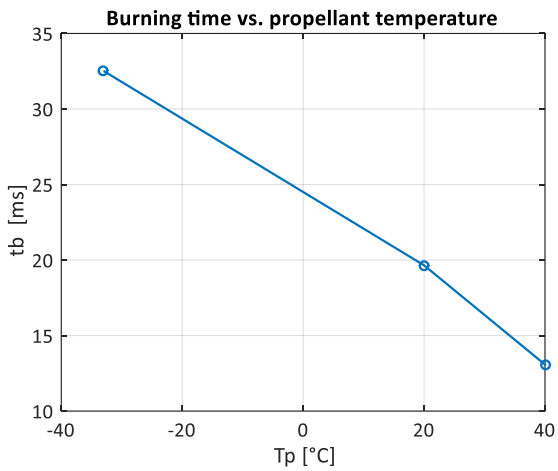

Figure 4. Burning time with respect to propellant temperature for AT rocket M79 OSA.

Statement of the Problem

Suppose that the function thrust with respect to time is known numerically for the two extreme temperature

$$F_i(T_{p.\max}, t_i),\ i = 1,2,..,n_+$$

$$F_j(T_{p.\min}, t_j),\ j = 1,2,..,n_-$$

where n_+ – number of data for plus temperature, and n_- – number of data for minus temperature, and maybe for one or two temperatures between them. Our task is to determine the $F_k(T_p, t_k), k = 1,2,..,m$ at any required temperature T_p, and time instant t_k in m points. One immediately can say "do interpolation between the two curves for known temperature". But the question is how to interpolate between two curves which do not have neither same abscissa nor same ordinate? Let us consider thrust functions for the rocket OSA (figure 1). The curves for maximum propellant temperature (40°C) and minimum temperature (-33°C) have totally different span in abscissa

and ordinate and direct interpolation between them is not possible. Suppose that we want to determine measured thrust function for the $T_p = 20\,°\mathrm{C}$ by interpolation between the two curves for extreme temperature. One, new, indirect method to do that is subject of this work.

2. METHOD OF INTERPOLATION

The Basic Idea of the Method

Consider the characteristics of the rocket motor for active-reactive mine 120 mm obtained by calculation by the program IBRocketMotor_M0 [4]. In figure 5 the thrust with respect to time for the three propellant temperatures – maximal value $T_p = +50\,°\mathrm{C}$, minimal value $T_p = -30\,°\mathrm{C}$, and some value between them – $T_p = 21\,°\mathrm{C}$ is shown.

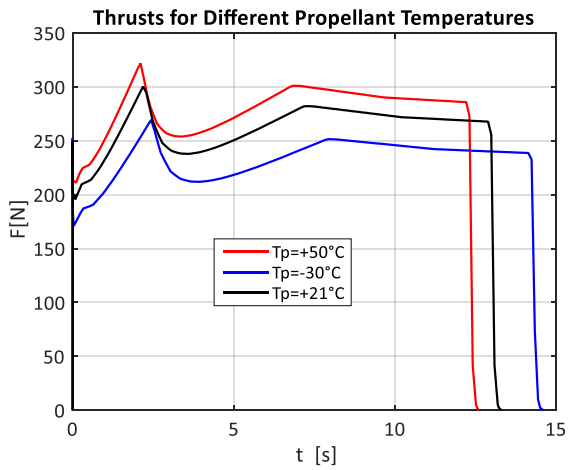

Figure 5. Calculated thrust with respect to time for the rocket motor of the AR mine.

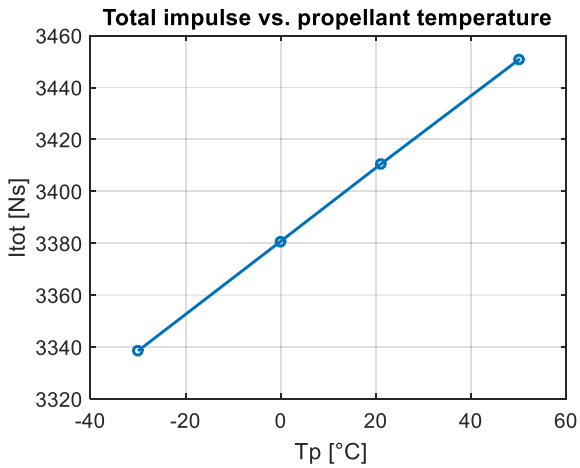

Figure 6. Total impulse with respect to propellant temperature for the rocket motor of the AR mine.

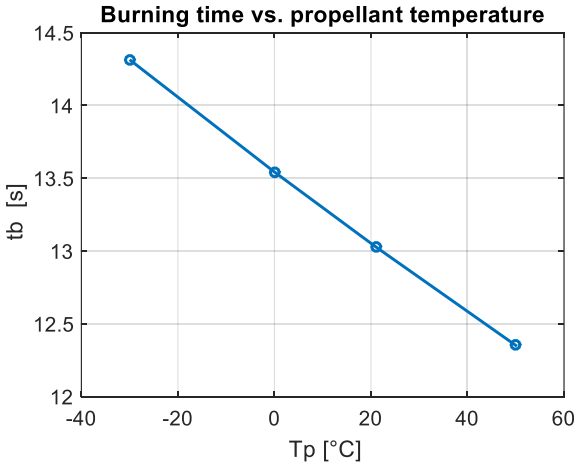

Figure 7. Burning time with respect to propellant temperature for the rocket motor of the AR mine.

For any function of thrust

$$F_i\left(T_p, t_i\right),\ i = 1,2,..,n$$

defined in n points we can calculate impulse from $t = 0$ to any point i, $i = 1,2,..,n$

$$I_t\left(T_p, t_i\right) = \mathrm{trapz}\left(t_k, F_k\right)\quad k = 1,2,..,i\ ,\ i = 1,2,..,n$$

where "trapz" denotes trapezoid method of calculation of integral. In the figure 8 the thrust with respect to impulse, and in figure 9 the burning time with respect to impulse calculated by the program IBRocketMotor_M0 [4], is shown.

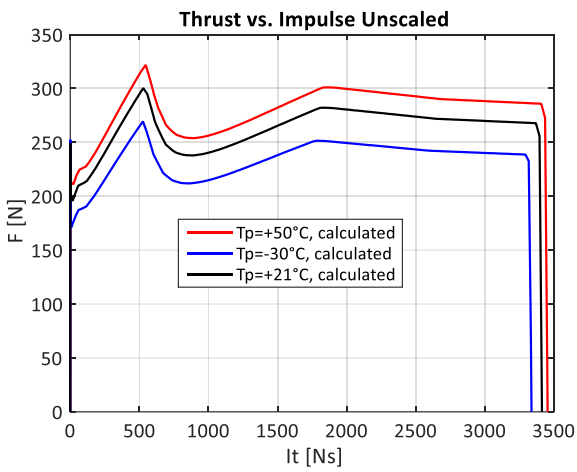

Figure 8. Thrust with respect to impulse for different propellant temperature for the rocket motor of the AR mine.

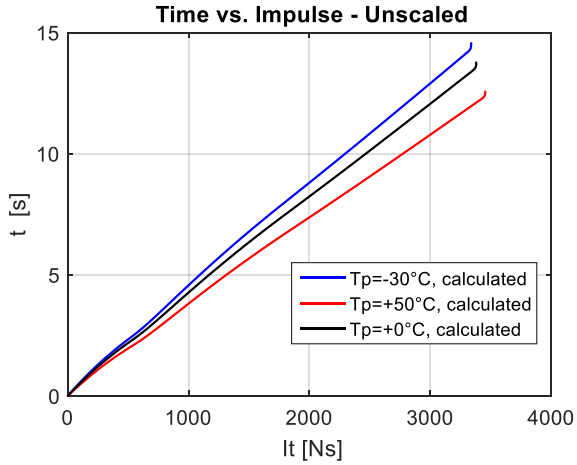

Figure 9. Burning time with respect to impulse for different propellant temperature for the rocket motor of the AR mine.

The Interpolation Procedure

If we compare the function $F(t)$ for different temperature of the propellant, shown in figure 5, with functions $F(I_t)$ in figure 8, we can conclude that thrust functions with respect to impulse almost satisfied conditions for the interpolation between different propellant temperatures. The problem is small difference in total impulse between the functions for different propellant temperatures as can be seen in figure 8. It can be solved by representing the functions $F(I_t)$ and $t(I_t)$, shown in figure 8 and 9, with respect to scaled impulse $\bar{I}_t$ for the temperature. Therefore, divide each function $I_t(T_p,t_i)$ by the total impulse for that temperature $I_{tot}(T_p)$ and obtain dimensionless scaled impulse

$$\bar{I}_{t,i}(T_p,t_i) = I_{t,i}(T_p,t_i)/I_{tot}(T_p)$$

Scaled impulse $\bar{I}_{t,i}(T_p,t_i)$ ranges between zero and unity. With scaled impulses we obtain new scaled functions $\bar{F}_i(\bar{I}_{t,i})$ and $\bar{t}_i(\bar{I}_{t,i})$ for each propellant temperature T_p. Although arrays $\bar{I}_{t,i}$ range from zero to unity for both propellant temperatures, they do not have the same discrete values. Therefore, we first have to choose the same abscissa for both boundary propellant temperatures, let say in hundred points $\bar{I}_{t,k} = 0.01, 0.02, .., 100$, for example, and then to interpolate $\bar{F}_i(\bar{I}_{t,i})$ and $\bar{t}_i(\bar{I}_{t,i})$ for both temperature for the new abscissa $\bar{I}_{t,k}$ with constant increment. It can be seen that conditions for interpolation of functions $\bar{F}_k(T_p,\bar{I}_{t,k})$ and $\bar{t}_k(T_p,\bar{I}_{t,k})$ between $\bar{F}_k(T_{p.\min},\bar{I}_{t,k})$, and $\bar{t}_k(T_{p.\max},\bar{I}_{t,k})$, $k = 1,2,..,n_m$, is now satisfied, where n_m – number of discrete points of scaled impulses. The scaled functions are shown in the figure 10 and 11 for the AR mine. Therefore, we can now interpolate thrust function and time function with respect to discrete values of scaled impulses for required propellant temperature by using any program for interpolation.

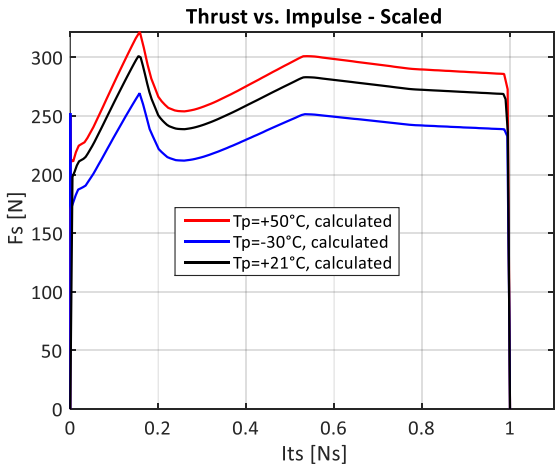

Figure 10. Thrust with respect to scaled impulse for different propellant temperature for the rocket motor of the AR mine.

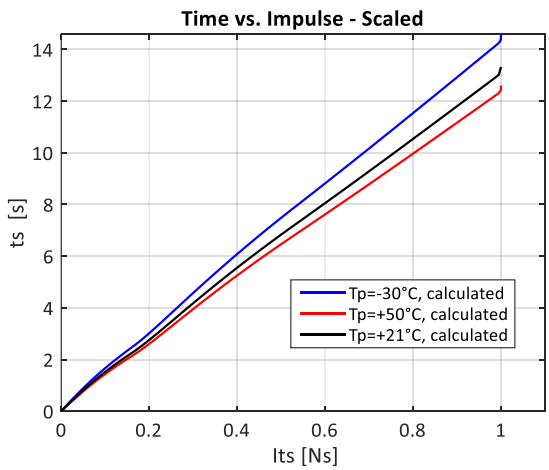

Figure 11. Burning time with respect to scaled impulse for different propellant temperature for the rocket motor of the AR mine.

After interpolation the interpolated thrust and time should be "unscaled" to actual value of total impulse for the required propellent temperature $I_{tot}(T_p)$, which is assumed known, as follows. First calculate total impulse of the interpolated thrust,

$$\bar{I}_{tot}(T_p) = \text{trapz}\left(\bar{t}_k(T_p,\bar{I}_{t,k}), \bar{F}_k(T_p,\bar{I}_{t,k})\right)$$

then calculate the ratio of the total impulses for the thrust at required temperature $I_{tot}(T_p)$ and total impulse of the interpolated scaled thrust

$$k_{T_p} = I_{tot}(T_p)/\bar{I}_{tot}(T_p),$$

and finally correct the interpolated scaled function of thrust with the coefficient of this ratio

$$F_k(T_p,t_k) = k_{T_p}\bar{F}_k(T_p,t_k), \quad k = 1,2,..,n_m$$

Coefficient of Interpolation Quality

Quality of the interpolation of thrust function can be measured by the coefficient of interpolation quality defined by

$$\bar{\sigma}_m = \sqrt{\bar{\sigma}_F^{\,2} + \bar{\sigma}_t^{\,2}}$$

where $\bar{\sigma}_F$ – Coefficient of interpolation quality of thrust

$$\bar{\sigma}_F = \frac{1}{F_{mean}} \sum_{k=1}^{n_m} \left(F_k - F_{k,m}\right)^2 \Big/ \left(n_m - 1\right)$$

and $\bar{\sigma}_t$ – Coefficient of interpolation quality of time

$$\bar{\sigma}_t = \frac{1}{t_b} \sum_{k=1}^{n_m} \left(t_k - t_{k,m}\right)^2 \Big/ \left(n_m - 1\right)$$

In the expression above quantities F_k and t_k are interpolated thrust and time, and $F_{k,m}$ and $t_{k,m}$ are measured thrust and time, n_m – number od data, and F_{mean} is mean value of thrust. Note that total impulse of the interpolated thrust is equal to the total impulse of the measured thrust for the cases where we compare interpolated thrust function with the known measured one.

Consideration of the Calculated Example

Based on explained procedure the program ThrustInterpolation for interpolation of thrust function is made [5]. Program does linear interpolation, but higher order can be implemented. Calculated values of thrust functions for the extreme temperatures we can consider as experimentally obtained values (figure 12).

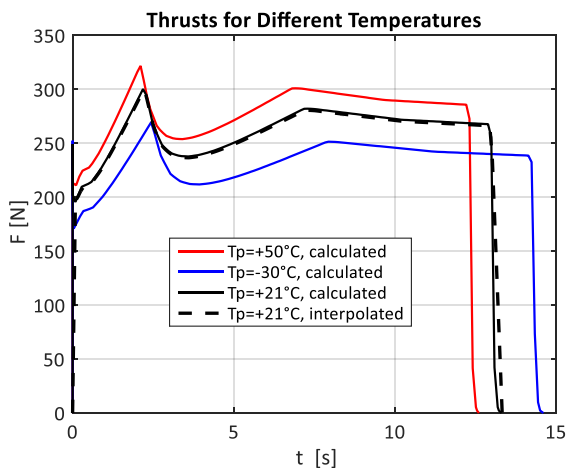

Figure 12. Interpolated thrust in comparison of the calculated for the rocket motor of the AR mine.

Based on these values and explained procedure we interpolated the thrust function for propellant temperature $T_p = 21\,°\mathrm{C}$. In the figure 12 interpolated thrust is represented by dushed line. On the same diagram the calculated value for propellant temperature $T_p = 21\,°\mathrm{C}$ is shown for the comparison. We can see excellent matching between calculated and interpolated curves. Calculated coefficient of interpolation quality is $\bar{\sigma}_m = 3.0\,\%$.

3. TESTING THE METHOD ON REAL EXAMPLES

AT Rocket 90 mm M79 OSA

In the introduction of this report, we stated basic characteristics of the anti-tank shoulder launch rocket 90 mm M79 OSA.

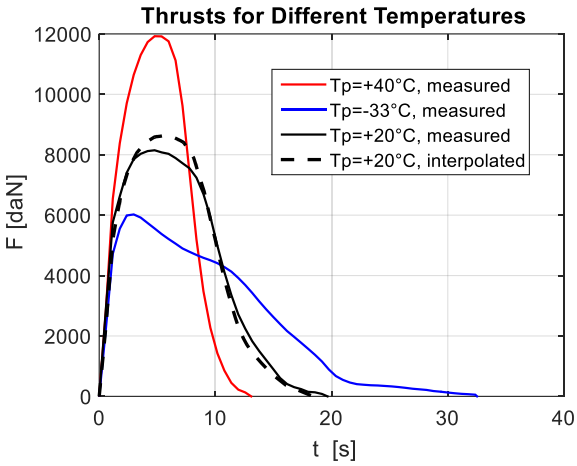

Figure 13. Interpolated thrust in comparison of the calculated for the AT rocket OSA.

Now let us interpolate thrust function for the propellant temperature $T_p = 20\,°\mathrm{C}$ for which measurement is available. By using the program ThrustInterpolation the interpolated function is calculated and shown in figure 13 in parallel with measured values. Taking in mind highly nonlinear dependance of the total impulse with respect to propellant temperature and large erosion in burning the propellant we can conclude that matching between calculated and interpolated curves are very good. Coefficient of interpolation quality is $\bar{\sigma}_m = 4.8\,\%$.

ART Rocket R-2

For the ART rocket R-2 we have measurement of the thrust

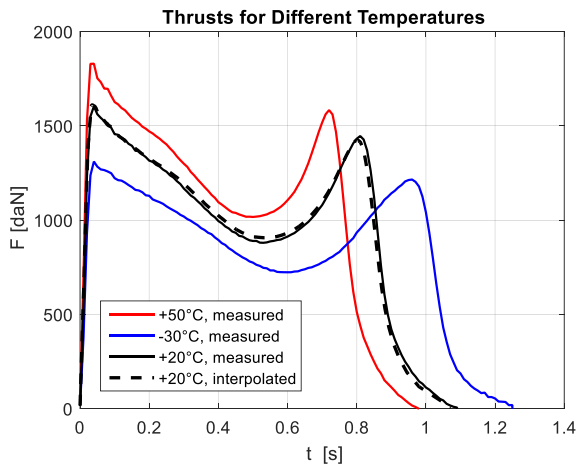

Figure 14. Interpolated thrust in comparison with the measured for the ART rocket.

for the three temperatures, (figure 14), maximum minimum and one at $T_p = 20°C$. Interpolated value for that temperature is also shown in the same figure.

We can see excellent matching between calculated and interpolated curve. Coefficient of interpolation quality is $\bar{\sigma}_m = 1.8\%$.

Guided Anti-tank Weapon BUMBAR

For the Guided Anti-tank Weapon BUMBAR available maximal value of the propellant temperature is $T_p = +50°C$, minimal value $T_p = -30°C$, and two values between them – $T_p = +35°C$ and $T_p = +20°C$ are also available, [6]. The thrusts in time are shown in figure 15. and 16. Therefore, we can test the algorithm in the four combinations.

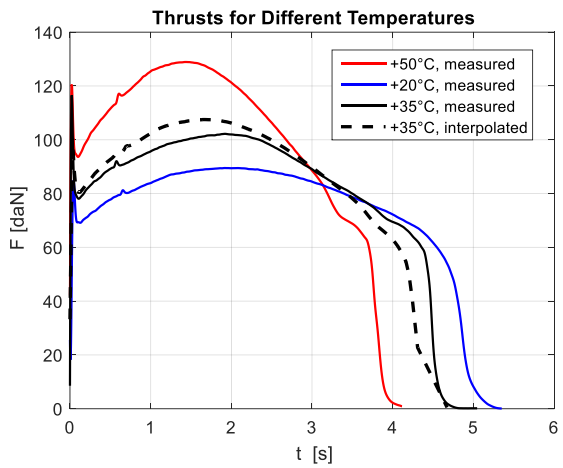

Figure 15. Interpolated thrust in comparison of the measured for the GAW BUMBAR, T_p =+35°C.

In figure 15 and 16 two results of interpolation are shown in parallel with corresponding measurements. Comparison of the interpolated and the measurement curves shows relatively good matching taking in mind relatively large erosive burning in rocket motor, [6]. Coefficient of interpolation quality for the interpolation of thrust for $T_p = +35°C$ is $\bar{\sigma}_m = 5.6\%$ and for $T_p = +20°C$ is $\bar{\sigma}_m = 4.2\%$.

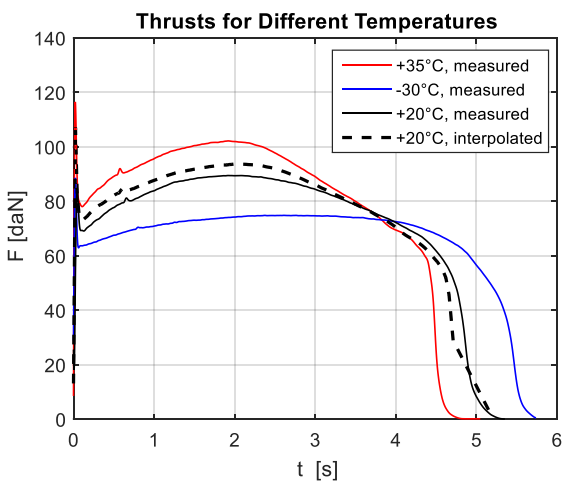

Figure 16. Interpolated thrust in comparison with the measured for the GAW BUMBAR, T_p =+20°C.

Sustainer Rocket Motor of the SAM R-3

For the sustainer rocket motor of the guided SAM R-3 maximal value of propellant temperature is $T_p = +50°C$, minimal value $T_p = -30°C$, and two values between them: $T_p = +18°C$ and $T_p = +0°C$ is shown in figure 17.

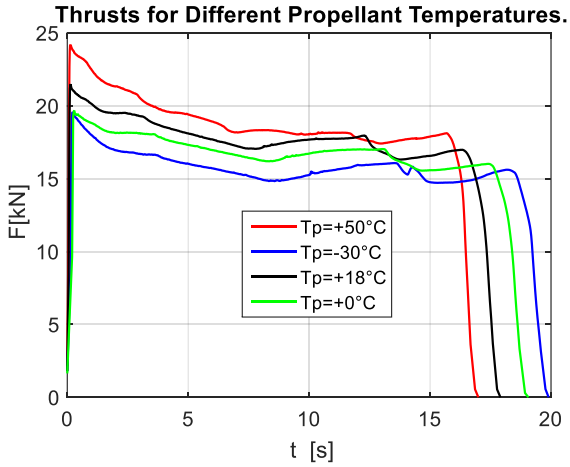

Figure 17. Measured thrusts of the rocket motor SAM R-3 for the four different propellant temperatures.

Let us interpolate thrust function for the powder temperature of $T_p = +18°C$ on two ways – first between curves for $T_p = +50°C$ and for $T_p = -30°C$ and the second between curves for $T_p = +50°C$ and for $T_p = 0°C$.

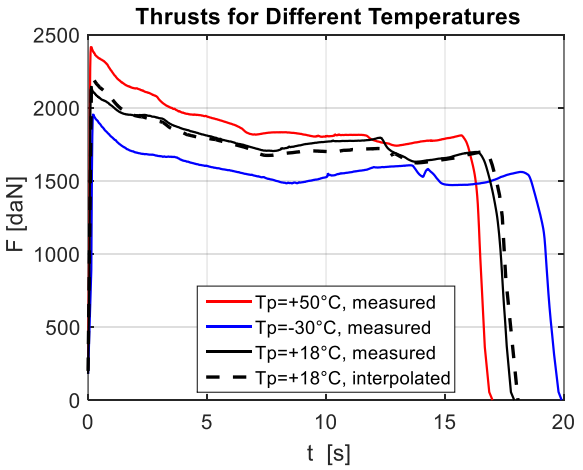

Figure 18. Interpolated thrust for T_p =+18°C between measurement T_p =+50°C and T_p =-30°C in comparison with the measured value for the rocket motor SAM R-3.

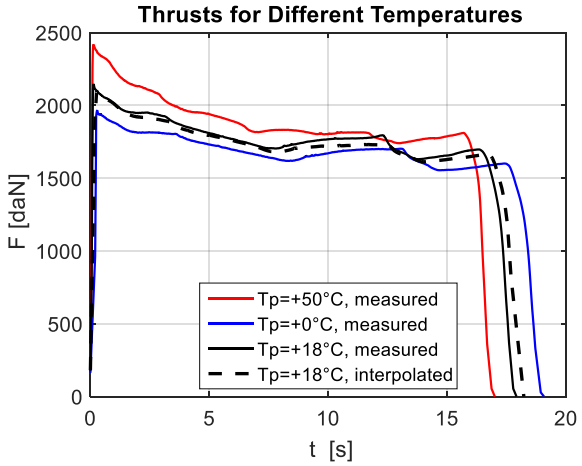

Figure 19. Interpolated thrust for T_p =+18°C between measurement T_p =+50°C and T_p =0°C in comparison with the measured values for the rocket motor SAM R-3.

The interpolated thrust function for the powder temperature $T_p = +18\,°\mathrm{C}$ between curves for $T_p = +50\,°\mathrm{C}$ and for $T_p = -33\,°\mathrm{C}$ is shown in figure 18, and in figure 19. between curves for $T_p = +50\,°\mathrm{C}$ and for $T_p = 0\,°\mathrm{C}$. Coefficient of interpolation quality is $\bar{\sigma}_m = 2.3\%$ for powder temperature $T_p = +18\,°\mathrm{C}$ and $\bar{\sigma}_m = 2.7\%$ powder temperature $T_p = 0\,°\mathrm{C}$.

Again, we can see the matching between interpolated and measured curves are fairly good for both approaches.

Guided Anti-tank Weapon MALYUTKA

For the Guided Anti-tank Weapon MALYUTKA, for the start motor, data are available for the maximal value of the propellant temperature $T_p = +50\,°\mathrm{C}$, minimal value $T_p = -30\,°\mathrm{C}$, and for the value between them – $T_p = +20\,°\mathrm{C}$ are also available, [6]. The thrusts in time are shown in figure 20.

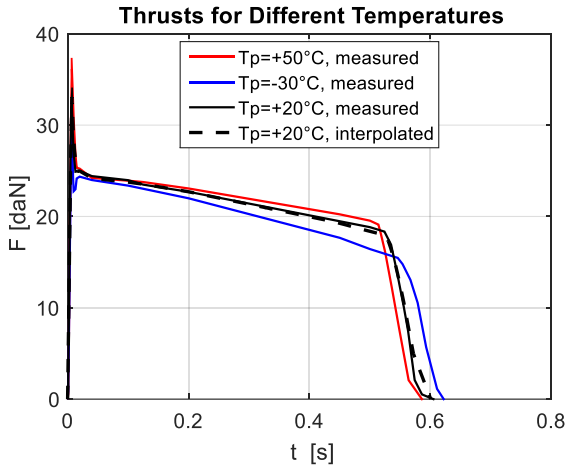

Figure 20. Interpolated thrust in comparison of the measured for the GAW MALYUTKA, T_p =+20°C.

We can see excellent matching between measured and interpolated thrust for $T_p = +20\,°\mathrm{C}$. Coefficient of interpolation quality is $\bar{\sigma}_m = 2.4\%$.

Artillery Rocket 122 mm

For the artillery rocket 122 mm data are available for the maximal value of the propellant temperature $T_p = +50\,°\mathrm{C}$, minimal value $T_p = -40\,°\mathrm{C}$, and for the value between them – $T_p = +20\,°\mathrm{C}$ are also available. The thrusts in time are shown in figure 21.

At minus temperature the thrust is almost constant. At plus maximum propellant temperature the thrust is almost constant after 0.25 s, but the maximum value of the thrust at the beginning of operation of motor is about fifty percent greater than that constant value. This is most likely due to high erosive burning at the beginning of the operation of motor. Even though we can see reasonable good interpolated function for the propellant temperature $T_p = +20\,°\mathrm{C}$ Coefficient of interpolation quality is $\bar{\sigma}_m = 6.4\%$.

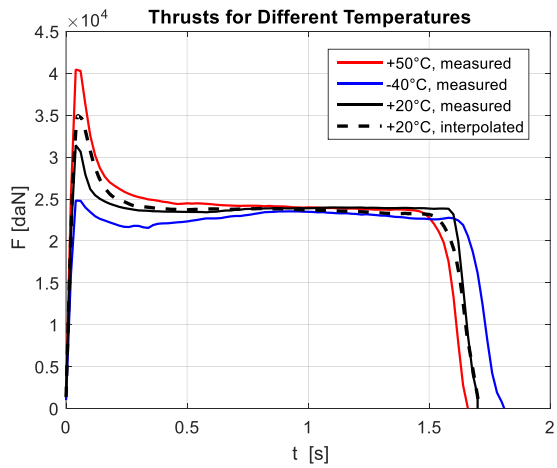

Figure 21. Interpolated thrust in comparison of the measured for the ART rocket, T_p =+20°C.

4. CONCLUSION

Proposed new numerical method to interpolate the thrust curve for a given propellant temperature, based on the known, measured thrust functions for one higher and one lower temperature, gives very good results for engineering application. The method is proved based, first on calculation, and then based on several data obtained by measurement of the rocket motor characteristics for different types of rockets and propellant temperature.

Method gives better results for the cases where burning of propellant is without erosive burning, but it can be used even at high level of erosive burning.

Abstract: *In this paper, the dynamic behavior of a hydraulic recoil mechanism during the firing process is analyzed by varying key parameters that influence the maximum recoil velocity and recoil length, the maximum recoil braking force and the total recoil resistance force. The behavior of the recoil resistance force was analyzed at an elevation angle of 45°, considering variations in the size of the flow control orifices. Additionally, the values of the additional (supplementary) mass and the total recoiling mass were varied. Following the parameter variations, the obtained results were analyzed individually for each case, as well as comparatively across all cases, in order to derermine the optimal combination of parameters that does not adversely affect the operation of the hydraulic recoil mechanism and consequently the stability of the artillery system.*

Keywords: *hydraulic recoil mechanism, barrel recoil, mortar, analysis.*

1. INTRODUCTION

Modern artillery systems require high levels of firing accuracy, reliability, and operational effectiveness. One of the most important stages in the design of artillery systems is the determination of the motion characteristics of their recoiling mass during projectile launch. Upon firing, the projectile and the powder charge acquire a certain amount of momentum, which is transferred to the launching system, i.e. to the weapon. If there were no elastic connection between the barrel and the carriage, the entire weapon would, at the instant the projectile leaves the barrel, receive the same amount of momentum, resulting in an impulsive load of very short duration and an extremely high mechanical force. This would cause the entire weapon to recoil, requiring the weapon to be respositioned and re-aimed at the selected target.

To prevent these adverse effects, the recoil impulse is transmitted to the recoiling parts of the weapon through the recoil mechanism. The action of the recoil mechanism slows down the recoil motion and prolongs the duration of the load acting on the carriage, while also reducing the mechanical force to an acceptable level (from the standpoint of weapon stability and structural integrity). The dynamics of the recoiling parts must be such that, during the projectile's travel through the barrel, they generate the smallest possible oscillations that could compromise firing precision and accuracy [1].

For large-caliber artillery systems, such as a 203 mm weapon with a smooth barrel, the recoil length is one of the key parameters directly affecting the design of the recoil mechanism, the loading of the carriage, and the overall performance of the system. The recoil length is influenced by a number of related parameters, including projectile characteristics, the powder charge, the mass of the moving parts, as well as the parameters of the hydraulic and pneumatic components of the recoil system.

In engineering practice, the design of artillery systems over the past decades has relied on conventional methods for determining the motion of recoiling parts during both recoil and counter-recoil. These methods are based on the approximate integration of the differential equations governing the motion of the recoiling mass, with the introduction of appropriate simplifying assumptions and hypotheses that enable the integration.

Advances in information technology and computer engineering have created the conditions for the numerical integration of differential equations and have enabled more sophisticated analyses of the behavior of artillery systems during projectile launch. Such analyses also make it possible to investigate the dynamic behavior of the weapon during firing and to perform a more detailed assessment of its structural integrity under dynamic and impulsive loading conditions [1].

For artillery systems equipped with an elastic carriage, stability during the firing process must be ensured. To achieve the required stability, an appropriate variation of the braking force during recoil and counter-recoil is necessary. Furthermore, it is required to establish the relationship between the velocity and displacement of the recoiling parts and the forces P_{kn} and R suring recoil, as well as the force R_v during counter-recoil, as functions of time or the displacement of the recoiling parts. Since no analytical lav describing the variation of $P_{kn}(t)$ exists, the kinematic quantities of the recoiling parts (V, X, y, t) cannot be determined by integrating the differential equation of motion of the recoiling parts [2].

Therefore, the analysis of the motion of the recoiling parts compromises the following three phases:

- the free recoil phase, i.e. motion under the action of the force P_{kn} without any braking;
- the braked recoil phase, i.e. motion under the action of the braking force R and
- the counter-recoil phase, i.e. motion under the action of the force R_v.

The motion of the recoiling parts during free recoil begins together with the projectile motion inside the barrel. To facilitate the calculations, the recoil process is divided into three periods:

- the first period (projectile travel through the barrel);
- the second period (outflow of powder gases) and
- the third period (inertial motion of the recoiling parts, P_{kn}=0) [2].

The kinematic quantities characterizing free recoil are the velocity W and the displacement L.

Braked recoil represents the actual motion of the recoiling mass during the firing process under the action of the forces acting on the recoiling mass (the force P_{kn} and the resultant recoil resistance force R). The motion of the recoiling parts during braked recoil is analyzed over the same periods as those considered for free recoil [2].

The law governing the variation of the resultant recoil resistance force R(t) is specified in advance, depending on the type of artillery system, and must satisfy the following requirements:

- the maximum value of the recoil resistance force must not exceed its maximum allowable value determined by the stability requirements of the weapon during recoil;
- the braking of the recoiling parts must be uniform, and their kinetic energy must be completely dissipated over the specified recoil length within the specified time interval;
- the loading of the carriage during firing must be kept as low as possible [2].

2. INPUT INTERNAL BALLISTIC PAREMETERS

The internal ballistic analysis is used to determine the maximum powder gas pressure (P_{max}), the propellant gas pressure at the muzzle (P_u), and the projectile muzzle velocity (v_0) [3]. The input data for the internal ballistic analysis are presented in Table 1. For the purposes of the analysis, a single type of powder was used.

Table 1. Input data for the internal ballistic analysis

No.	Characteristic parameter	Value
1.	Barrel cross-sectional area, S [m^2]	0.032360
2.	Total forward travel of the projectile in the barrel, X_u [m]	3.34
3.	Initial volume of the powder chamber, W_0 [m^3]	0.02150
4.	Cross-sectional area of the clearance between the projectile body and the barrel wall, S_z [m^2]	0.000001
5.	Clearance shape coefficient, ξ	0.61
6.	Projectile mass, m [kg]	100
7.	Projectile cross-sectional area, S_{pr} [m^2]	0.032360
8.	Specific work of the powder gases of the supplementary powder charge, f_b [J/kg]	1080000
9.	Covolume of the powder gases of the supplementary powder charge, α	0.00077
10.	Powder density, ρ [kg/m^3]	1600
11.	Burning rate coefficient of the supplementary powder charge, u_{z0} [m/sPa]	$6.158 \cdot 10^{-8}$
12.	Ratio of specific heats, κ	1.2
13.	Half-thickness of the powder grain, r_0 [m]	0.00026
14.	Shape coefficient, κ_1	1.2026
15.	Shape coefficient, λ_1	-0.16846
16.	Specific work of the powder gases of the main powder charge, f_{b0} [J/kg]	1080000
17.	Covolume of the powder gases of the main powder charge, α_0	0.00077
18.	Mass of the one bag of the supplementary powder charge, m_{dbp} [kg]	0.7
19.	Mass of the main powder charge, m_{obp} [kg]	0.078

The muzzle velocity and the maximum pressure depend on the mass of the powder charge, which was varied by adding one to six bags of the supplementary powder charge. Table 2 presents the values of the muzzle velocity and the maximum powder gas pressure as functions of the powder charge mass and the projectile mass, while their variations are illustrated in Figures 1 and 2.

Table 2. Values of the muzzle velocity and maximum powder gas presure

Powder charge mass	1	2	3	4	5	6
m_{bp} [kg]	0.778	1.478	2.178	2.878	3.578	4.278
V_0 [m/s] 75 kg	176.23	248.06	303.54	352.21	394.80	434.29
P_m [bar] 75 kg	219.59	516.21	836.54	1176	1534.26	1912.05
V_0 [m/s] 100 kg	154.49	215.55	263.32	304.96	342.09	376.58

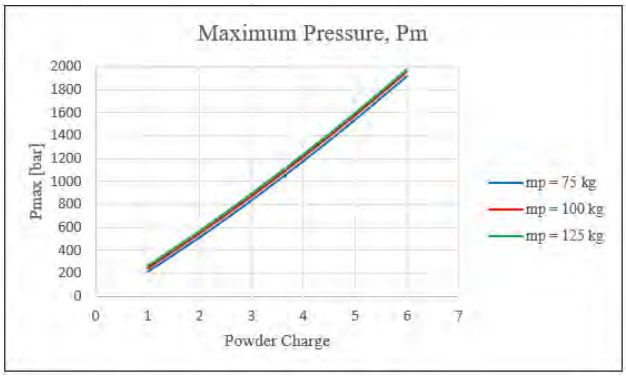

Figure 2. Variation of the maximum propellant gas pressure as a function of the amount of the supplementary powder charge

3. CALCULATION OF THE RECOIL RESISTANCE FORCE

To investigate the possibility of achieving the desired law governing the variation of the recoil resistance force, it is necessary to analyze its components. These components are: the recuperator force (F_p), the recoil brake force (F_{kt}), the friction force acting on the cradle guideways and the seals (F_{tr}) and the projection of the weight of the recoiling parts onto the direction of recoil ($M_0 g \sin\varphi$). The general equation for determining the recoil resistance force at an elevation angle φ is given by [1]:

$$R = F_p + F_{kt} + F_{tr} - M_0 g \sin\varphi \tag{1}$$

The recoil resistance force acts along the line passing through the center of mass of the recoiling parts (parallel to the bore axis) and is independent of the arrangement of the recoil mechanism components on the weapon. The approximate value of the friction force acting on the cradle guideways and in the seals of the recoil mechanism is given by the following equation [1]:

$$F_{tr} = M_0 g (f \cos\varphi + \nu) \tag{2}$$

where:

f - coefficient of friction i ν - proportionality coefficient for the seal fricition force.

From the diagram illustrating the variation of the forces acting on the recoiling parts during recoil (Figure 3), it can be observed that the desired braking law can be achieved only by an appropriate selection of the hydraulic resistance force in the recoil brake. For engineering design calculations, the friction forces may be considered constant throughout the entire recoil stroke with sufficient accuracy. The recuperator force is determined based on the requirement that the recoiling mass returns to its forward position after the completion of recoil and remains in that position at all elevation angles. Therefore, the only parameter that can be adjusted is the law governing the variation of the force in the hydraulic recoil brake.

Consequently, one of the fundamental requirements in the design of the recoil brake is to achieve the prescribed variation of its resistance force throughout the recoil stroke [1].

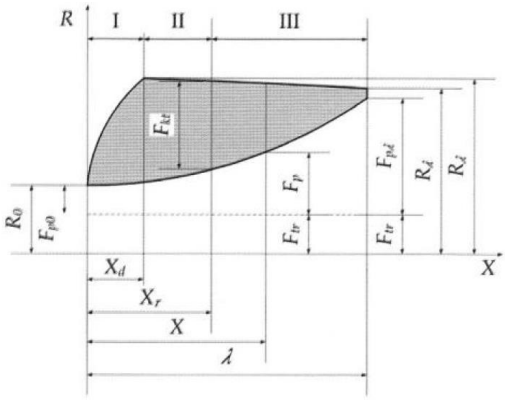

Figure 3. Components of the recoil resistance force [1]

Furthermore, it is well established that, for artillery systems with given energy characteristics and a prescribed recoil length, the loading of the carriage is minimized when the braking of the recoiling parts is achieved by a constant braking force throughout the entire recoil stroke.

It should be borne in mind that all design calculations are performed for specified and known operating conditions of the artillery system. If any of the operating conditions change, the system behavior and structural integrity must be re-evaluated under the new conditions [1].

The initial value of the recoil resistance force is determined by the following equation:

$$R_0 = F_{p0} + F_{tr} - M_0 g sin\varphi \quad (3)$$

4. ANALYSIS OF THE HYDRAULIC RECOIL BRAKE PERFOMANCE UNDER VARIATIONS OF INFLUENTIAL PARAMETERS

To provide a clearer evaluation of the behavior of the hydraulic recoil brake during the firing process under different operating conditions, the following parameters were varied: the powder charge (by adding from one to six bags of powder, each bag containing 700 g of the same type of powder), the projectile mass, m_p (75, 100 and 125 kg), the recoiling mass, m_t (the existing recoiling mass increased by 100, 200 and 300 kg, as well as the original mass without any increase), and the flow area of the ports in the hydraulic recoil brake, which is determined by the positions of the long and short grooves in the recoil brake counter-piston. The positions of the long and short grooves are adjusted by rotating the counter-piston, thereby regulating their opening percentages. The analysis was carried out for a 203 mm artillery system with a smooth barrel. An elevation angle of 45° was selected. Table 3 presents the combinations of the opening of the long and short grooves used in the analysis.

Table 3. Combinations of the opening percentages of the long and short grooves

Long	100%	100%	100%	100%	Long
Short	0%	25%	50%	75%	100%
Long	0%	25%	50%	75%	Short 100%
Short	100%	100%	100%	100%	

Figures 4-7 present the maximum recoil length, X_{max}, the maximum recoil velocity, V_{max}, the maximum recoil resistance force, R_{max} and the maximum hydraulic recoil brake force, F_{kmax}, for all previously described paremeter combinations.

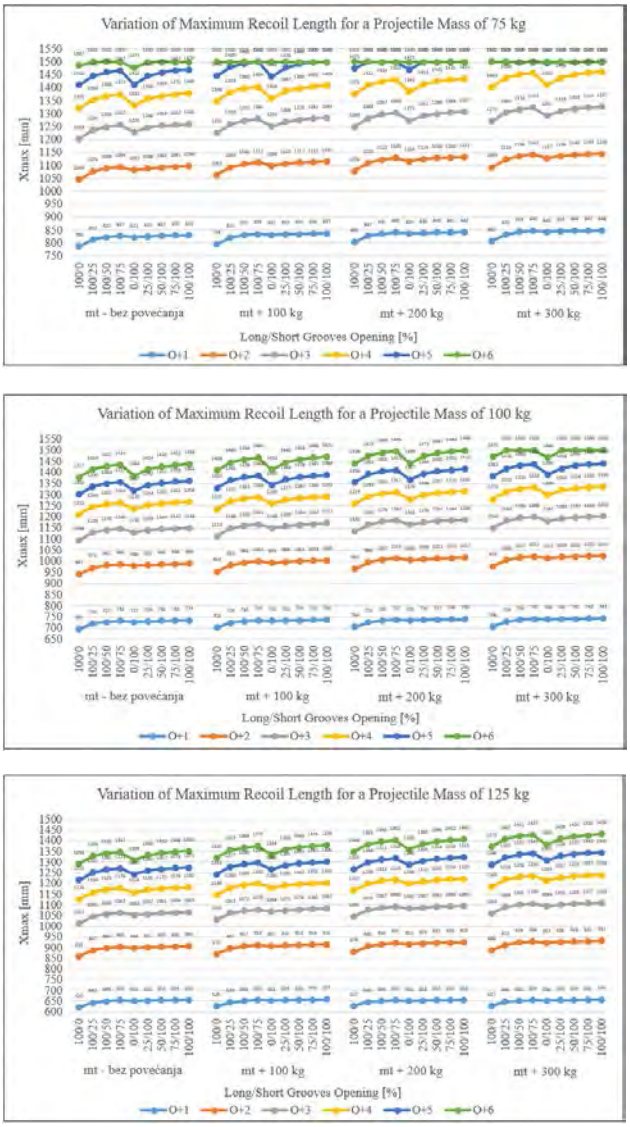

Figure 4. Maximum recoil length

The analysis of the diagram showing the maximum recoil length (X_{max}) indicates that, in all cases considered, the minimum recoil length is achieved with the combination of a fully open long groove and a fully closed short groove. This trend remains unchanged independent of the projectile mass, the recoiling mass, and the powder charge used. As the opening percentage of the short groove increases, the maximum recoil length gradually increases.

When the effects of the recoiling mass and the projectile mass are considered, it can be observed that a 75 kg projectile exceeds the acceptable recoil length limit for all

supplementary powder charges. Without an increase in the recoiling mass, firing is permissible up to supplementary powder charge No. 5, while for configurations with an increased recoiling mass, the upper permissible limit is supplementary powder charge No. 4.

For a 100 kg projectile, acceptable recoil length values for all six supplementary powder charges are achieved when the recoiling mass is unchanged or increased by 100 kg or 200 kg. However, for safety reasons and to ensure the protection of the weapon system, firing should be carried out using the configuration with a fully open long groove and a fully closed short groove.

An increase in the recoiling mass by 300 kg limits the use of all supplementary powder charges, as the highest supplementary charge must not be used because it results in the maximum permissible recoil length being reached.

With a 125 kg projectile, the most favorable results are obtained under all operating conditions considered. Nevertheless, even in this case, firing with the long grooves fully open and the short grooves fully closed in the recoil brake counter-piston is recommanded.

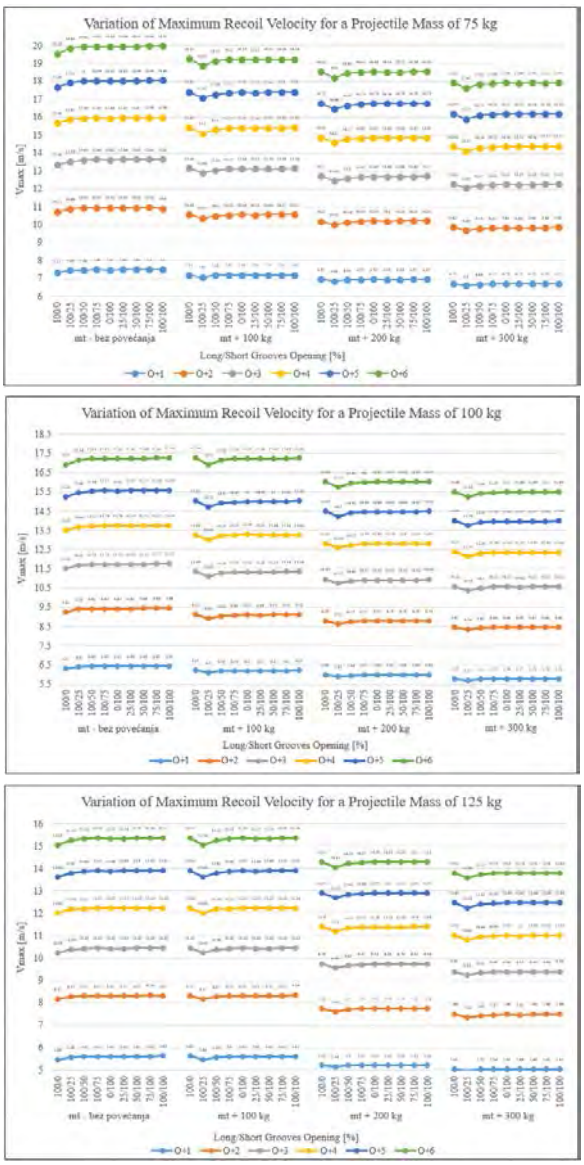

Figure 5. Maximum recoil velocity

In all cases considered, the largest recoiling mass results in the lowest maximum recoil velocity (V_{max}). An increase in the projectile mass leads to a reduction in the maximum recoil velocity, while an increase in the barrel mass further decreases the maximum recoil velocity. The highest recoil velocities are obtained for a 75 kg projectile and the lowest barrel mass, whereas the lowest recoil velocities are achieved for a 125 kg projectile and the highest barrel mass

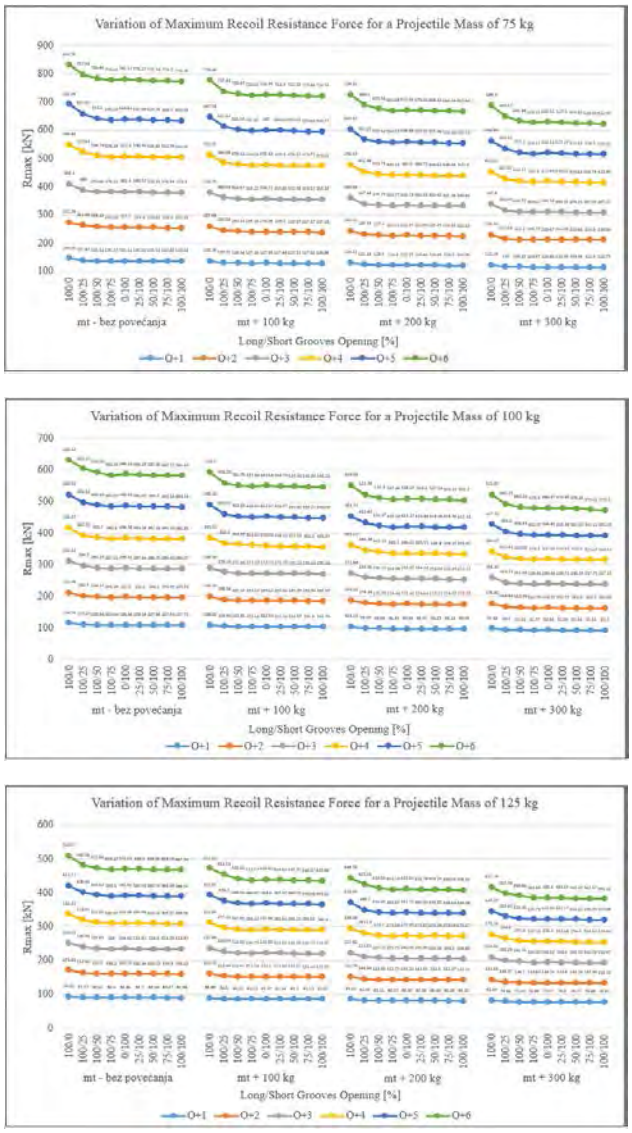

Figure 6. Maximum recoil resistance force

As the recoiling mass and the projectile mass increase, the maximum recoil resistance force (R_{max}) decreases. The maximum recoil resistance force is achieved with the combination of a fully open long groove and a fully closed short groove in the recoil brake counter-piston, whereas the minimum value is obtained when both grooves are fully open. It can also be observed that increasing the amount of the supplementary powder charge results in a significant increase in the maximum recoil resistance force.

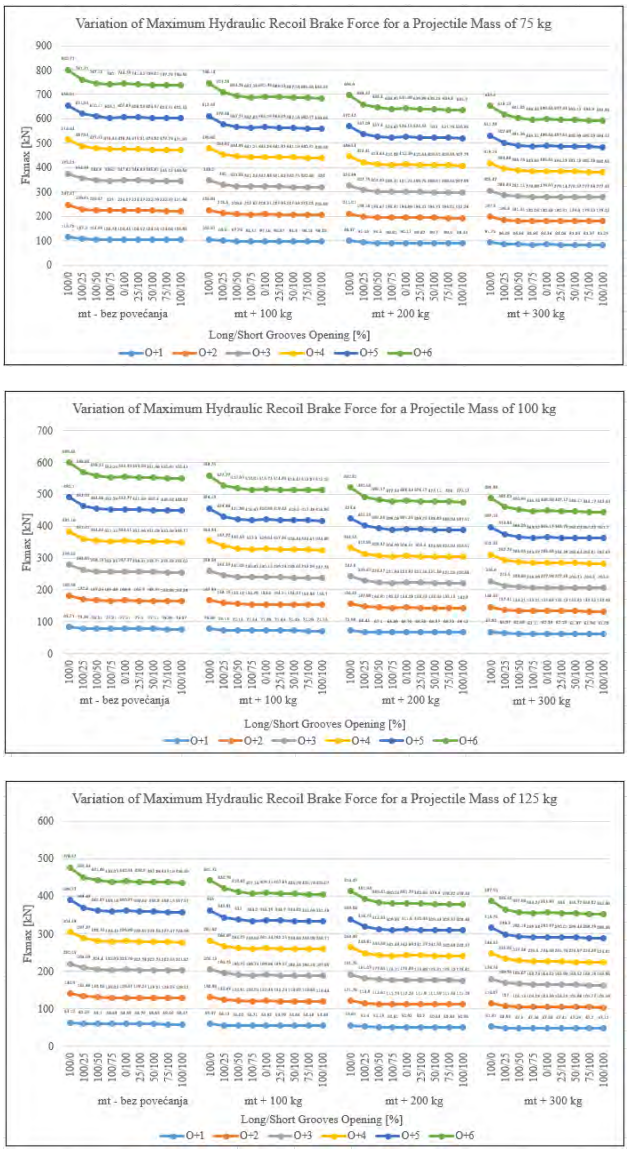

Figure 7. Maximum hydraulic recoil brake force

The maximum hydraulic recoil brake force (F_{kmax}) decreases with increasing projectile mass as well as with increasing recoiling mass. The powder charge has a significant influence on the maximum hydraulic recoil brake force, which increases significantly with an increase in the powder charge mass.

5. OPTIMIZATION OF THE INPUT PARAMETERS

Based on the conducted analysis of the effects of the projectile mass, the recoiling mass, and the grooves opening configuration of the hydraulic recoil brake counter-piston on the fundamental parameters governing the performance of the recoil brake (maximum recoil length X_{max}, maximum recoil velocity V_{max}, maximum recoil resistance force R_{max} and maximum hydraulic recoil brake force F_{kmax}), the system was optimized with the objective of enabling the use of all six powder charges without causing damage to the 203 mm artillery system.

The analysis of the obtained results showed that the counter-piston channel configuration with the long grooves fully open and the short grooves fully closed provides the most favorable operating characteristics of the system. This configuration yields the minimum values of the maximum recoil length and maximum recoil velocity while also producing the maximum values of the recoil resistance force and the hydraulic recoil brake force, indicating the most efficient deceleration of the recoiling parts during the recoil process. Therefore, this configuration was adopted as the optimal design solution.

During the optimization process, an additional design constraint was adopted, according to which the maximum recoil length must not exceed 1450 mm, although the structurally permissible limit is 1500 mm. The provides an additional 50 mm safety reserve, thereby enchancing the reliability of the system under operating conditions.

The results showed that the 75 kg projectile does not satisfy the established requirement for the highest powder charge (O+6), since the maximum recoil stroke exceeds the adopted limit. In contrast, the 100 kg and 125 kg projectiles satisfy the specified requirement, with the 125 kg projectile exhibiting the lowest values of all analyzed parameters.

It is particularly important that the 125 kg projectile, in combination with the configuration featuring fully open long grooves and fully closed short gloves, and without any additional increase in the recoiling mass, achieves a maximum recoil stroke of 1292 mm with the O+6 powder charge, providing a 158 mm safety reserve with respect to the adopted limit of 1450 mm.

At the same time, this configuration yields the lowest values of both the maximum recoil resistance force and the maximum hydraulic recoil brake force compared with all other analyzed configurations.

Based on the overall analysis, the optimal system configuration was identified as the combination of a 125 kg projectile, a counter-piston configuration with the long grooves fully open and the short grooves fully closed, without any increase in the recoiling mass. This configuration enables the use of all six additional powder charges while satisfying the established design constraints and providing the most favorable operating characteristics of the recoil system.

A particularly important advantage of the proposed optimal solution is that it is achieved without increasing the recoiling mass, thereby avoiding any additional structural loading of the system. Table 4 presents the values of the hydraulic recoil brake performance indicators for the selected optimal configuration.

Table 4. Performance indicators of the hydraulic recoil brake for the selected optimal configuration

	O+1	O+2	O+3	O+4	O+5	O+6
X_{max} [mm]	620	859	1013	1126	1216	1292
V_{max} [m/s]	5.48	8.17	10.23	12.02	13.62	15.04
R_{max} [kN]	94.01	171.45	252.03	336.41	422.21	510.07
F_{kmax} [kN]	63.12	140.9	220.15	304.49	389.77	476.52

6. CONCLUSION

This paper analyzes the behavior of the hydraulic recoil system of a 203 mm artillery system, with a smooth barrel with respect to the main parameters of the recoil process. Following the presentation of the theoretical background and the internal ballistic parameters used in the calculations, a numerical analysis was performed to investigate the influence of different recoil brake flow-grooves configurations, projectile mass, and additional recoiling mass on the main performance characteristics of the system, including the maximum recoil length, maximum recoil velocity, maximum recoil resistance force and maximum hydraulic recoil brake force.

The obtained results indicate that increasing the projectile mass leads to a reduction in all previously analyzed parameters describing the performance of the hydraulic recoil brake. It was also found that the selected combination of long and short grooves openings provides the most favorable operating characteristics of the system by achieving the lowest values of the maximum recoil velocity and maximum recoil length, while while also ensuring the highest braking efficiency of the recoiling mass.

Based on the optimization results, the optimal configuration consists of a 125 kg projectile, with the long grooves fully open and the short grooves fully closed without increasing the recoiling mass. This configuration enables the use of all six analyzed powder charges while satisfying the maximum allowable recoil length of 1450 mm and providing a sufficient design safety reserve with respect to the permissible travel limit of the recoiling parts under the most critical operating conditions.

The results demonstrate that an appropriate selection of the flow-grooves geometry and the main mass-related parameters can significantly improve the performance of the recoil system without increasing the mass of the recoiling components. Consequently, reliable operation of the artillery system is ensured for all analyzed powder charges, while reducing structural loading and maintaining system stability throughout the firing process.

Abstract: *This paper presents a dynamic analysis of the operating mechanism of a 30 mm automatic cannon based on the gas-operated principle. By utilizing internal ballistics parameters obtained through the Drozdov method and the Bravin mathematical-mechanical model, a dynamic analysis of the bolt motion was performed. A MATLAB model of the 30 mm automatic cannon's bolt kinematics was developed, focusing on the dynamics during the recoil and counter-recoil cycles. This approach enabled the calculation of the theoretical rate of fire and illustrated the bolt velocity variations as a function of time. Finally, the obtained results were compared and validated against experimental data.*

Keywords: *30 mm automatic cannon, dynamic analysis, gas-operated mechanism, bolt kinematics, MATLAB modeling*

1. INTRODUCTION

A weapon based on the principle of gas operation is one that diverts part of the propellant gases through an opening in the barrel wall after the projectile passes that opening. This weapon uses the energy of the diverted gases to move the main assembly, which in turn drives all other parts of the weapon, while also accumulating energy in the return springs of the main assembly.

The device for diverting the propellant gases is most commonly called the gas regulator (gas piston system), and it consists of the following elements: the gas cylinder (often called the gas chamber), the working volume — the space into which the gas flows, ensuring the thermal process and the mechanical action of the gas — the gas port, a channel of various shapes through which the propellant gases pass from the barrel bore into the working volume of the gas regulator, the piston, which converts the gas action into kinetic energy, and the clearances and vent ports through which the propellant gases escape from the working volume, Fig. 1.

The problem of selecting the design parameters of the gas-operating system has given rise to a number of sub-variants of the piston-operated gas system: static, dynamic, static-dynamic, and others [1].

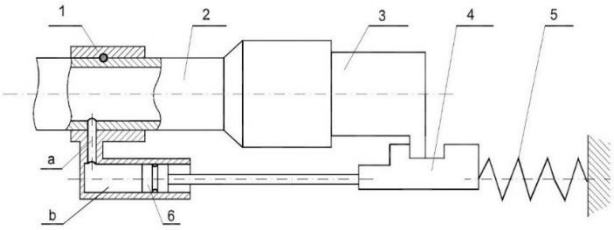

Figure 1. Diagram of automatic weapon based on the gas-operated principle
1-gas chamber, 2-barrel, 3-bolt, 4- bolt carrier, 5 – return spring, 6- piston, a- gas port, b – gas cylinder [2].

Figure 2 shows the characteristic variation of pressure in the gas regulator relative to the propellant gas pressure in the barrel, from the moment the projectile passes the gas port to the moment the outflow of the propellant gases ends.

The propellant gases behind the projectile, once its base passes the port, flow through the gas port and fill the cylinder containing the piston. The pressure of the diverted gas pushes the piston in the cylinder, so this work can be used to perform certain functions of the automatic weapon. This work is usually used to unlock the bolt or to actuate other automatic mechanisms.

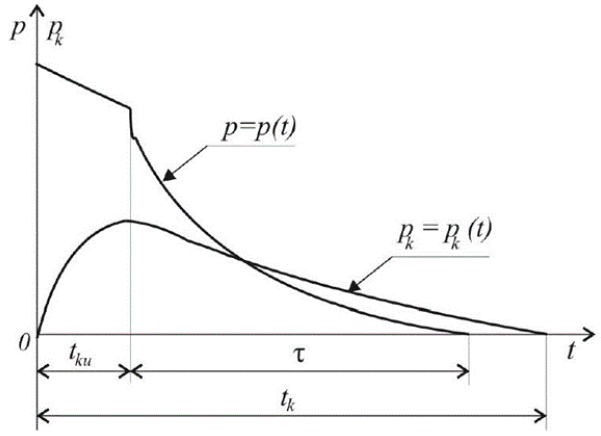

Figure 2. Pressure diagrams in the barrel and in the gas cylinder

The work of the diverted propellant gases can be used for various mechanisms, with the most common design solution being a cylinder with a piston and a piston rod for force transmission.

At the moment of firing, the bolt is firmly locked to the barrel. The force that propels the projectile and gases forward simultaneously acts on the case head in the opposite direction and produces recoil of the entire weapon.

When the projectile passes the gas port, the gases enter the gas port channel and generate a force on the gas piston.

The amount of gas required to move the piston is relatively small and does not significantly affect the muzzle velocity of the projectile.

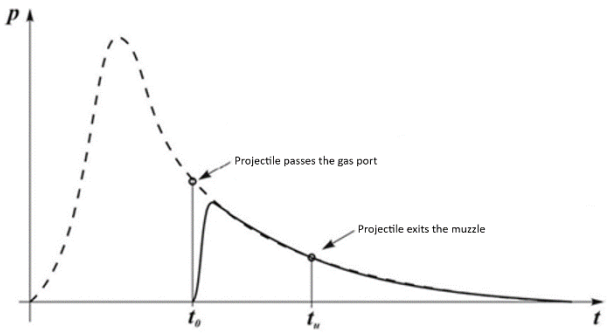

Figure 3. Propellant Gas Pressure Diagram

A piston with a larger effective area receives a greater impulse, and the magnitude of the impulse depends on the duration and magnitude of the gas pressure. This impulse depends directly on the size and shape of the port in the barrel wall. The magnitude of the piston energy depends on the piston mass, and for a given impulse, a piston of smaller mass has greater energy, since:

$$E = \frac{1}{2}mv^2 = \frac{1}{2}\frac{(mv)^2}{m} = \frac{1}{2}\frac{I^2}{m} \quad (1)$$

In accordance with this, the influencing factors that determine the kinetic energy of the piston are:

- the pressure in the barrel,
- the position and size of the gas port,
- the cylinder diameter (shape of the port),
- the piston area and its mass [1] [3] [4].

2. PROPELLANT GAS PRESSURE

The internal ballistics calculation was performed using the Drozdov method. The Drozdov method is used for weapons that employ a single type of propellant. These include small arms, guns, and howitzers when firing charges made of only one type of propellant. This method is based on the analytical solution of the system of internal ballistics equations [5].

For the adopted propellant data and the structural characteristics of the barrel of the 30 mm automatic cannon, an internal ballistics calculation was performed, followed by optimization aimed at achieving a higher initial velocity and lower propellant gas pressure, and the final law of propellant gas pressure variation along the barrel as a function of the projectile's travel distance was obtained, Figure 4.

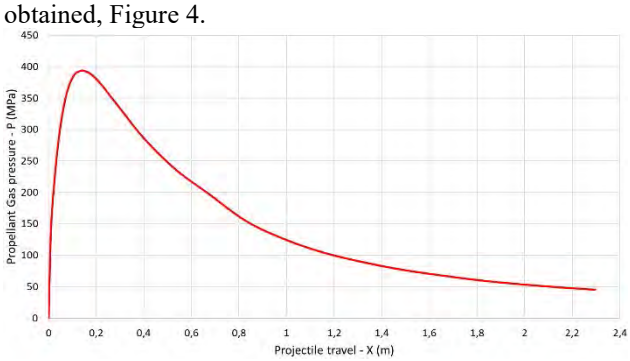

Figure 4. Optimized diagram of propellant gas pressure versus travel distance

Both domestic and foreign scientists have studied the examination of propellant gas pressures in gas regulators, with the aim of determining the law of variation *p=f(t)* and using that law to calculate the motion characteristics of the automatic weapon's main assembly. The problem of pressure in the gas regulator was addressed by Blagonravov A.A., Mamontov M.A., Bravin E.L., Paul Vieille, Jean Constantinet, Karl Becker, Hermann Scherer, Fiedner and Hutchings and others.

Bravin does not treat the process of gas outflow into the chamber as a thermodynamic process but instead offers an empirical expression for the propellant gas pressure in the gas chamber and on the piston of the main assembly, in order to represent as accurately as possible, the law of pressure variation of the gases entering the gas chamber [6].

As the basic factors influencing the law of propellant gas pressure variation on the piston, Bravin E.L.,[7] takes:

- the ratio of the cross-sectional areas of the gas port and the piston:

$$\sigma_0 = \frac{S_\phi}{S_n} \quad (2)$$

- the transverse load of the piston:

$$K_0 = \frac{M_0}{S_n} \quad (3)$$

In doing so, the following expression for the variation of gas pressure on the piston as a function of time is used:

$$p = p_\phi e^{-\frac{t}{b}}\left(1 - e^{-\alpha\frac{t}{b}}\right) \quad (4)$$

Where: $\alpha = n\frac{S_w M_w}{S_2^n}$; $b = \frac{i_0}{p_\phi}$; $i_0 = \frac{p_\phi + p_u}{2}t_n + \frac{p_u}{A}$

α – coefficient of useful action (efficiency);

b – Bravin's coefficient;

i_0 – unit impulse of the propellant gases in the barrel;

p_ϕ - the propellant gas pressure in the barrel bore at the moment the projectile passes the gas port;

p_u - the propellant gas pressure in the barrel bore at the moment the projectile exits the barrel;

$$A = 0.365\frac{\beta^2}{\beta - 0.5} * \frac{\vartheta_0}{L'} \quad (5)$$

$$\beta = C\frac{d}{\vartheta_0}\sqrt{\frac{p_\partial L' g}{\omega}} \quad (6)$$

C – an experimental coefficient equal to $C = 1.5$

t_n - the time from the moment the projectile passes the gas port until it exits the barrel;

M_n - the mass of the automatic weapon's driving assembly

i_0 - the unit impulse of the propellant gas pressure in the barrel bore during time t_g

Then, for the unit (specific) impulse in the gas-operating device, we obtain:

$$i_k = \int_0^t p_\phi e^{-\frac{t}{b}}\left(t - e^{-\alpha\frac{t}{b}}\right)dt =$$
$$= p_\phi b\left[\frac{\alpha}{1+\alpha} + \frac{\alpha}{1+\alpha}e^{-(1+\alpha)\frac{t}{b}} - e^{-\frac{t}{b}}\right] \quad (7)$$

For $t \to \infty$ $i_k = p_\phi b\frac{1}{1+\alpha}$ where $\frac{\alpha}{1+\alpha} = \eta$

The quantity η represents the efficiency coefficient of the gas-operating system.

For $\eta = 1$ the entire pressure impulse in the barrel bore would be transferred to the piston without losses.

The total unit impulse in the barrel bore is:

$$i_0 = \frac{p_\phi + p_\partial}{2}t_n + \frac{p_\partial}{A} \quad (8)$$

гд where A is from equation (4),

then: $p_\phi b = i_0$ and $b = \frac{i}{p_\phi}$

In doing so, when $\alpha \to \infty$ the expression for the pressure in the gas chamber takes the form:

$$p = p_\phi e^{-\frac{t}{b}}\left(1 - e^{-\alpha\frac{i}{e}}\right) \quad (9)$$

For $\alpha \to \infty$:

$$p = p_\phi e^{-\frac{t}{b}} \quad (10)$$

and will represent the limiting family of curves:

$$p = p_\phi e^{-\frac{t}{e}}\left(1 - e^{-\alpha\frac{t}{b}}\right) \quad (11)$$

The dependence: $p = p_\phi e^{-\frac{t}{b}}$ can approximately express the law of pressure variation in the barrel bore after the projectile passes the gas port until the end of the period.

The impulse of the propellant gas pressure force on the piston is determined based on the expression:

$$S_n i_k = S_n\left(\frac{\alpha}{1+\alpha} + \frac{1}{1+\alpha}e^{-(1+\alpha)\frac{t}{b}} - e^{-\frac{t}{b}}\right)p_\phi b \quad (12)$$

But since $M_n V = S_n i_k$:

$$M_n V = S_n\left(\frac{\alpha}{1+\alpha} + \frac{1}{1+\alpha}e^{-(1+\alpha)\frac{t}{b}} - e^{-\frac{t}{b}}\right)p_\phi b \quad (13)$$

For $t \to \infty$: $M_n V = S_n\frac{\alpha}{1+\alpha}$; for $M_n = const$ the expression for $M_n V$ allows the velocity of the main assembly to be determined at any moment in time.

By integrating the expression for velocity, we obtain the expression for the displacement of the main assembly:

$$X = \int_0^x dX = \int_0^t V dt = \frac{S_n b}{M_n}\left(\frac{\alpha}{1+\alpha}\cdot\frac{t}{b} - \frac{\alpha(2+\alpha)}{(1+\alpha)^2} - \frac{1}{(1+\alpha)^2}e^{-(1+\alpha)\frac{t}{b}} + e^{-\frac{t}{b}}\right)i_0 \quad (14)$$

For easier use of the expressions for determining p, V, X, coefficient tables have been formed:

$$K_p = e^{-\frac{t}{b}}\left(1 - e^{-\alpha\frac{t}{b}}\right) \quad (15)$$

$$K_v = \frac{\alpha}{1+\alpha} + \frac{1}{1+\alpha}e^{-(1+\alpha)\frac{t}{b}} - e^{-\frac{t}{b}} \quad (16)$$

$$K_x = \frac{\alpha}{1+\alpha}\cdot\frac{t}{b} - \frac{\alpha(2+\alpha)}{(1+\alpha)^2} - \frac{1}{(1+\alpha)^2}e^{-(1+\alpha)\frac{t}{b}} + e^{-\frac{t}{b}} \quad (17)$$

Then we obtain:

$$p = p_\phi K_p \quad (18)$$

$$V = \frac{S_n i_0}{M_n}K_v \quad (19)$$

$$X = \frac{S_n b i_0}{M_n}K_x = \frac{Vb}{K_v}K_x \quad (20)$$

To determine the quantity $\eta_k = \frac{\alpha}{1+\alpha}\eta_0 v_0 v_g v_{g0}$ dependency tables have been formed

$$\eta_0 = f(\sigma_\Pi, \sigma_\Delta)$$
$$v_0 = f(\sigma_\Pi, \sigma_0)$$
$$v_g = f(\sigma_\Pi, \sigma_g)$$
$$v_{g0} = f(\sigma_0, \sigma_g)$$

The stated tables for determining the impulse efficiency coefficients can be used to calculate the pressure and motion characteristics of the automatic weapon's main assembly during its free travel, both according to the method of Mamontov M.A. and according to the method of Bravin E.L. [6] [7].

For the purpose of simulating the pressure in the gas

cylinder, a software solution was developed in MATLAB, whose algorithm is shown in Figure 5.

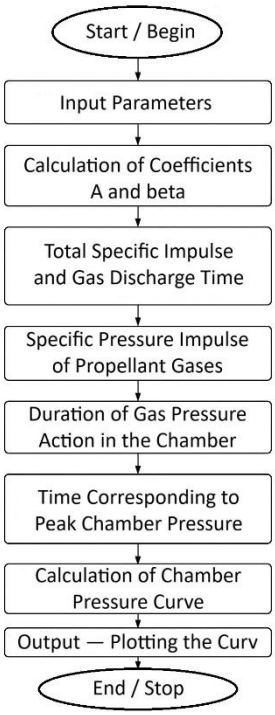

Figure 5. Algorithm of the software solution of Bravin's method

The software solution also enables the calculation of the gas-operating system parameters by simply varying the adopted design parameters. The input quantities used are the barrel caliber, projectile mass, propellant charge mass, bolt mass, initial projectile velocity, maximum propellant gas pressure, the propellant gas pressure at the muzzle and the propellant gas pressure at the gas port location obtained from the internal ballistics calculation, the diameter of the gas port, the piston diameter, the diametral clearance between the piston and the chamber, the initial chamber volume, the reduced barrel length, the projectile travel time from the gas port to the muzzle, the initial return spring force, the return spring stiffness, and the sliding friction coefficient. As output, a diagram of pressure variation in the barrel and in the gas regulator chamber is obtained [8].

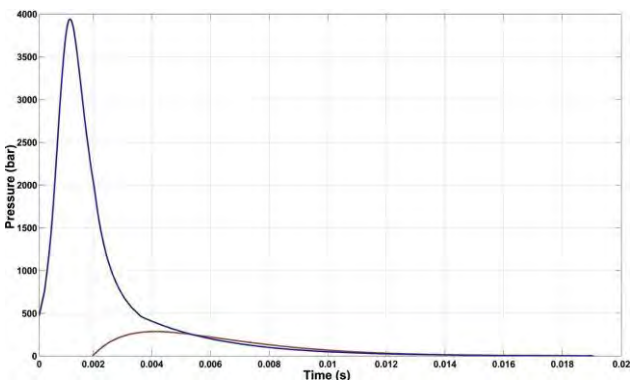

Figure 6. Diagram of pressure variation in the barrel and in the gas regulator chamber.

The obtained pressure variation diagram (Figure 6) correlates with the theoretical diagram shown in Figure 4. The pressure in the chamber begins to rise from the moment t_{k0} = 0.0020 *s*, i.e., when the projectile passes the gas port. The pressure in the barrel is dropping sharply, and at the moment the projectile is at the gas port it equals 2105 *bar*. Based on the diagram, it can be observed that the pressure in the chamber rises more slowly than the pressure in the barrel and is maintained long enough to ensure reliable operation of the automatics even when the barrel pressure is lower. It reaches its maximum value p_{km} = 284 *bar*. The total duration of the propellant gas action in the chamber is t_k = 0.0188 *s*. The pressure curves in the barrel and chamber nearly coincide and continue to decrease during the period of after-effect of the propellant gases, reaching zero after 0.02 *s*.

3. DYNAMIC ANALYSIS

3.1. Work Cycle Diagram

The work cycle diagram of the automatic mechanism represents a graphical or tabular depiction of the interconnected operating phases that occur during a single shot, i.e., during the entire operating cycle of the weapon. The cycle diagram shows the sequence, duration, and overlap of individual processes. Essentially, the cycle diagram is a schematic model of the working process, serving as a basis for studying, designing, and improving the weapon.

For the purpose of researching the operation of the automatics of the 30 mm automatic cannon, a high-speed camera was used, the *Phantom v1212.* The use of a high-speed camera represents one of the key methods for the nonlinear analysis of part motion in real time. Given that the bolt's operating cycle takes place within fractions of a second, standard measurement methods often cannot capture the critical moments that define phase changes. Based on the high-resolution recordings, a work cycle diagram of the 30 mm automatic cannon was constructed (Table 1). The masses of the automatic mechanism's elements are shown in Table 2.

Table 1. Work cycle diagram of the 30 mm automatic cannon

Phases	No.	Motion of parts	Travel distance (*mm*)	Time (*s*)	Mass (*kg*)
Recoil	1	Unlocking	0-35	0.01	m1+m7+m6
	2	Joint motion	35-350	0.02	m3+m4+m6+m7
	3	Impact on case ejector	350		
	4	Case ejection	350-400	0.006	m3+m6+m7
	5	Impact on buffer	400		
	6	Buffer compression and end of recoil	400-420	0.004	m1+m2+m6+m7
Counter-recoil Phases	1	Joint motion	420-390	0.05	m1+m2+m6+m7
	2	Impact of bolt on case head	390		
	3	Joint motion	390-35	0.04	m3+m5+m6+m7
	4	Impact of bolt on rear of barrel	35		

Table 2. Masses of the automatic mechanism's elements

Piston	m6
Return spring	m7

4. BOLT MOTION KINEMATICS

In the paper, a model of the kinematics of the motion of the bolt of the 30 mm automatic cannon was developed using code, focusing on the multi-phase dynamics during the recoil and counter-recoil cycle. The model uses the real propellant gas pressure profile in the gas chamber as input to the dynamic model of the motion of the bolt assembly.

The simulation is based on the numerical solution of a system of second-order differential equations describing the motion of the bolt as a function of time. The complete cycle is divided into seven discrete phases, where each phase has a defined displacement length, the action of the propellant gas force, and the influence of the buffer. For each phase, the ODE system is solved separately using the function *ode45*, using an *event* -function for automatic detection of the end of the phase. This achieves a modular and physically consistent simulation [9].

The input pressure *pk(t)* is loaded from a *.mat* file obtained from the previous calculation of the pressure in the gas cylinder and is interpolated in time. The dynamics of the bolt include the effect of the spring, friction, and buffer, with parameters defined according to the technical characteristics of the system. The recoiling mass dynamically changes in the corresponding phases depending on the mechanical state (presence of the cartridge, case, etc.).

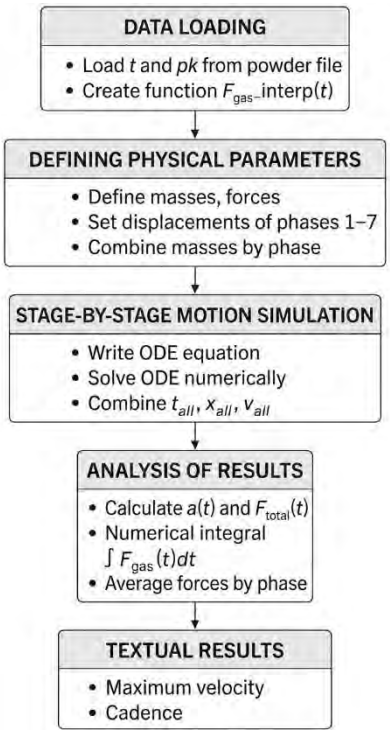

Figure 7. Algorithm of the bolt motion kinematics

Based on the numerical results, the key values of the system were calculated, including the maximum bolt velocity and the rate of fire.

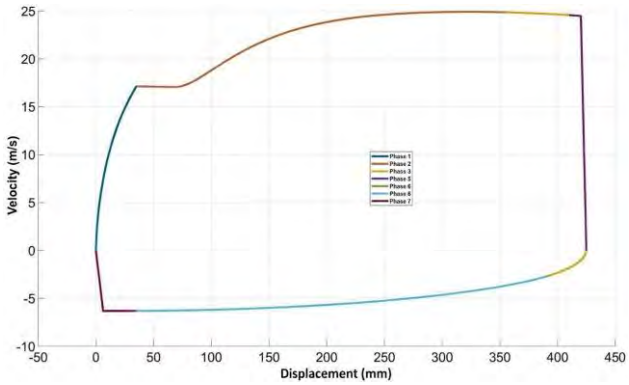

Figure 8. Bolt velocity as a function of position (V=f(x)).

The first phase represents the unlocking of the bolt. In this phase, the propellant gases exert the greatest influence on the system. The velocity of the bolt carrier increases sharply, and the diagram shows that the maximum acceleration occurs precisely here. This phase is crucial for the initial actuation of the mechanism and confirms that the gas profile correctly transfers energy to the piston.

After the initial acceleration and unlocking, the second phase involves extraction of the case, during which the entire bolt assembly together with the case joins the recoiling mass. Based on the diagram in Figure 9 and 10, a brief interval of constant bolt-assembly velocity can be observed at the very beginning of the second phase. This occurrence is a consequence of the sudden increase in inertial mass. Namely, the propellant gas pressure at that moment acts on a mass approximately three times greater than in the initial phase of motion. Thereafter, the velocity remains high but stable, while the gas force gradually decreases. The second phase ensures continuity of motion and shows that the system has enough energy to overcome the inertia of the bolt mass.

In the third phase, the gas impulse ceases, and the bolt continues its motion owing to the accumulated energy. The velocity decreases, and the average force is smaller. In this phase, the ejection of the case occurs which additionally slows the system down and represents a real mechanical effect in the operation of the weapon.

In the fourth phase, the bolt strikes the buffer. This phase clearly shows the dissipation of energy. The bolt velocity decreases, and the buffer absorbs the impact, which is seen through the sudden drop in force.

The bolt then comes to a temporary stop, which is reflected in the negative velocity values. The fifth phase provides a brief pause in the cycle and enables mechanical preparation for the return stroke. The diagram shows that the forces in this phase are negative, which is a consequence of the return action of the spring.

The longest phase of the return motion is the motion of the bolt together with the cartridge. The velocity is negative and stable, and the average forces indicate the dominant influence of spring and friction. This phase is crucial for chambering the next cartridge and preparing for the

following cycle.

The final phase represents the locking of the bolt. The bolt completes its return motion and assumes its initial position. The velocity decreases toward zero. This phase ensures the stabilization of the system and prepares it for the next firing cycle.

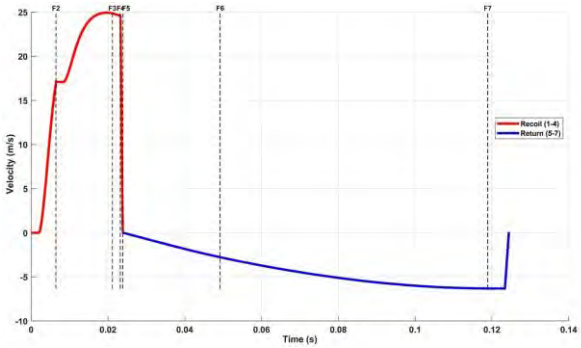

Figure 9. Variation of bolt velocity as a function of time (V=f(s)).

Analysis of the diagrams and tables confirms that the bolt dynamics proceed in accordance with the expected physical principles. The obtained rate of fire of 482 *rounds/min* shows a relative deviation of ~5%, compared to the know value. The diagram of bolt velocity variation, with a maximum value of 24.92 *m/s*, is free of sudden oscillations that could lead to dynamic overloads, which indicates stable operation of the system.

5. CONCLUSION

Based on the available data on the 30 mm automatic cannon and the 30×173 mm cartridge, dynamic analysis of 30 mm automatic cannon operating mechanism was performed.

The internal ballistics calculation was performed using the Drozdov method, and after optimization, the maximum propellant gas pressure in the barrel of the 30 mm automatic cannon was obtained as $P_m=394\ MPa$, while the muzzle velocity of the projectile is $V_0=1104\ m/s$.

Starting from the conditions of the set task, the method of theoretical examination of propellant gas pressures in gas-operating devices according to Bravin's method was considered. The resulting pressure curve in the gas cylinder fully correlates with the theoretical and experimental work in this field. The maximum pressure value in the chamber is $p_{km}=283.76\ bar$, the duration of the propellant gas action in the chamber is $t_k=0.0188\ s$, and the time corresponding to the maximum pressure in the chamber is $t_{km}=0.0021\ s$.

Based on the constructed work cycle diagram of the 30 mm automatic cannon, a simulation of the bolt motion through seven phases with variable masses was performed, using numerical integration by means of the *ode45* method. The previously obtained pressure curve in the chamber was used as the input data. The displacement and velocity diagrams by phase show that the greatest acceleration occurs in the first phases (1–2), when the gases act directly on the piston and the bolt carrier. In phase 3, the force and velocity decrease due to the resistance of case extraction, while phase 4 clearly shows the dissipation of energy through the buffer. The return phases (5–7) are characterized by negative velocity, confirming the correct return of the bolt to its initial position. This distribution confirms that the model successfully captures the transition between recoil and counter-recoil, and that the buffer plays a key role in stabilizing the system. A rate of fire of 482 rounds per minute was obtained, which deviates from the experimental value by ~5%, confirming that the simulation faithfully describes the real operation of the bolt. Each phase has a clearly defined dynamic, ranging from the initial acceleration under the gas impulse, through energy dissipation in the buffer, to the return motion and stabilization by locking of the bolt. The obtained results are consistent with the expected mechanical behavior and represent a reliable basis for further optimization of the design.

Further improvements to the simulation could be achieved by introducing spring nonlinearities for a more realistic representation of the elastic forces, as well as by applying different loss coefficients in the gas system. In addition, instead of idealized viscous friction, a real friction model that better reflects the actual mechanical operating conditions should be introduced. Finally, extending the simulation to a multi-cycle regime, instead of a single-cycle one, would enable the analysis of the system's durability, stability, and reliability under conditions of intensive use.

Abstract: *This paper presents the internal ballistic design of a 30 x 173 mm automatic cannon. The initial section provides general observations on 30 mm automatic cannons, including the domestic M12 automatic model. The internal ballistic calculation was conducted using the Drozdov method. Through the variation of ballistic parameters, an optimal variant was selected. Furthermore, experimentally determined internal ballistic (IB) data are presented, and a comparative analysis between the obtained results and theoretical models has been performed.*

1. INTRODUCTION

Modern armed conflicts and the rapid evolution of land, naval, and air combat doctrines have imposed increasingly demanding requirements on small- and medium-caliber automatic weapon systems. Within the category of automatic cannons intended for installation on infantry fighting vehicles (IFVs), tactical aircraft, naval platforms, and air defense systems, the 30 mm caliber has become the optimum compromise between ballistic performance, system mass, and recoil-force management [1].

The transition from 20 mm and 25 mm weapon systems to the 30 mm caliber has primarily been driven by the increasing effectiveness of modern armor protection systems and the demand for greater terminal effectiveness against a wide spectrum of targets. The larger projectile volume available in the 30 mm caliber enables the employment of highly efficient Armor-Piercing Fin-Stabilized Discarding Sabot (APFSDS) projectiles, as well as advanced programmable airburst ammunition (ABM), which has become essential for engaging concealed targets and countering unmanned aerial systems (C-UAS).

1.1. 30 mm Automatic Cannons

Modern single-barrel 30 mm automatic cannons are generally equipped with dual-feed ammunition systems, allowing rapid selection between two different ammunition types and thereby significantly improving combat effectiveness against various ground, aerial, and naval targets. Typically, one ammunition belt is loaded with High-Explosive (HE), High-Explosive Tracer (HET), or High-Explosive Incendiary Tracer (HEIT) projectiles, whereas the second belt contains Armor-Piercing (AP), Armor-Piercing Tracer (APT), or Armor-Piercing Incendiary Tracer (APIT) ammunition. Fragmentation ammunition is additionally employed against enemy personnel and lightly protected targets.

The 30 × 173 mm caliber is widely adopted by NATO member states and countries operating NATO-compatible weapon systems, whereas the 30 × 165 mm caliber is predominantly used by the armed forces of the Russian Federation.

Among the most widely deployed 30 × 173 mm automatic cannons are:

- Oerlikon KCE (Switzerland)
- GAU-8/A Avenger (United States)
- Bushmaster II Mk44 (United States)
- Rheinmetall Mk30-2 (Germany)

The primary armament of numerous United States armored combat vehicles is the Bushmaster II Mk44 automatic cannon (Figure 1). The Bushmaster II Mk44 is a 30 × 173 mm dual-feed automatic cannon with a cyclic rate of fire of approximately 200 rounds per minute and an effective firing range of up to 3,000 m. It is recognized for its exceptional reliability and operational performance on modern armored vehicles and naval platforms.

Figure 1. General view of the Bushmaster II Mk44

The domestically developed M12 30 mm automatic cannon, shown in Figure 2, is designed for engaging

DOI: 10.5937/OTEH26028M

personnel, armored and unarmored ground targets, as well as aerial threats. The system provides an effective firing range of at least 3,000 m against ground and surface targets and at least 1,500 m against aerial targets.

Table 1. Technical characteristics of 30 mm cannon M12

Weapon type:	single-barrel automatic cannon
Caliber:	30 × 173 mm
Automatic operating principle:	gas-operated with barrel recoil
Length:	3255 mm
Barrel length	2460 mm
Barrel rifling:	progressive, from 2.5° to 8.5°
Number of grooves:	16
Cannon mass:	195 kg
Rate of fire:	from 350 rds/min to 430 rds/min
Initial velocity of projectile:	(1100 ± 15) m/s
Firing mechanism:	mechanical
Recoil force:	from 15 kN to 20 kN
Operating temperature range:	from –30 °C to +50 °C
Barrel ballistic life:	up to 6000 rounds

Figure 2. External view of the M12 30 mm automatic cannon

1.2. 30 x 173 mm Ammunition

Ammunition for 30 × 173 mm automatic cannons is generally manufactured in three primary variants:

- High-Explosive (HE);
- Armor-Piercing (AP);
- Armor-Piercing Fin-Stabilized Discarding Sabot (APFSDS).

HE projectiles are available in tracer configurations, whereas AP projectiles may incorporate tracer and incendiary elements to improve target indication and post-penetration effectiveness. Table 2 summarizes the principal technical characteristics of representative 30 × 173 mm cartridges. Figure 3 illustrates the general appearance of several cartridge types, while Figure 4 presents a cartridge fitted with an APFSDS projectile.

Table 2. Technical characteristics of 30x173 mm cartridges

	Mk238 High-explosive fragmentation with tracer	**Mk239** Training round with tracer	**Mk268** Armor-piercing with tracer	**Mk310** High-explosive
Round length	290 mm	290 mm	290 mm	290 mm
Round mass	670 g	675 g	725 g	713 g
Mass of projectile	362 g	372 g	235 g	423 g
Propellant charge mass	153 g	153 g	176 g	150 g
Fuze	Impact, instantaneous action, with self-destruct	Inert	No fuze	Programmable fuze
Projectile velocity	1050 m/s	1050 m/s	1050 m/s	980 m/s
Maximum pressure	3450 bar	3450 bar	3450 bar	3600 bar
Dispersion	0,5 mr	0,5 mr	0,5 mr	0,5 mr

2. INTERNAL BALLISTIC ANALYSIS

The internal ballistic analysis was performed using the Drozdov analytical method, which is applicable to weapon systems employing a single type of propellant. This method is commonly used in the internal ballistic design of small arms, automatic cannons, field guns, and howitzers firing ammunition loaded with a single propellant type. The Drozdov method is based on the analytical solution of the governing equations of internal ballistics [2].

The mathematical description of projectile motion during the firing cycle is obtained by solving the system of equations over several characteristic periods of the firing process. The exception is the time function, which is evaluated continuously throughout the entire firing cycle.

Because the actual internal ballistic process is highly complex and several influencing parameters cannot be determined precisely, the Drozdov method introduces a number of simplifying assumptions that enable an analytical solution of the governing equations. These assumptions are summarized as follows:

- Propellant combustion follows the geometric burning law.
- Combustion takes place under the average pressure of the propellant gases.
- The burning-rate law is assumed to be linear with pressure.
- Secondary work performed by the propellant gases is assumed to be proportional to the translational work of the projectile and is accounted for through the fictitious coefficient, φ.

- Heat losses are considered indirectly by reducing the specific energy of the propellant gases or by increasing the thermodynamic exponent θ.
- The composition of the combustion products remains constant throughout the firing process; therefore, both the specific energy of the propellant gases (fb) and the co-volume (α) are assumed constant.
- The work required for engraving the rotating band into the rifling is neglected. The projectile is assumed to remain stationary until the propellant-gas pressure reaches the forcing pressure (p_0).
- Projectile engraving is assumed to occur instantaneously rather than progressively.
- Projectile motion is analyzed only until the projectile base exits the muzzle.
- Elastic deformation of the barrel, gas leakage between the rotating band and the bore, and aerodynamic resistance inside the barrel are neglected.
- In gas-operated weapon systems, propellant-gas extraction begins simultaneously with projectile motion and is assumed to be steady, without expulsion of unburned propellant particles.

All constant quantities appearing in the governing equations are defined as input parameters whose numerical values are known in advance. These parameters are grouped into three categories:

- barrel characteristics: S_c, W_0, X_u;
- projectile characteristics: m, p_0, φ and
- propellant characteristics: m_b, f_b, α, u_{z0}, ρ_b, θ, $2r_0$, κ, λ, μ, (κl, λl).

The Drozdov method is originally formulated for regressive-burning propellant grains. When progressive-burning grains, such as seven-perforated cylindrical propellant grains, are employed, the grain web thickness is multiplied by a factor of 10/7, while the grain-shape coefficients are determined using the equivalent single-perforated cylindrical grain geometry [3] [4].

The firing cycle is divided into three characteristic periods, Preliminary, First and Second. During the preliminary period, the projectile remains stationary while the propellant burns within a constant chamber volume. Consequently, only the state variables at the end of this period are required, since they constitute the initial conditions for the subsequent calculation. The first period extends from projectile motion initiation until complete combustion of the propellant charge. During this stage, the maximum chamber pressure is reached. The second period begins after complete propellant combustion and lasts until the projectile exits the muzzle. During this interval, the projectile continues to accelerate solely under the action of the expanding propellant gases. A third period, commonly referred to as the after-effect period, describes the influence of the propellant gases after projectile exit and is not included in the present internal ballistic calculation [3].

2.1. SOFTWERE IMPLEMENTATION

The computational algorithm is organized according to the characteristic periods of the firing process defined by the Drozdov analytical method. Initially, the program reads all input parameters from the ULD100 input file. These parameters are subsequently used to calculate the required constants and the characteristic quantities corresponding to the preliminary period. For the first period, the initial conditions, computational interval, and integration step are defined. Based on the selected interval and the number of calculation points, the computational step size is determined. A DO loop is then used to calculate the following internal ballistic parameters at each computational step: chamber pressure, *p(x)*; projectile travel, *X(x)*; projectile velocity, *V(x)*; elapsed time, *t(x)*. During this period, the program automatically determines the maximum chamber pressure. The second period is solved using the same computational procedure. Appropriate initial conditions, computational interval, and step size are defined, after which the following quantities are calculated for every integration step: chamber pressure, *p(X)*; projectile velocity, *V(X)*; elapsed time, *t(X)*. The ULD100 file contains all input parameters separated by commas and organized into four rows. During execution, the program automatically generates the output file I100, in which all calculated ballistic parameters are stored through successive WRITE commands.

The developed computational procedure is universal and can therefore be applied to any weapon system employing a single type of propellant [5].

The internal ballistic analysis presented in this study was carried out for the 30 mm automatic cannon. This weapon employs NC-52 seven-perforated cylindrical propellant grains, illustrated in Figure 5, consisting of one central perforation surrounded by six equally spaced peripheral perforations arranged in a regular hexagonal pattern.

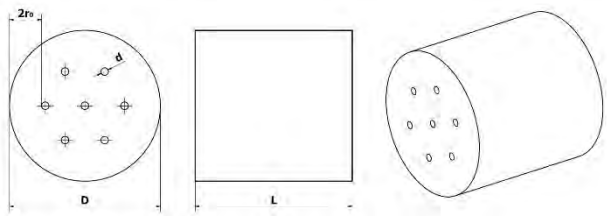

Figure 5. General appearance of the NC-52 propellant grain.

The data required for the internal ballistic (IB) calculation are:

- Powder chamber volume:

$$W_0 = \frac{m_b}{\rho} \quad (1)$$

$$W_0 = \frac{0{,}161}{700} = 0{,}00023$$

ρ for high-power artillery weapons, from 650 to 780 kg/m^3

- Barrel cross-sectional area:

$$S_c = n_s \cdot d^2 \quad (2)$$

$$S_c = 0{,}82 \cdot 0{,}030^2 = 0{,}000738\ m^2$$

- Total travel of the projectile in the barrel:

$$X_u = 2296\ m$$

- Fictitiousness (form) coefficient:

$$\varphi = K + \frac{1}{3} \cdot \frac{m_b}{m} = 1{,}03 + \frac{1}{3} \cdot \frac{0{,}161}{0{,}357} = 1{,}1767505 \quad (3)$$

Where

K is approximately 1.03 for high-power guns

- Projectile mass:

$$m = 0{,}357\ kg$$

- Propellant mass:

$$m_b = 0{,}161\ kg$$

- Density of the propellant charge:

$$\rho_b = 1600\frac{kg}{m^3}$$

- Covolume of the propellant gases:

$$\alpha = \left(1456 - \frac{0{,}524}{4{,}187}\cdot Q_w\right)\cdot 10^{-6} \qquad (4)$$

$$\alpha = \left(1456 - \frac{0{,}524}{4{,}187}\cdot 3300\right)\cdot 10^{-6} = 0{,}00104300741$$

Where:

Q_w = 3200–3400 J/kg – heat quantity of the propellant at constant volume.

- Ratio of specific heats minus 1:

$$\theta = 0{,}269$$

- Half-thickness of the propellant grain:

$$r_0 = 0{,}3$$

- Shape coefficients:

For seven-perforated propellant, the grain thickness is multiplied by a factor of 10/7, and the shape coefficients are calculated as for a cylindrical single-perforated grain.

$$\kappa = 1 + \beta\,, \qquad \lambda = -\frac{\beta}{1+\beta}\,, \qquad \mu = 0 \qquad (5)$$

$$\kappa_1 = \kappa\left(1 - \frac{\mu}{2}\right), \qquad \lambda_1 = \frac{1}{\kappa_1} - 1 \qquad (6)$$

$$\beta = \frac{2r_0}{2c} = 0{,}3296703$$

$$\kappa_1 = 1{,}32967\,, \qquad \lambda_1 = -0{,}247934$$

- Specific work of the propellant gases:

$$f_b = \left(6546 + \frac{3.4001}{4.187}\cdot Q_w\right)\cdot 10^2 \qquad (7)$$

$$f_b = \left(6546 + \frac{3.4001}{4.187}\cdot 3300\right)\cdot 10^2 = 922580$$

- Forcing pressure

$$p_0 = 40\cdot 10^6$$

- Unit burning rate of the propellant:

$$u_{z0} = \left(-76.6 + \frac{0.179}{4.187}\cdot Q_w\right)\cdot 10^{-11} \qquad (8)$$

$$u_{z0} = \left(-76.6 + \frac{0.179}{4.187}\cdot 3300\right)\cdot 10^{-11}$$

$$= 6{,}45\cdot 10^{-10}\ \frac{m}{sPa}$$

Table 3. Input data for the internal ballistic calculation

Name	Symbol	Value	Unit
Initial powder chamber volume	W_0	0,00023	m^3
Barrel cross-sectional area	S_c	0,000738	m^2
Total travel of the projectile	x_u	2,296	m
Fictitiousness coefficient	φ	1.17675	/
Projectile mass	m	0,357	kg
Propellant mass	m_b	0.161	kg
Bulk density	ρ_b	1600	kg/m^3
Covolume of the propellant gases	α	0,00104301	m^3/kg
Ratio of specific heats minus 1	Θ	0,269	/
Half-thickness of the propellant grain	r_0	0,0003	m
Shape coefficient	κ_1	1,32967	/
Shape coefficient	λ_1	- 0,247934	/
Specific work of the propellant gases	f_b	922580	J/kg
Forcing pressure	p_0	$40\cdot 10^6$	Pa
Unit burning rate of the propellant	u_{z0}	$0{,}000645\cdot 10^{-6}$	m/sPa

The graphical interpretation of the obtained results was done using the software package *Microsoft Excel,* showing the dependence of propellant gas pressure (*P*) on time (*t*) and travel (*X*), as well as the change in projectile velocity (*V*) with time (*t*)), is shown in Figures 6, 7, and 8.

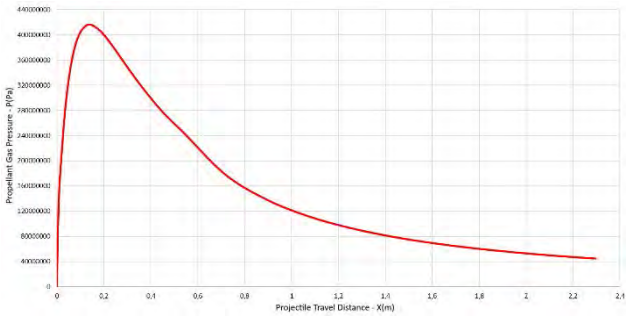

Figure 6. Change in propellant gas pressure as a function of travel

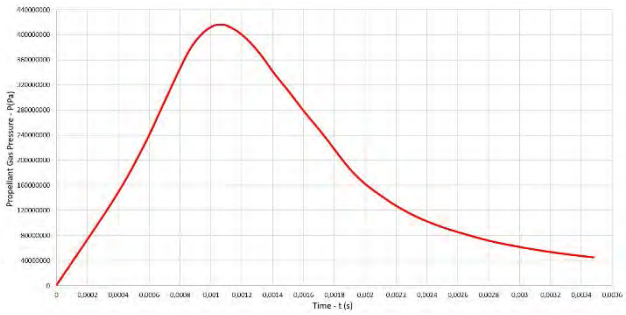

Figure 7. Change in propellant gas pressure as a function of time

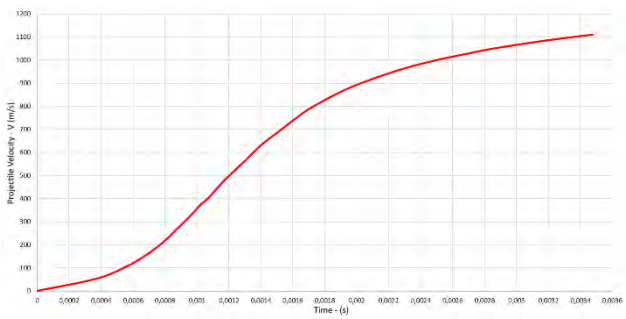

Figure 8. Change in projectile velocity with time

From the presented IB calculation, it can be seen that the maximum propellant gas pressure in the barrel of the 30 mm M12 cannon is P_m=*416 MPa*, the time elapsed from firing until the projectile leaves the muzzle is t_u=*0,00348*

s, the distance traveled by the projectile is x_u=*2,3 m*, while the projectile velocity at the muzzle is V_0=*1110 m/s*.

3. PARAMETRIC ANALYSIS OF IB PARAMETARS

The ballistic characteristics of the propellant are those characteristics on which the law governing the development of propellant gas pressure depends. In order to determine the influence of individual parameters on the magnitude of the propellant gas pressure in the barrel and on projectile velocity, they will be varied within a range of ±2.5% and ±5%. Parameters will be varied one at a time, while the remaining parameters retain their baseline value. In this way, an optimal solution can be reached. The goal is to find parameter values such that the propellant gas pressure in the barrel is as low as possible while the initial projectile velocity is as high as possible. The parameters that are varied are:

- the covolume of the propellant gases α,
- the specific work of the propellant gases f_b,
- the unit burning rate of the propellant u_{z0}.

3.1. Influence of the propellant gas covolume (α)

The covolume of the propellant gases (α) represents the smallest volume to which the propellant gases produced by burning 1 *kg* of propellant can be compressed. It is, in essence, the volume of the propellant gas molecules [3] [4].

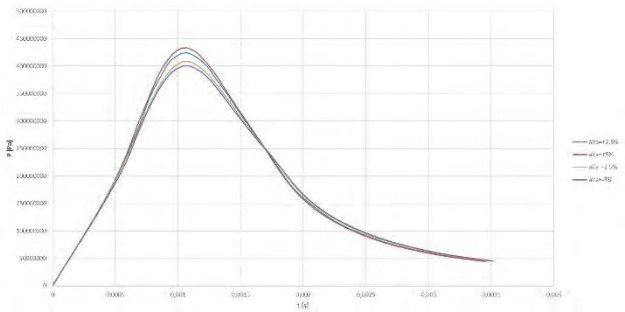

Figure 9. Influence of the propellant gas covolume on the propellant gas pressure in the barrel

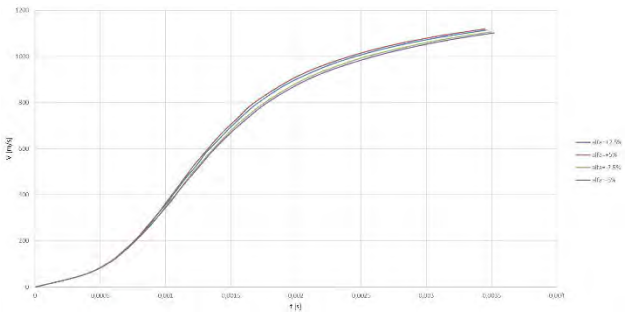

Figure 10. Influence of the covolume on projectile velocity in the barrel

Based on the diagrams in Figures 9 and 10, it can be concluded that as the propellant gas covolume α increases, the propellant gas pressure in the barrel and the projectile velocity increase, and vice versa with a decrease.

3.2. Influence of the unit burning rate (u_{z0})

The unit burning rate (u_{z0}) is a constant from the burning law of the propellant grain:

$$u_z = u_{zo}p \tag{9}$$

For nitrocellulose propellants it amounts to (5.5–8)10^{-10} *m/sPa*, while for nitroglycerine propellants it is (4–12)10^{-10} *m/sPa*.

The ignition velocity, i.e., the rate of flame propagation over the surface of the propellant grain, is 2–4 *mm/s* for smokeless propellants and 1–3 *m/s* for black powder. The burning rate, i.e., the rate of flame penetration into the depth of the propellant grain, is 1–1.5 *mm/s* for smokeless propellants and about 1 *cm/s* for black powder [3] [4].

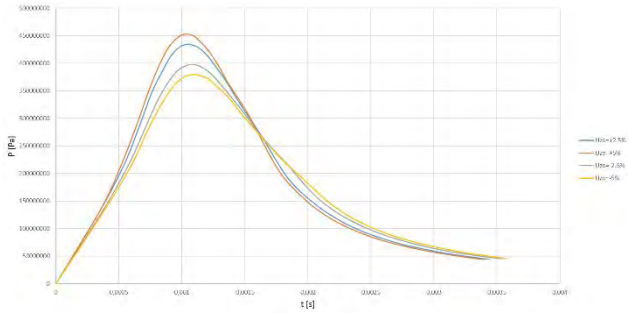

Figure 11. Influence of the unit burning rate on the propellant gas pressure in the barrel

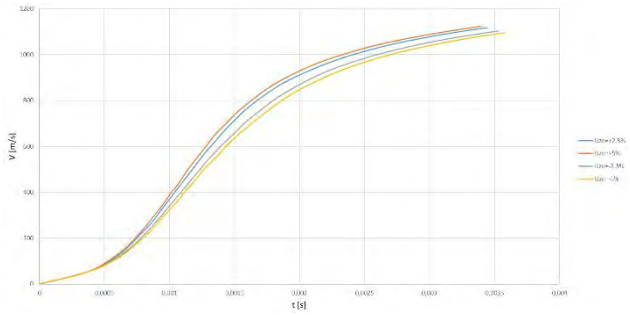

Figure 12. Influence of the unit burning rate on projectile velocity in the barrel

Figure 11 shows the change in propellant gas pressure with travel due to a change in the unit burning rate, while Figure 14 shows the change in projectile velocity with travel. The unit burning rate has the same effect as the propellant gas covolume, i.e., increasing its nominal value increases the propellant gas pressure and the projectile velocity.

3.3. Influence of the specific work of the propellant gases (f_b)

The specific work of the propellant gases (f_b) represents the work that could be performed by the propellant gases produced by burning 1 *kg* of propellant if cooled to 0˚*C* and expand at atmospheric pressure. It ranges within 1±0.25 *MJ/kg*. It is determined experimentally by burning the propellant in a manometric bomb, or by thermochemical calculation using the expression:

$$f_b = MRT_m \tag{10}$$

Where:
M - total number of moles of the gas mixture

R - universal gas constant, and
T_m - maximum temperature of the propellant gases.

The gas constant is determined from the ideal gas equation of state, for a molar volume of W_m=0.02241 m^3/mol, atmospheric pressure p_a=101334 Pa and temperature T_a=273,15 K:

$$R = \frac{p_a W_m}{T_m} = 8.314 \frac{J}{mol \cdot K} \quad (11)$$

Figures 13 and 14 show the change in propellant gas pressure and the change in projectile velocity in the barrel due to the influence of the specific work of the propellant gases (f_b).

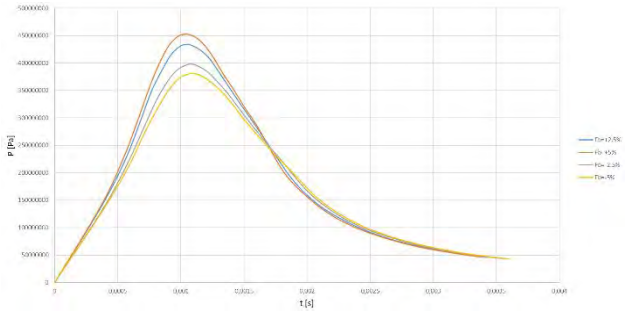

Figure 13. Influence of the specific work of the propellant gases on the propellant gas pressure in the barrel

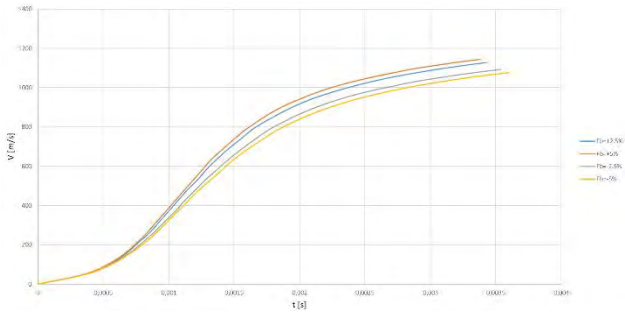

Figure 14. Influence of the specific work of the propellant gases on projectile velocity in the barrel

Reducing the specific work of the propellant gases reduces the maximum propellant gas pressure in the barrel and the initial velocity. Compared with the propellant gas covolume and the unit burning rate, for the same percentage change relative to the nominal value, the specific work of the propellant gases has the greatest influence on the change in pressure and velocity.

3.4. Optimal Ballistic Solution

The automatic 30 mm M12 cannon has a maximum barrel pressure of P_m=420 MPa, and an initial projectile velocity of V_0=1100 m/s. The task is to find a solution that satisfies the relations P_m<420 MPa, V_0>1100 m/s.

Table 4 gives the values of the maximum propellant gas pressure and the initial projectile velocity when varying the selected parameters.

Table 4. Values of Pm and V_0 for variation of the parameters

	-2.5%P_m [MPa]	-2.5%V_0 [m/s]	-5%P_m [MPa]	-5%V_0 [m/s]	P_m [MPa]	V_0 [m/s]	+2.5%P_m [MPa]	+2.5%V_0 [m/s]	+5%P_m [MPa]	+5%V_0 [m/s]
α	408	1106	401	1102	416	1110	424	1115	433	1119
u_{z0}	398	1103	380	1094	416	1110	435	1118	454	1124
f_b	398	1094	381	1076	416	1110	434	1127	453	1144

The propellant gas covolume gives the optimal solution when its value is increased by 2.5%. Comparing the specific work of the propellant gases with the unit burning rate, it is observed that for the same maximum pressure, the unit burning rate yields a higher initial velocity.

The diagrams in Figures 15, 16, and 17 show the change in the propellant gas pressure in the barrel and the projectile velocity during optimization, i.e., a reduction of the unit burning rate by 5 % and an increase of the propellant gas covolume by 5%.

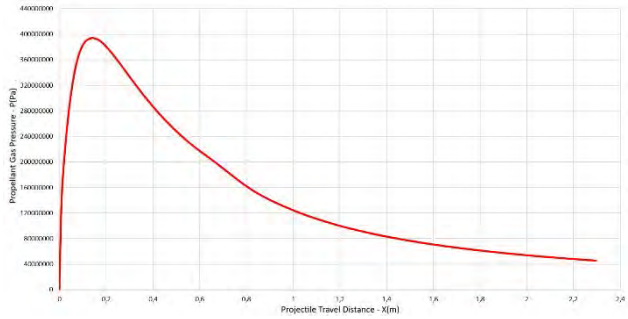

Figure 15. Dependence of propellant gas pressure on travel during optimization

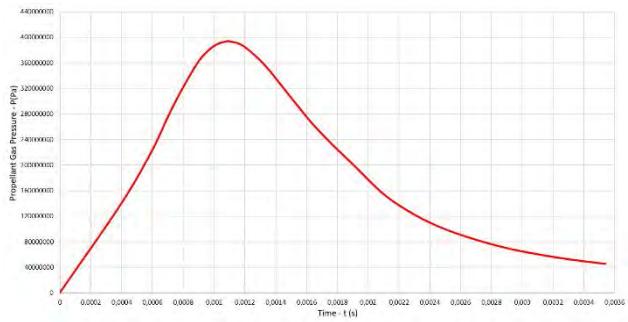

Figure 16. Dependence of propellant gas pressure on time during optimization

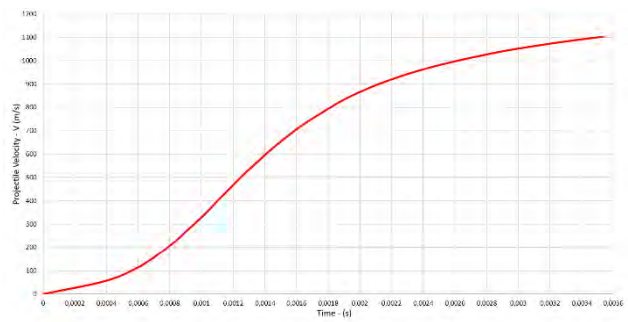

Figure 17. Dependence of velocity on time during optimization

4. EXPERIMENTAL VERIFICATION

For the purpose of verifying the calculation, testing of the 30 mm round with a training projectile was carried out.

Pressure was measured using a KISTLER type 62215 SN4161790 probe, and velocity was measured using a WEIBEL SL-520PE radar. Figure 18 graphically shows the propellant gas pressure curve as a function of time, obtained during the experimental determination of the pressure curve for a single firing.

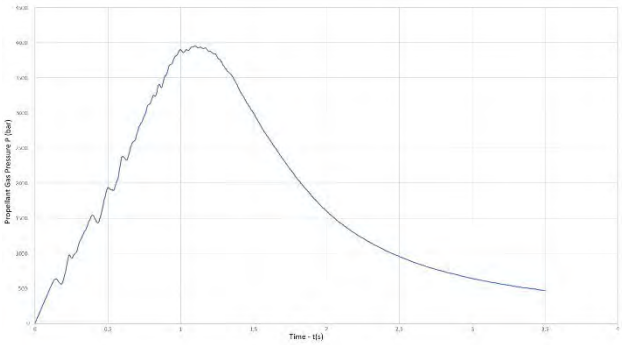

Figure 18. Dependence of propellant gas pressure on time – measured values

4.1. COMPARATIVE ANALYSIS OF THE OBTAINED RESULTS

A comparative analysis of results obtained by the Drozdov method, by parameter optimization, and by experimental testing is presented in Table 5. The comparative results of the propellant gas pressure curves from optimization and experiment are shown in Figure 19.

Table 5. Comparative analysis of the obtained results

	DROZDOV	OPTIMIZATION	EXPERIMENT
P_m [MPa]	416	394	393
V_0 [m/s]	1110	1104	1092
DROZDOV–EXPERIMENT RELATIVE DEVIATION		OPTIMIZATION–EXPERIMENT RELATIVE DEVIATION	
P_m [MPa] - 5,58% V_0 [m/s] - 1,65%		P_m [MPa] - 0,25% V_0 [m/s] - 1,09%	

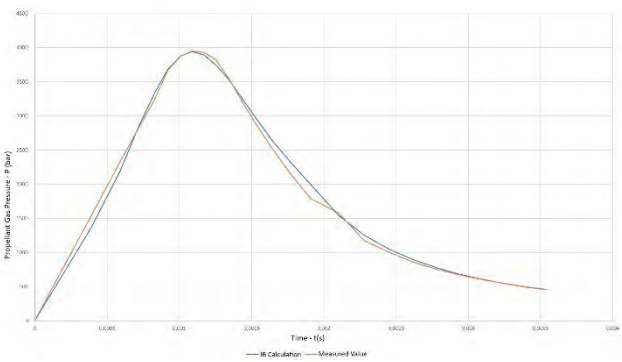

Figure 19. Dependence of propellant gas pressure on time – comparison of measured and calculated values

5. CONCLUSION

This paper presented the internal ballistic analysis of a 30x173 mm automatic cannon using the analytical method. Based on the available geometric, ballistic, and thermodynamic characteristics of the 30 mm automatic cannon and its associated ammunition, an analytical internal ballistic model was established to predict the pressure development within the barrel and the projectile motion throughout the firing cycle.

The performed calculations yielded a maximum chamber pressure of 416 *MPa*, a muzzle velocity of 1110 *m/s*, a projectile travel of 2,30 *m*, and a barrel transit time of 3.48 *ms*. These results are fully consistent with the expected ballistic performance of the weapon system and provide a reliable analytical basis for further optimization.

To improve the ballistic characteristics of the system, a comprehensive parametric analysis was conducted by independently varying the propellant-gas co-volume, the propellant burning-rate coefficient, and the specific energy of the propellant gases. The analysis demonstrated that the specific energy has the greatest influence on both chamber pressure and muzzle velocity, while the burning-rate coefficient provides the most favorable balance between pressure reduction and ballistic performance. The optimal solution was achieved by reducing the burning-rate coefficient by 5% and increasing the propellant-gas co-volume by 5%, resulting in a maximum chamber pressure of 394 MPa and a muzzle velocity of 1104 m/s. This represents a significant reduction in peak pressure while maintaining the required ballistic effectiveness.

The analytical predictions were validated through experimental firing tests using instrumented pressure measurements and Doppler radar velocity measurements. The comparison between the optimized analytical model and the experimental data showed an excellent agreement, with relative deviations of only 0.25% for the maximum chamber pressure and 1.09% for the muzzle velocity. These results confirm the validity of the adopted analytical approach and demonstrate that the proposed optimization procedure significantly improves the predictive capability of the Drozdov method.

The presented methodology provides an efficient engineering tool for the preliminary design and optimization of automatic cannon ammunition, particularly during the early stages of weapon development when extensive experimental testing is not yet available. The developed analytical model can considerably reduce both development time and the number of experimental iterations required during the design process.

Future research will focus on extending the analytical model by incorporating more advanced combustion models, temperature-dependent propellant characteristics, and numerical optimization techniques.

Abstract: *This paper presents and analyzes the tooth root load-carrying capacity of spur gears under standard single and double mesh conditions. A newly developed analytical model of the relative stress factor is used to approximately determine and compare the tooth root stresses. An Octave program is used to calculate the geometric and kinematic parameters of the pinion and wheel gear. A three-dimensional (3D) model of the pinion and wheel gear is created in CATIA, while two-dimensional (2D) model of their teeth is developed in AutoCAD Mechanical. Bending tests are performed on the gear teeth are performed at characteristic contact points. The tooth root stress values obtained using the finite element method (FEM) are compared with those calculated according to the ISO standard.*

Key words: *spur gear, tooth root stress, single and double mesh, finite element method (FEM).*

1. INTRODUCTION

The load-carrying capacity of gear teeth is limited, among other factors, by the bending strength of the teeth root [1–5]. The calculation of gear pairs has been based on many researches and analyses [6–15].

To accunt for the load distribution among simultaneously meshing tooth pairs, the load distribution factor K_α is defined in the literature [1, 2]. This factor represents the degree of participation of each simultaneously meshing tooth pair in transmitting the total load.

From the viewpoint of load distribution, two characteristic extreme cases may occur in simultaneously meshing tooth pairs. The first corresponds to an ideal uniform load distribution, whereas the second represents an extremely uneven load distribution. The actual load distribution lies between these two extreme cases (Fig. 1).

In the case of extremely uneven load distribution, the entire load is transmitted by a single tooth pair, even when two or more tooth pairs are simultaneously in mesh. In this case, the load distribution factor reaches its maximum value ($K_\alpha = 1$ for single mesh). In the case of ideal uniform load distribution, all simultaneously meshing tooth pairs equally participate in transmitting the total load of the gear pair ($K_\alpha = 1/2$ for double mesh, $K_\alpha = 1/3$ for triple mesh, etc.).

The transverse contact ratio ε_α represents the average number of simultaneously meshing tooth pairs transmitting the total load. In this paper, the case of $1 \le \varepsilon_\alpha \le 2$, corresponding to the range $0{,}5 \le K_\alpha \le 1$, is considered.

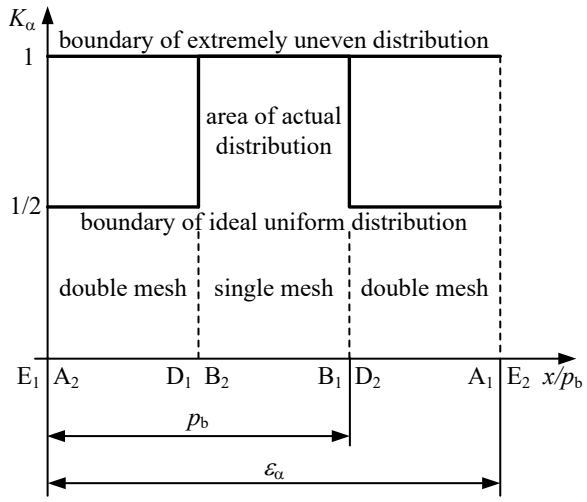

Figure 1. Boundary and actual load distributions in standard meshing gear tooth pairs

2. ANALYTICAL MODEL OF TOOTH ROOT STRESS

Based on the analyses presented in the literature [3], the general expression for the tooth root stress at any contact

Corresponding author: P. Dobratić
E-mail: dobraticp@yahoo.com
DOI: 10.5937/OTEH26029M

point during simultaneous meshing of the tooth profiles can be written as follows:

$$\sigma_{FX} = \sigma_0 \cdot K_{\alpha X} \cdot Y_{FX} \cdot Y_{SX} \qquad X \in (A, ..., E) \tag{1}$$

where σ_0 is the stress component that remains constant throughout the contact period from point $A \equiv A_1 \equiv A_2$ to point $E \equiv E_1 \equiv E_2$ (Fig. 1).

The variation of the tooth root stress during the contact period is analyzed by considering the ratio between the stress at an arbitrary contact point (X) and the stress at the outer point of the double mesh (point A in Fig. 1):

$$\frac{\sigma_{FX}}{\sigma_{FA}} = \frac{K_{\alpha X}}{K_{\alpha A}} \cdot \frac{Y_{FX} \cdot Y_{SX}}{Y_{FA} \cdot Y_{SA}} \tag{2}$$

Equation (2) can also be written in the following form:

$$\frac{\sigma_{FX}}{\sigma_{FA}} = \frac{K_{\alpha X}}{K_{\alpha A}} \cdot Y_{\varepsilon X} \tag{3}$$

where $Y_{\varepsilon X}$ is relative stress factor at the observed contact point.

2.1. Relative stress factor

The relative stress factor is defined as the ratio of the form factor and the stress correction factor at the observed contact point to the corresponding factors at the outer point of the double mesh:

$$Y_{\varepsilon X} = \frac{Y_{FX} \cdot Y_{SX}}{Y_{FA} \cdot Y_{SA}} \tag{4}$$

According to Eq. (4), the relative stress factor reaches its maximum value at the tooth contact at the outer point of the double mesh, i.e. $Y_{\varepsilon A} = 1$.

The relative stress factor is determined separately for both the pinion and wheel gear tooth pairs:

$$Y_{\varepsilon Xi} = \frac{Y_{FXi} \cdot Y_{SXi}}{Y_{FAi} \cdot Y_{SAi}} \tag{5}$$

where i=1 and 2 for the pinion tooth and wheel tooth.

Determination of the relative stress factor using Eq. (5) requires the values of the form factor and the stress correction factor at an arbitrary contact point, as well as the corresponding values at the outer point of the double mesh. Owing to the large number of influencing parameters, this procedure is suitable mainly for highly loaded or safety-critical gear pairs. For approximate calculations, the relative stress factor may be evaluated using simplified equations derived from appropriate approximations.

2.2. Approximate model of the relative stress factor

To simplify the determination of the relative stress factor, a linear variation during the contact period is assumed. In addition, it is assumed that the relative stress factor is identical for simultaneously meshing pinion and wheel gear teeth. Based on these assumptions, the relative stress factor during the contact period can be expressed as:

$$Y_{\varepsilon X} = 1 + \frac{Y_{\varepsilon E} - 1}{\varepsilon_\alpha} \cdot \frac{x}{p_b} \tag{6}$$

where are $Y_{\varepsilon E}$ – the relative stress factor for the inner point of the double mesh (point E in Fig. 2) and x/p_b – position of the contact point relative to the outer point of the double mesh (point A in Fig. 2).

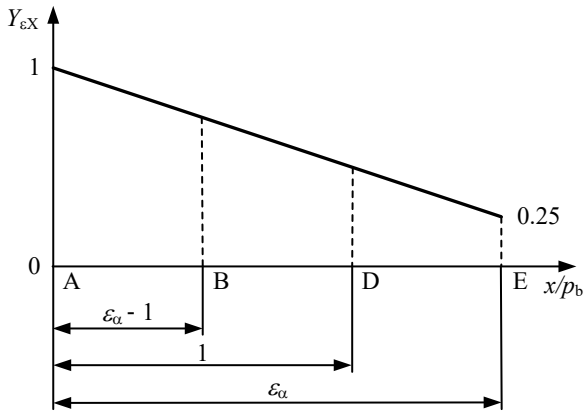

Figure 2. Approximation of the relative stress factor

Assuming that the minimum value of the relative stress factor occurs at the inner point of the double mesh $Y_{\varepsilon E} = 0.25$ (Fig. 2), the relative stress factor can be approximately determined for each characteristic point based on Eq. (6). Approximate equations for determining the relative stress factor are shown in Table 1.

Table 1. Approximate equations of the relative stress factor

point	$\frac{x}{p_b}$	$Y_{\varepsilon X}$	$Y_{\varepsilon\,apro}$	$Y_{\varepsilon\,apro}$ ($Y_{\varepsilon E} = 0.25$)
A	0	$Y_{\varepsilon A}$	$Y_{\varepsilon\,max}$	1
B	$\varepsilon_\alpha - 1$	$Y_{\varepsilon B}$	$1 + \frac{Y_{\varepsilon E} - 1}{\varepsilon_\alpha} \cdot (\varepsilon_\alpha - 1)$	$0.25 + \frac{0.75}{\varepsilon_\alpha}$
D	1	$Y_{\varepsilon D}$	$1 + \frac{Y_{\varepsilon E} - 1}{\varepsilon_\alpha}$	$\frac{\varepsilon_\alpha - 0.75}{\varepsilon_\alpha}$
E	ε_α	$Y_{\varepsilon E}$	$Y_{\varepsilon\,min}$	0.25

2.3. Analytical model of tooth root stress under ideal uniform load distribution

In the case of ideal uniform load distribution on simultaneously meshed teeth pairs, the values of the load distribution factor vary from $K_{\alpha X} = 1/2$ (for double mesh) to $K_{\alpha X} = 1$ (for single mesh). Substituting the limiting values of the load distribution factor into Eq. (1), analytical expressions for determining the tooth root stress at characteristic contact points at ideal uniform load distribution, according to the exact model, are obtained:

$$\sigma_{FX} = \frac{\sigma_0 \cdot Y_{FX} \cdot Y_{SX}}{2} \quad X \in (A \wedge E) \tag{7}$$

$$\sigma_{FX} = \sigma_0 \cdot Y_{FX} \cdot Y_{SX} \quad X \in (B \wedge D) \tag{8}$$

and by arranging Eq. (3), the tooth root stress at the characteristic contact points at ideal uniform load distribution can also be determined based on the following expressions, according to an approximate model:

$$\sigma_{FX} = Y_{\varepsilon X} \cdot \sigma_{FA} \quad X \in (A \wedge E) \tag{9}$$

$$\sigma_{FX} = 2 \cdot Y_{\varepsilon X} \cdot \sigma_{FA} \quad X \in (B \wedge D) \tag{10}$$

If it is assumed that the minimum value of the relative stress factor is at the inner point of the double mesh $Y_{\varepsilon E} = 0{,}25$, the tooth root stress at ideal uniform load distribution is, based on the expressions in Table 2 and Eqs. (9) and (10), given for:

- the outer point of the double mesh (point A)

$$\sigma_{FA} = 1 \cdot \sigma_{FA} \tag{11}$$

- the outer point of the single mesh (point B)

$$\sigma_{FB} = 2 \cdot \left(0.25 + \frac{0.75}{\varepsilon_\alpha}\right) \cdot \sigma_{FA} \tag{12}$$

- the inner point of the single mesh (point D)

$$\sigma_{FD} = 2 \cdot \left(\frac{\varepsilon_\alpha - 0.75}{\varepsilon_\alpha}\right) \cdot \sigma_{FA} \tag{13}$$

- the inner point of the double mesh (point E)

$$\sigma_{FE} = 0.25 \cdot \sigma_{FA} \tag{14}$$

When the minimum value of the relative stress factor at the inner point of the double mesh is $Y_{\varepsilon E} = 0.25$, for the tooth root stress with ideal uniform load distribution, based on Eqs. (11) to (14) according to the approximate model, it follows that $\sigma_{FB} > \sigma_{FA} > \sigma_{FD} > \sigma_{FE}$. The tooth root stress at ideal uniform load distribution on simultaneously meshed teeth pairs is greatest at the outer point of the single mesh.

2.4. Analytical model of tooth root stress under extremely uneven load distribution

In the case of extremely uneven load distribution, the values of the load distribution factor vary from $K_{\alpha X} = 0$ (when the tooth does not transmit the load at all) to $K_{\alpha X} = 1$ (when the tooth transmits the total load). By substituting only the limiting value of the load distribution factor $K_{\alpha X} = 1$ into Eq. (1), analytical expression for determining in the tooth root stress at characteristic contact points at extremely uneven load distribution when the total load is transmitted over one tooth pair, according to the exact model, is obtained:

$$\sigma_{FX} = \sigma_0 \cdot Y_{FX} \cdot Y_{SX} \quad X \in (A, ..., E) \tag{15}$$

and by arranging Eq. (3), the tooth root stress at the characteristic contact points at extremely uneven load distribution when the total load is transmitted over one tooth pair can also be determined based on the following expression, according to an approximate model:

$$\sigma_{FX} = Y_{\varepsilon X} \cdot \sigma_{FA} \quad X \in (A, ..., E) \tag{16}$$

If it is assumed that the minimum value of the relative stress factor is at the inner point of the double mesh $Y_{\varepsilon E} = 0.25$, in the tooth root stress when the entire load is transmitted through a single tooth pair is, based on the expressions in Table 2 and Eq. (16), given for:

- the outer point of the double mesh (point A)

$$\sigma_{FA} = 1 \cdot \sigma_{FA} \tag{17}$$

- the outer point of the single mesh (point B)

$$\sigma_{FB} = \left(0.25 + \frac{0.75}{\varepsilon_\alpha}\right) \cdot \sigma_{FA} \tag{18}$$

- the inner point of the single mesh (point D)

$$\sigma_{FD} = \left(\frac{\varepsilon_\alpha - 0.75}{\varepsilon_\alpha}\right) \cdot \sigma_{FA} \tag{19}$$

- the inner point of the double mesh (point E)

$$\sigma_{FE} = 0.25 \cdot \sigma_{FA} \tag{20}$$

When the minimum value of the relative stress factor at the inner point of the double mesh is $Y_{\varepsilon E} = 0.25$, for the tooth root stresses when the total load is transmitted over one tooth pair, based on Eqs. (17) to (20) according to the approximate model, it can be concluded that $\sigma_{FA} > \sigma_{FB} > \sigma_{FD} > \sigma_{FE}$. The tooth root stress at extremely uneven load distribution when the entire load is transmitted through a single tooth pair is greatest at the outer point of the double mesh.

3. 3D MODELS OF SPUR GEAR AND 2D MODELS OF GEAR TEETH

All geometric and kinematic parameters required for the 3D modelling of spur gear are determined using the Octave program, and the most relevant ones are presented in this paper. A spur gear pair with a pinion/wheel tooth number of z_1=29, z_2=118, standard module m_n=6,5mm, pressure angle α=20°, profile shift coefficients for the pinion and wheel gear x_1=0.2, x_2=0.2, center distance a=480.24mm, and transverse contact ratio ε_α=1.75 is considered. Based on these geometric and kinematic parameters, 3D models of the pinion and wheel gear are created in CATIA program is created (Figs. 3 and 4).

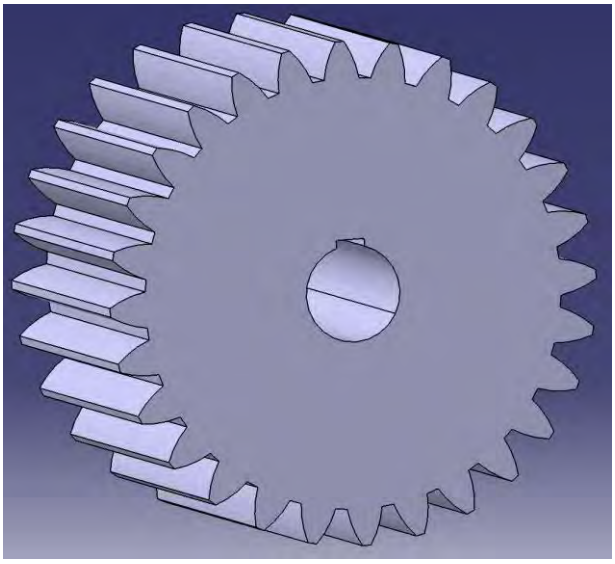

Figure 3. Model of the pinion gear

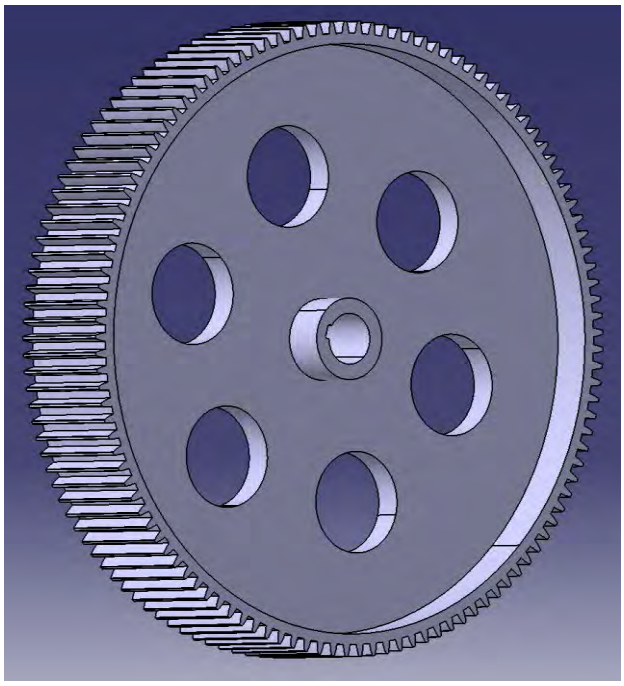

Figure 4. Model of the wheel gear

To determine the tooth root stress values, 2D tooth models of both gears are developed using FEM in AutoCAD Mechanical and are subjected to an identical load of 6518.73N (Figs. 5 to 8).

The tooth root stress is evaluated at two characteristic points, A and B, as these represent the most critically loaded locations.

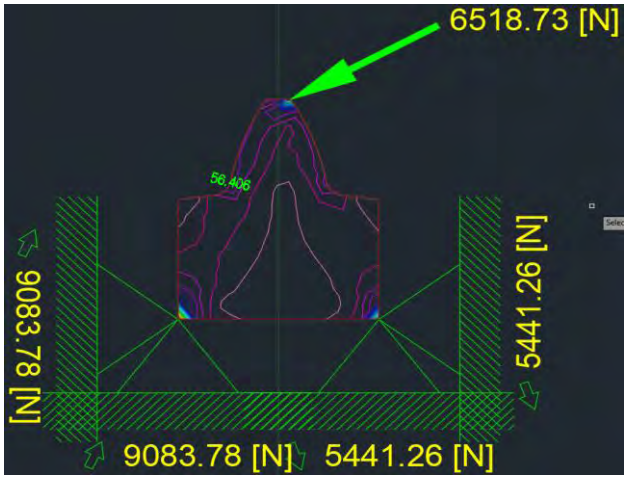

Figure 5. Pinion gear tooth model (load applied at point A)

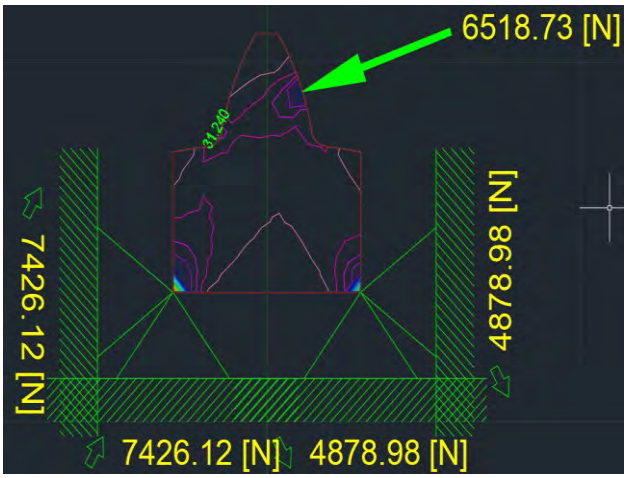

Figure 6. Pinion gear tooth model (load applied at point B)

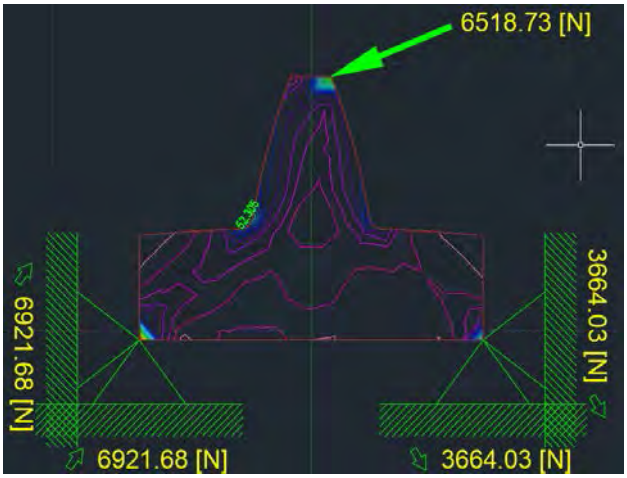

Figure 7. Wheel gear tooth model (load applied at point A)

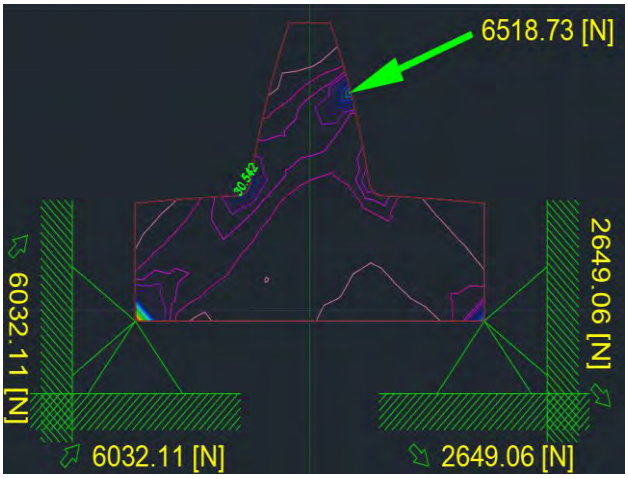

Figure 8. Wheel gear tooth model (load applied at point B)

Table 2 presents the tooth root stress values for both gears at points A and B, obtained using FEM.

Table 2.Tooth root stress values at points A and B

point	σ_F [N/mm^2]	pinion gear	wheel gear
A	σ_{FA}	56.41	52.31
B	σ_{FB}	31.24	30.54

4. ISO CALCULATION OF TOOTH ROOT STRESS AND COMPARATIVE ANALYSIS

For Method "B" specified in the ISO standard [16, 17], detailed guidelines for the calculation procedure are provided; therefore, only this method is considered in the present study. According to Method B, the tooth root stress is determined at point B, assuming an ideal uniform load distribution. The tooth root stress values at point B calculated according the ISO standard are presented in Table 3.

Table 3. Tooth root stress values at point B

point	σ_F [N/mm^2]	pinion gear	wheel gear
B	σ_{FB}	31.19	30.61

To validate the tooth root stress analysis performed according to Method B of the ISO standard, as well as the proposed analytical (approximate) model, a numerical model based on the FEM is developed in AutoCAD Mechanical.

A comparison of the tooth root stress values obtained using Method B of the ISO standard with those obtained from the FEM analysis shows excellent agreement. At point B, the deviation is less than 0.01%. This negligible difference results from the accurate generation of the numerical model and the appropriate selection of the analysis parameters, such as the material properties of the gears.

If the tooth root stress value at point A listed in Table 2 is divided by two to account for the double-mesh condition, i.e., if both the load distribution factor and the tooth geometry are taken into account, the stress at the outer point of the single mesh (point B) becomes greater than that at the outer point of the double mesh (point A). This behavior is also predicted by the developed analytical model for ideal uniform load distribution.

In the case of extremely uneven load distribution, where the entire load is transmitted through a single tooth pair, the tooth root stress at the outer point of the double mesh (point A) is greater than that at the outer point of the single mesh (point B). The same trend is observed in the FEM results (Figs. 5-8) and in the data presented in Table 2. This behavior is a consequence of neglecting the load distribution factor while considering only the influence of tooth geometry.

5. CONCLUSION

Based on the developed analytical and numerical models for tooth root stress, it can be concluded that the variation of the tooth root stress depends on the variation of the load distribution factor, the form factor, and the stress correction factor, all of which vary with the position of the contact point along the tooth profile. The developed analytical models can be used for the simplified determination of the relative stress factor and for the approximate evaluation of the tooth root stress.

A comparative analysis of the results obtained using Method B of the ISO standard and the numerical model showed excellent agreement between the two approaches. For engineering applications, it is recommended that both methods be used in combination: the ISO method for the rapid assessment and verification of less critical gear pairs, and 2D or 3D numerical models for the final analysis and optimization of highly loaded or safety-critical gear pairs.

This combined approach enables the design of gear pairs that are not only safe and reliable but also economical, ensuring efficient material utilization and an extended service life.

Abstract: *The design of planetary gearboxes involves a strongly coupled set of geometric, kinematic, and tribological parameters whose simultaneous optimization is computationally demanding, particularly when load-dependent efficiency is treated as a design objective rather than a post-evaluation metric. This paper presents an optimization framework that integrates the genetic algorithm with a deep neural network (DNN) surrogate trained to reproduce a semi-analytical mechanical power-loss model accounting for sliding and rolling friction and electrohydrodynamic lubrication effects in both external and internal gear meshes. Replacing the iterative instantaneous-efficiency computation with the trained DNN reduces the per evaluation cost by several orders of magnitude, enabling genetic algorithm to explore large populations over many generations within practical runtimes. Numerical results show that the proposed algorithm yields a denser and better-distributed Pareto frontier, achieving comparable or superior compromise solutions with substantially reduced computational effort, and confirm that data-driven surrogates can be reliably embedded within evolutionary design loops for power-dense mechanical transmissions.*

Keywords: *planetary gearbox; multi-objective optimization; neural network; surrogate model; gear efficiency*

1. INTRODUCTION

Planetary gear trains are widely employed in mechanical transmission systems, including industrial drives, rotorcraft, automotive powertrains, wind turbines, and robotic actuators [1], [2]. Compared with conventional parallel-axis gear trains, they offer more compact dimensions, higher power densities, lower noise, and superior torque-to-weight ratios, which makes them especially attractive in aerospace and defense applications where mass minimization is critical. These advantages, however, are obtained at the cost of a considerably more involved design process, because the load is shared among several planet branches and the total efficiency of the train is determined by the interaction of multiple external and internal gear meshes [1].

Accurate prediction of power losses during the design stage allows the designer to introduce appropriate modifications before the gearbox is manufactured and tested. A large body of work addresses gear efficiency and power loss in parallel-axis systems [3], [4], the majority of it concerned with mechanical (load-dependent) power loss. Far fewer studies treat the power losses of planetary systems, and most of those that do are based on the analysis of gear-train kinematics, using speed and torque equations to evaluate effectiveness [3]. Such kinematic models neglect the lubricant interactions that occur when non-uniform normal loads acting along the line of action, and they rarely consider the simultaneous minimization of mass and maximization of efficiency.

Many engineering design problems have recently been tackled with nature-inspired metaheuristic algorithms, such as the genetic algorithm (GA) [5], particle swarm optimization, differential evolution, and the firefly algorithm [6], [7]. These methods are derivative-free, easily adapted to different problem formulations, and capable of locating global optima of multimodal functions. For multi-objective gearbox design the non-dominated sorting genetic algorithm II (NSGA-II) [8] has become a de facto standard, since it returns a well-spread approximation of the Pareto frontier in a single run. The principal obstacle to its use is computational: every candidate design must be evaluated by an expensive constraint and objective analysis, and when load-dependent efficiency is included as an objective, each evaluation requires the numerical integration of an instantaneous-efficiency model along the line of action of every mesh.

To overcome this bottleneck, the present work treats efficiency as a first-class design objective and replaces its costly numerical evaluation with a deep neural network (DNN) surrogate [9]. The surrogate is trained offline on a dataset generated by a semi-analytical power-loss model that accounts for sliding and rolling friction together with elastohydrodynamic lubrication (EHL) effects in both external (sun-planet) and internal (planet-ring) meshes. Once trained, the DNN predicts the average mesh

DOI: 10.5937/OTEH26030R

efficiency from the gear-pair parameters in a single forward pass, reducing the per-evaluation cost by several orders of magnitude. The surrogate is embedded directly within an NSGA-II loop, in which gearbox volume, contact ratio, and load-dependent efficiency are optimized simultaneously subject to bending-strength, pitting-resistance, assembly, and geometric constraints formulated according to ISO 6336 [9].

The remainder of the paper is organized as follows. Section 2 formulates the multi-objective optimization problem together with the objective functions and constraints. Section 3 describes the semi-analytical gear-mesh efficiency model. Section 4 introduces the proposed DNN surrogate and reports its training accuracy. Section 5 outlines the surrogate-assisted NSGA-II procedure, and Section 6 presents and discusses the numerical results. Conclusions are drawn in Section 7.

2. OPTIMIZATION PROBLEM FORMULATION

A single-stage planetary gear set is considered, consisting of a floating sun gear, three equally spaced planet gears, and a ring gear rigidly fixed to the housing, as illustrated in Fig. 1. Following the notation common in the literature, a denotes the sun, g the planet, b the ring, and s the carrier. The design is governed by the decision vector

$$\mathbf{x} = \left[z_a, z_g m, x_a, x_g, b\right]^T, \tag{1}$$

which collects the sun and planet tooth numbers z_a, z_g the normal module m, the profile-shift coefficients x_a, x_g, and the face width b. The ring tooth number follows from the assembly condition and the prescribed transmission ratio. Because low mass and high efficiency are mutually conflicting requirements, the design task is posed as a multi-objective optimization (MOO) problem

$$\min F(\mathbf{x}) = \min\left[V(\mathbf{x}), 1-\eta^H(\mathbf{x}), \varepsilon_\alpha(\mathbf{x})\right]^T \tag{2}$$

subject to the inequality and equality constraints $g_i(\mathbf{x}) \le 0$, $i = 1,\ldots,m$, and $h_j(\mathbf{x}) = 0$, $j = 1,\ldots,p$.

The first objective is the structural volume of the gear set, which under the assumption of a homogeneous material is proportional to its mass:

$$V(\mathbf{x}) = \frac{\pi}{4}\left[b d_a^2 + n_w\left(d_a^2 - D^2\right) + \left(d_g^2 - d_s^2\right)\right], \tag{3}$$

where d_a is the sun pitch diameter, D the outer ring diameter, d_s the bearing-bore diameter, $n_w = 3$ the number of planets, and b the face width. The second objective is the load-dependent mesh efficiency η^H of the planetary train, derived in Section 3, while the third objective maximizes the transverse contact ratio ε_α, which governs load sharing and meshing smoothness.

The constraints ensure mechanical integrity and geometric feasibility. Tooth-root bending and flank pitting are limited through the ISO 6336 safety factors [10],

$$\begin{aligned} g_1(\mathbf{x}) &= S_{F\min} - S_F(\mathbf{x}) \le 0, \\ g_2(\mathbf{x}) &= S_{H\min} - S_H(\mathbf{x}) \le 0 \end{aligned} \tag{4}$$

where S_F and S_H are the computed safety factors against bending and pitting and $S_{F\min}, S_{H\min}$ the prescribed minima. The simultaneous meshing of the sun and planets imposes the assembly (equality) constraint

$$h_1(\mathbf{x}) = (z_a + z_b)/n_w - k = 0,\ k \in \square \tag{5}$$

while a neighbouring-planet (space) constraint prevents interference between adjacent planets. Since the evolutionary algorithm cannot handle constraints directly, a static penalty formulation is adopted, in which each violated constraint augments the corresponding objective with a quadratic penalty term proportional to the squared constraint violation, thereby transforming the constrained problem into a sequence of unconstrained ones.

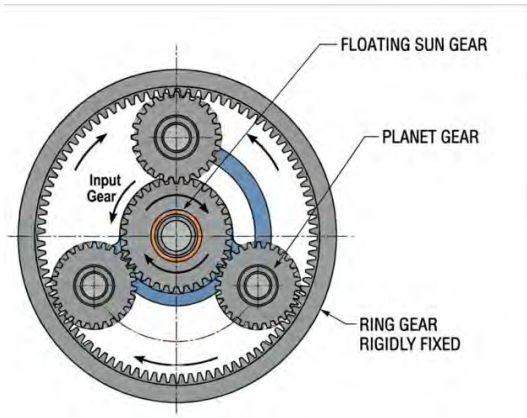

Figure 1. Single-stage planetary gear set considered in the optimization model.

3. GEAR-MESH EFFICIENCY MODEL

The efficiency of each gear pair is evaluated with a semi-analytical, load-dependent power-loss model. The total tangential friction force in a mesh is decomposed into a sliding and a rolling component. The sliding friction force is

$$F_s(\mathbf{x}) = \mu(\mathbf{x}) F_n(\mathbf{x}), \tag{6}$$

where $F_n(\mathbf{x})$ is the normal load and the friction coefficient μ is obtained from an empirical elastohydrodynamic relation

$$\mu(\mathbf{x}) = 0{,}0127 \log\left[29{,}66 F_n / \left(b v_s v_0^2\right)\right] R_a^{0{,}43}, \tag{7}$$

with b the face width, v_s and v_0 the sum and entrainment velocities at the contact, and R_a the surface roughness. The rolling friction force is proportional to the lubricant film thickness h,

$$F_r(\mathbf{x}) = C h(\mathbf{x}) b, \tag{8}$$

and the central EHL film thickness is estimated from a Dowson-Higginson-type relation

$$h(\mathbf{x}) = 1,6\alpha^{0,6}\left(\eta_0 v_0\right)^{0,7} E^{0,03} R^{0,43} F_n^{-0,13}, \qquad (9)$$

where α is the pressure-viscosity coefficient, η_0 the dynamic viscosity, E the equivalent elastic modulus, and R the equivalent radius of curvature. Because the number of tooth pairs in contact and the load they carry change along the line of action, the friction forces and the resulting torque loss are evaluated for the single-pair and double-pair contact zones separately. The instantaneous efficiency at a contact position is then

$$\eta_i(\mathbf{x}) = \frac{T_2}{T_1 u_{1-2}}, \qquad (10)$$

with T_1, T_2 the input and output torques and u_{1-2} the gear ratio. The average mesh efficiency is obtained by integrating the instantaneous efficiency over the active length L_a of the line of action (between points A and E), e.g.

$$\eta = \frac{1}{L_a}\int_A^E \eta_i(l)\,dl\,. \qquad (11)$$

For the planetary train the overall efficiency is assembled from the relative efficiencies of the external sun-planet mesh η_{ag} and the internal planet-ring mesh η_{gb}, combined through the carrier kinematics as

$$\eta^H = \frac{1-\eta_{ag}\eta_{gb}u_{ab}^H}{1-u_{ab}^H}, \qquad (12)$$

where u_{ab}^H is the relative (carrier-fixed) gear ratio. Equations (6)-(12) constitute the reference numerical model: each efficiency evaluation requires the iterative computation of the geometry, the contact kinematics, and the integration along the line of action for both meshes, which makes its repeated use inside an evolutionary loop computationally very expensive.

4. DEEP NEURAL NETWORK SURROGATE

To eliminate the cost of the iterative model, a feed-forward DNN is trained to approximate the mapping from the gear-pair parameters to the average mesh efficiency, $\bar{\eta} = f(\mathbf{x};\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ denotes the network weights and biases. The input vector comprises eleven features, e.g. the tooth numbers z_1, z_2 the module m, the pressure angle α_n, the profile shifts x_1, x_2, the face width b, the helix angle β, the input angular speed ω_1, the input torque T_1 and the lubricant viscosity. The network has two hidden layers with rectified-linear (ReLU) activations and a single linear output neuron.

A dataset of 4608 samples was generated by evaluating the semi-analytical model of Section 3 over a space-filling design covering realistic ranges of the input parameters. The data were split into training, validation, and test subsets in a 70/15/15 ratio, and all inputs were standardized to zero mean and unit variance using the training statistics. Training minimized the mean-squared-error loss

$$L(\theta) = \frac{1}{N}\sum\left(\bar{\eta}_i - \hat{\eta}_i\right)^2 \qquad (13)$$

with the Adam optimizer (initial learning rate 3×10^{-3}, up to 300 epochs, mini-batch training, and early stopping on the validation loss). On the held-out test set the surrogate reproduces the reference efficiencies with a coefficient of determination $R^2 = 0,935$, a root-mean-square error $RMSE = 0.0011$, and a mean absolute percentage error $MAPE = 0.09\,\%$. The typical prediction error is therefore only about 0.11 %, well within the modelling uncertainty of the reference efficiency model itself. Fig. 2 shows the corresponding parity plot, in which the predicted and reference efficiencies cluster tightly along the 45° line across the entire efficiency range.

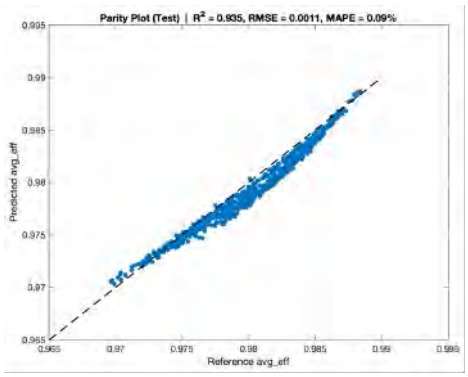

Figure 2. Parity plot of DNN-predicted versus reference average efficiency on the test set.

Because a single forward pass requires only two small matrix-vector products and ReLU evaluations, the surrogate replaces the iterative line-of-action integration with a closed-form mapping, reducing the cost of one efficiency evaluation by several orders of magnitude while preserving accuracy. This makes it feasible to evaluate the efficiency objective for every individual across many generations of the evolutionary search.

5. SURROGATE-ASSISTED OPTIMIZATION

The multi-objective optimization problem of Eq. (2) is solved within a surrogate-assisted evolutionary framework. The trained DNN surrogate of Section 4 replaces the iterative gear-mesh efficiency model inside the optimization loop, so that the load-dependent efficiency objective η^H is evaluated by a single forward pass through the network rather than by the numerical integration of Eqs. (6)-(12). The structural volume V and the transverse contact ratio ε_α are computed analytically from the decision vector at negligible cost, and the ISO 6336 bending and pitting safety factors are obtained from closed-form expressions. Constraint violations are handled through a static quadratic penalty: each violated constraint augments the corresponding objective by a term proportional to the squared violation, transforming

the constrained problem into a sequence of unconstrained evaluations.

5.1 Non-Dominated Sorting Genetic Algorithm II (NSGA-II)

The evolutionary engine of the framework is the Non-dominated Sorting Genetic Algorithm II (NSGA-II) [8] a population-based metaheuristic that returns a well-distributed approximation of the Pareto-optimal set in a single run. Starting from an initial population of N_p candidate designs, NSGA-II iteratively applies genetic operators to generate offspring, merges parents and offspring into a combined pool, and selects the survivors for the next generation using two ranking criteria: non-domination rank and crowding distance.
A candidate design $\mathbf{x}_i$ is said to dominate $\mathbf{x}_j$ if

$$\begin{aligned} &F_k(\mathbf{x}_i) \le F_k(\mathbf{x}_j) \quad \forall k \\ &\wedge F_k(\mathbf{x}_i) < F_k(\mathbf{x}_j) \quad \exists k, \end{aligned} \tag{14}$$

where F_k denotes the k-th component of the objective vector.

Fast non-dominated sorting partitions the combined pool $R_g = P_g \cup Q_g$ of size $2N_p$ into a sequence of fronts $\mathrm{F}_1, \mathrm{F}_2, \ldots$ such that every solution in F_1 is non-dominated within R_g, every solution in F_2 is non-dominated after the removal of F_1, and so on. The algorithm assigns rank $r(\mathbf{x}) = k$ to every individual belonging to F_k.

Crowding distance

Within a given front, diversity is preserved through the crowding distance $d_c(\mathbf{x}_i)$, defined as the normalized perimeter of the smallest axis-aligned cuboid enclosing the two nearest neighbors of $\mathbf{x}_i$ in objective space

$$d_c(\mathbf{x}_i) = \sum_{k=1}^{M} \frac{F_k(\mathbf{x}_{i+1}) - F_k(\mathbf{x}_{i-1})}{F_k^{\max} - F_k^{\min}}, \tag{15}$$

where $M = 3$ is the number of objectives, the indices $i-1$ and $i+1$ denote the left and right neighbours of $\mathbf{x}_i$ when the front is sorted by F_k, and $F_k^{\max}$, $F_k^{\min}$ are the extreme values of objective k within the front. Boundary solutions are assigned $d_c = \infty$ to ensure they are always retained. The crowded-comparison operator $\prec_c$ then defines a total order on the population: $\mathbf{x}_i \prec_c \mathbf{x}_j$ if

$$\begin{aligned} &r(\mathbf{x}_i) < r(\mathbf{x}_j), \vee r(\mathbf{x}_i) = r(\mathbf{x}_j) \\ &\wedge \; d_c(\mathbf{x}_i) > d_c(\mathbf{x}_j). \end{aligned} \tag{16}$$

Selection

Binary tournament selection is used to form the mating pool. Two individuals are drawn at random from the current population and the winner is determined by the crowded-comparison operator of Eq.(16) the process is repeated until N_p parents have been selected.

Crossover

Real-valued design variables (m, x_a, x_g, b) are recombined by Simulated Binary Crossover (SBX). Given two parent values $x^{(1)}$ and $x^{(2)}$ ($x^{(1)} \le x^{(2)}$), SBX produces two offspring values

$$x_{\text{off}}^{(1,2)} = \tfrac{1}{2}\left[(1 \pm \beta_q)x^{(1)} + (1 \mp \beta_q)x^{(2)}\right], \tag{17}$$

where the spread factor β_q is sampled from a polynomial probability distribution controlled by the distribution index η_c

$$\beta_q = \begin{cases} (2u)^{1/(\eta_c+1)}, & u \le 0.5, \\ \left[1/(2(1-u))\right]^{1/(\eta_c+1)}, & u > 0.5, \end{cases} \tag{18}$$

with $u \sim \mathrm{U}(0,1)$. A larger η_c biases offspring towards the parents (exploitation), while a smaller value promotes wider exploration. The integer tooth numbers z_a and z_g are recombined by uniform integer crossover, after which the ring tooth number z_b is recovered from the assembly constraint of Eq. (5) by rounding to the nearest integer satisfying $h_1(\mathbf{x}) = (z_a + z_b)/n_w - k = 0$, $k \in \square$. Crossover is applied with probability p_c.

Mutation.

Polynomial mutation perturbs each real-valued variable independently with probability p_m. For a variable x with bounds $[x^L, x^U]$, the mutated value is

$$x' = x + \delta_q (x^U - x^L), \tag{19}$$

where the perturbation δ_q is drawn from a polynomial distribution parameterized by the distribution index η_m

$$\delta_q = \begin{cases} (2u)^{1/(\eta_m+1)} - 1, & u < 0.5, \\ 1 - \left[2(1-u)\right]^{1/(\eta_m+1)}, & u \ge 0.5, \end{cases} \tag{20}$$

with $u \sim \mathrm{U}(0,1)$. Integer variables are subjected to random integer mutation, replacing the current value with a uniformly drawn integer within the prescribed bounds. Variable bounds are enforced after every mutation step.

Survivor selection and termination

The next population P_{g+1} is assembled from the combined pool $R_g = P_g \cup Q_g$ by accepting fronts $\mathrm{F}_1, \mathrm{F}_2, \ldots$ in rank order until the N_p capacity would be exceeded; the remaining slots are filled by the solutions with the largest crowding distance from the first front that does not fit entirely. The procedure terminates after $G_{\max}$ generations or when the hypervolume indicator of the current first front F_1 does not improve over ΔG consecutive generations.

Compromise solution extraction.

Because the conflicting objectives yield a set of trade-off designs rather than a unique optimum, a representative compromise solution is extracted from the final Pareto set $\mathrm{P}^* = \mathrm{F}_1^{(G)}$.

The ideal point $\mathbf{f}^{\text{ideal}}$ is formed by the individually optimal value of each objective over P^*. Since this point is generally unattainable, the compromise design is selected as the Pareto-optimal solution nearest to $\mathbf{f}^{\text{ideal}}$ in the normalized objective space:

$$\mathbf{x}^* = \arg\min_{\mathbf{x}\in \mathrm{P}^*} \left\| \frac{F(\mathbf{x}) - \mathbf{f}^{\text{ideal}}}{\mathbf{f}^{\text{nadir}} - \mathbf{f}^{\text{ideal}}} \right\|_2, \tag{21}$$

where $\mathbf{f}^{\text{nadir}}$ collects the worst objective values over P^*. This minimum-distance criterion identifies the knee region of the frontier, where a small sacrifice in one objective yields the largest gain in the others.

6. SIMULATION RESULTS

The surrogate-assisted framework was applied to an example single-stage planetary gear set with three equally spaced planets and a ring gear fixed to the housing; the main fixed parameters are listed in Table 1. To assess the benefit of the surrogate-assisted strategy, the proposed NSGA-II framework was compared with a conventional, single-front GA driven by the same objective and constraint evaluations.

Table 1. Parameters of the example planetary gear set

Parameter	Value
Input power, P [kW]	200
Input speed, n [rpm]	2750
Normal pressure angle, α [°]	20
Gear material	18CrNiMo8
Surface roughness, R_a [μm]	0.8
Bending safety factor, $S_{F\min}$	1.20
Pitting safety factor, $S_{H\min}$	1.25
Number of planets, n_w	3

Figure 3 shows the volume-efficiency Pareto frontier obtained with the surrogate-assisted NSGA-II and the conventional GA, the two primary and mutually conflicting objectives of the design problem. Figure 4 reprojects the same set of optimal designs onto the contact-stress-contact-ratio plane, with the flank contact stress σ_H plotted against the transverse contact ratio ε_α. The runs used a population of 200 individuals evolved over 400 generations.

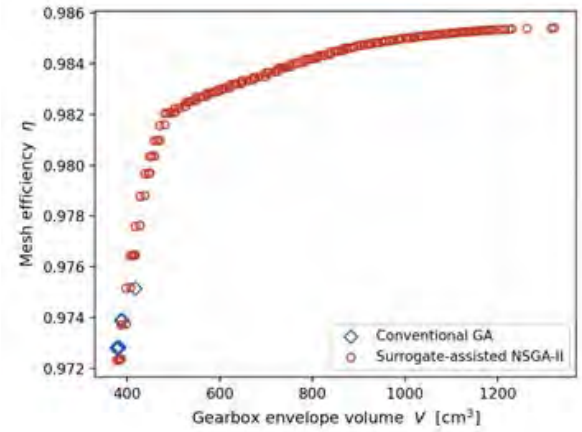

Figure 3. Volume-efficiency Pareto frontier for the surrogate-assisted NSGA-II and the conventional GA.

Comparing the two algorithms, NSGA-II returns a dense, smooth, and uniformly distributed frontier that spans the whole trade-off region, from compact designs of about 380 cm³ at a mesh efficiency near 0.972 up to larger designs of about 1320 cm³ reaching 0.985. The conventional GA, by contrast, collapses to a small cluster of solutions in the minimum-volume corner ($V \approx$ 380-420 cm³, $\eta \approx$ 0.973-0.975) and fails to recover the rest of the frontier. This illustrates the role of the crowding-distance operator in maintaining diversity: without it, selection pressure drives the population to a single region and the trade-off curve is lost.

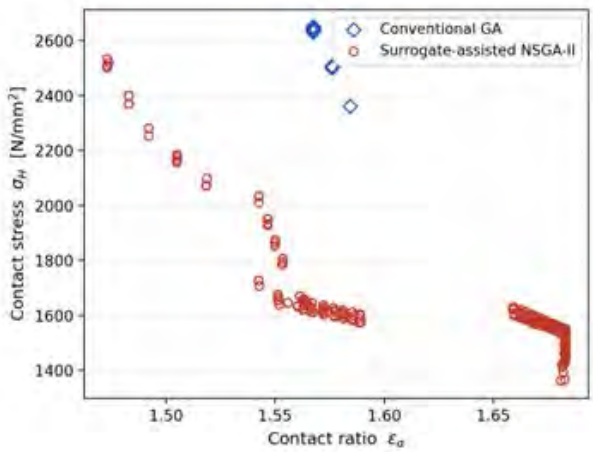

Figure 4. Projection of the optimal designs onto the contact-stress-contact-ratio plane.

The reprojection in Fig. 4 confirms the expected design trend: as the contact ratio increases the flank contact stress decreases, from about 2530 N/mm² at $\varepsilon_\alpha \approx 1.47$ down to about 1360 N/mm² at $\varepsilon_\alpha \approx 1.68$. The ideal point combines the minimum attainable volume (about 380 cm³) with the maximum efficiency (about 0.985); since it is not attainable simultaneously, a compromise design is selected as the Pareto point of minimum normalized distance to the ideal point. This knee design has an envelope volume of about 530 cm³, a mesh efficiency of 0.982, a contact ratio of 1.56, and a contact stress of about 1.66×10³ N/mm², offering a near-optimal efficiency at a

fraction of the largest volume. All Pareto-optimal designs satisfy the contact-ratio and strength constraints by construction.

Crucially, these results were obtained with the DNN surrogate carrying the entire efficiency-objective workload inside the optimization loop. Replacing the iterative model with the surrogate reduced the per-evaluation cost by several orders of magnitude, which is what made it practical for NSGA-II to evaluate large populations over many generations and thereby resolve the frontier so finely. The close agreement between the surrogate predictions and the reference model (Fig. 2) confirms that this acceleration is achieved without sacrificing the fidelity of the efficiency objective.

7. CONCLUSION

This paper presented a surrogate-assisted framework for the multi-objective optimization of single-stage planetary gearboxes, in which load-dependent efficiency is treated as a design objective rather than a post-evaluation metric. A deep neural network surrogate was trained to reproduce a semi-analytical, EHL-based gear-mesh power-loss model and embedded directly within an NSGA-II loop that simultaneously optimizes gearbox volume, contact ratio, and efficiency subject to ISO 6336 strength, assembly, and geometric constraints.

The surrogate reproduces the reference efficiency with $R^2 = 0.998$, RMSE = 2×10^{-4}, and MAPE = 0.016 %, while reducing the cost of an efficiency evaluation by several orders of magnitude. As a result, the proposed algorithm explores large populations over many generations within practical runtimes and yields a denser, better-distributed Pareto frontier than a conventional genetic algorithm, achieving comparable or superior compromise designs with substantially reduced computational effort. The study confirms that data-driven surrogates can be reliably integrated into evolutionary design loops for power-dense mechanical transmissions. Future work will extend the approach to multi-stage architectures and to the prediction of stress distributions in asymmetric gears, where the surrogate could replace computationally expensive finite-element evaluations within the optimization model.

Abstract: *In conditions of high use of unmanned platforms that are tasked with transferring a payload and performing a specific activity, and the same platform can be used multiple times, there is a need for a device that will enable safe operation and manipulation of the equipment, reliable activation of the executive elements, as well as their re-securing in the event that the platform has to return with the payload. To enable all of the above, the device should contain multiple mutually conditioned electromechanical protection elements that will provide it with the required level of safety and reliability.*

Keywords: *unmanned platforms, securing executive mechanism, S&EM, remote activation.*

1. INTRODUCTION

The evolution of the modern battlefield and the adoption of new technical solutions – particularly the mass deployment of unmanned platforms in both the air and on the ground – are continuously transforming the way frontline troops operate and altering the nature of the front as a whole. These technical solutions and their impact on tactics are bringing about constant and significant changes to the battlefield. Consequently, certain types of weaponry and equipment are beginning to lose their place on the front line. One such weapon is undoubtedly the handheld rocket launcher firing unguided rockets.

For a long time, this type of weaponry held a significant place in the combat formations of armies worldwide, for a variety of reasons: inexpensive production, ease of training and operation, and the ability to inflict serious damage on the target. As such – particularly rocket launchers equipped with shaped-charge warheads – they have been employed in all conditions, ranging from the front line and urban combat to sabotage and special operations.

With the evolution of the battlefield and new conditions – driven primarily by the use of unmanned platforms – leading to a significant expansion of the line of separation between opposing forces, handheld rocket launchers face a dwindling number of potential targets that can be engaged using conventional tactics, due to their limited range.

Given the current situation, two possible scenarios lie ahead for handheld rocket launchers: their gradual phasing out, or their adaptation for integration into unmanned combat platforms, thereby overcoming their limitations on the modern battlefield.

To achieve this, the handheld rocket launcher itself must be adapted for launch from unmanned platforms, and an adequate mechanism must be developed to ensure safe handling and reliable launching.

2. THEORETICAL BASIS

Unmanned platforms represent one of the most significant technological advancements that has fundamentally altered the nature of modern armed conflicts. Their deployment has enhanced the effectiveness of reconnaissance, surveillance, precision strikes, and intelligence gathering, while simultaneously reducing risks to personnel. Thanks to their relatively low cost, rapid technological development, and widespread

DOI: 10.5937/OTEH26031B

availability, unmanned platforms have become a key factor reshaping tactics, operational procedures, and the conduct of modern military operations, significantly influencing the balance of power and the dynamics of conflict.

Equipping reusable unmanned platforms for precision strikes against lightly armored combat vehicles and fortified enemy positions requires outfitting them with appropriate effectors in a manner that ensures maximum operational efficiency and effectiveness, alongside high operational reliability.

To meet these requirements, it is necessary to develop a suitable device – a so-called securing and executive mechanism (S&EM) – whose electronic subsystem must ensure the following:

- The electronics unit must decode two commands from the drone receiver transmitted over a single protocol line;
- The signal from the remote control receiver enters the electronics unit via a single line;
- One command relates to launch preparation, while the other initiates the launch itself;
- The device must meet specific requirements regarding operational safety and the servicing of the armed unmanned platform, as well as operational reliability, ensuring a high level of effector availability on the unmanned platform under all operating conditions.

3. INITIAL HYPOTHESES

3.1 Technical Requirements

The initial requirements to be met by the S&EM defined a set of technical characteristics the device must possess to satisfy these requirements.

Accordingly, in addition to the command-decoding electronics unit, the assembly must incorporate electromechanical safety features that ensure:

- Interruption of the power supply to the entire electronics assembly during the handling of the drone and the launcher-missile unit, lasting until the moment immediately prior to drone takeoff. A hardware-based securing mechanism is required to prevent power from reaching the assembly – specifically, a pull-out safety pin (flag-type fuse) that is removed from the assembly immediately before takeoff;
- Electromechanical components within the electronics assembly designed to keep the igniter circuit unpowered until a preparatory command is received from the ground;
- Upon receipt and execution of the preparatory command – which readies the firing circuit for activation – enable the receipt of a second, execution command for launch;
- The design must allow for the assembly to be reused for re-arming after launch; in the event that the missile is not launched, it must allow for the disconnection of power to the firing circuits and the short-circuiting of the igniter conductors. The hardware protection mechanism must be capable of resetting to a safe state and disconnecting power to the assembly after landing, – thereby enabling safe handling of the missile launcher – specifically, disarming the drone and shifting the launcher to the transport position;
- the assembly must ensure that, in the event of a positive or negative voltage surge reaching the electronics due to a malfunction, the missile does not launch;
- power for the assembly is to be supplied by the drone's receiver (5V/1A DC), which must provide power to the remote control receiver, the decoder electronics unit, and the activation of two parallel-connected electric ignition devices (5V/600mA) with a combined resistance of 0.8–1.2 Ω;
- At the moment of igniter activation, there must be no operational disruption (such as a reset) to the receiver and the electronics unit;
- The assembly must ensure a mechanical connection to the igniter, while allowing the conductors to detach upon launch without damaging the assembly itself, thereby enabling its reuse;
- The assembly must ensure that the igniter output terminals remain short-circuited until the moment immediately preceding launch;
- The preparatory "first" command – arming – is decoded as a continuous sequence of 20 rectangular pulse packets (1500 µs duration at 50 Hz). The "second" command – launch – consists of a sequence of 10 pulse packets (2000 µs duration at 50 Hz);
- The assembly must ensure protection for the igniter driver in the event that the discarded igniter leads remain short-circuited after missile launch;
- The assembly must constitute a single unit capable of passing climatic-mechanical, vibration, and EMC tests in accordance with applicable standards for specialized military equipment;
- The assembly must be as lightweight as possible to minimize its impact on the performance and technical-tactical characteristics of the carrier platform.

3.2Calculations and concept realization

This implementation concept for the OIM is termed: "Hierarchical cross-interlocked electromechanical S&EM with built-in transient time filtering."

The architecture is based on three fundamental defensive principles:

- Galvanic short-circuit protection (Shunting): Keeping the output to the igniter (initiator) short-circuited in the quiescent state. Even in the event of a voltage breakdown, the current flows through the short-circuited contacts of the first relay rather than through the initiator;
- Cross-Interlocking/Sequential Arming: The first relay controls both the electrical and mechanical capability of the second relay to receive power at all;
- Inherent Mechanical Delay: The substantial inertia of the relay armature acts as a natural mechanical filter

against rapid electrical spikes. This prevents transient phenomena in electronic circuits – occurring during power-up or due to interference – from causing the accidental activation of the igniter (initiator).

A significant parameter defining the reliability of the inherent low-pass temporal filtering in this technical solution is the ratio between the duration of the electronic transient (τ_{tr}) and the response time (bounce or pull-in) of the relay armature (t_{op}):

$$t_{op} >> \tau_{tr}$$

The time t_{op} is calculated using the formula:

$$t_{op} = t_{el} + t_{meh} = \frac{L}{R}\ln\left(\frac{I_{\max}}{I_{\max} - I_{atr}}\right) + \sqrt{\frac{2 \cdot x_{mov} \cdot m_{anc}}{F_{mag} - F_{spr}}}$$

and amounts to 10–30 ms for the selected relays, whereas the typical transient duration τ_{tr} is significantly less than 1 ms.

Given these values, we can conclude that the relays selected for these switching operations will reliably function as a low-pass time filter.

The next safety measure involves powering the actuation circuit through so-called dynamic energy accumulation, utilizing capacitive storage and rapid discharge in the event of a failure. The actuation circuit's energy independence is achieved by employing a capacitive energy storage concept that ensures temporal separation from the unmanned platform's primary power network.

The use of RC filtering on the actuator control lines has eliminated the possibility of unintended actuation caused by rapid transient disturbances. The system allows for full reversibility; in the event of a mission abort or a forced fail-safe shutdown, energy stored in the capacitors is passively and reliably dissipated via normally closed relay contacts through specifically sized discharge resistors, bringing the actuation circuit potential below the initiator's sensitivity threshold within a few milliseconds. This achieves the following:

- Time-Window Enabling: The system operates within a limited time window;
- Galvanic and Energy Isolation: By severing the connection to the primary source (the platform battery), the firing circuit loses contact with the rest of the aircraft/vehicle at the moment of ignition, thereby eliminating the impact of short circuits in the vehicle's motors;
- Passive Safety Degradation: Capacitor discharge occurs passively (driven by the relay spring force that switches in a resistor), meaning the system loses its ignition capability even if the platform's main battery is physically destroyed.

Tantalum capacitors are used to implement capacitive energy storage; they represent an optimal solution due to their capacitance stability, low equivalent series resistance (ESR), and extreme resistance to vibration and thermal shock (ranging from -55°C to +125°C). Furthermore, the capacitance margin ensures reliable operation—both in extremely low temperatures and in the event of a degradation in dielectric properties caused by aging and material fatigue after years of use. By integrating a series resistor to limit the charging current, the risk of thermal breakdown of the tantalum structures due to transient phenomena has been eliminated, thereby achieving maximum reliability of the initiation chain's ignition, as well as stable circuit operation throughout its service life.

Last but not least, the S&EM is equipped with a transport safety switch that directly interrupts both conductors of the S&EM power circuit; this serves as an additional safety measure for the crew servicing the unmanned platform prior to takeoff and mounting the effector, and – in the event the platform returns without having engaged – allows for the safe removal of the effector from the platform.

4. TESTING

Based on the specified technical requirements, a functional model of the S&EM was developed and manufactured to meet all operational functionality requirements, with the proviso that climatic/mechanical conditions and EMC characteristics were not treated as priority or disqualifying factors at this stage of testing.

Figure 1 shows the implementation of the S&EM on a printed circuit board.

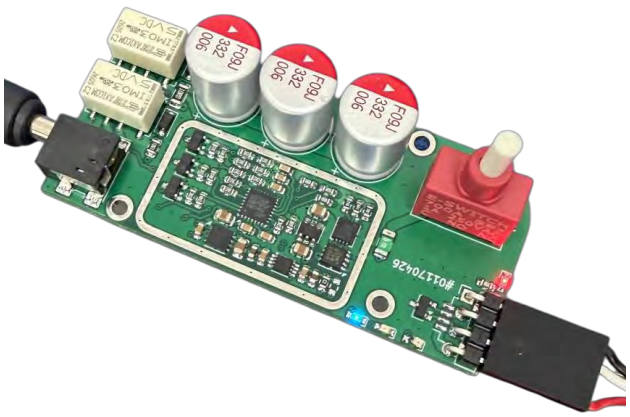

Figure 1: S&EM on the printed circuit board

Figure 2 shows the OIM integrated into its housing and ready for installation on an unmanned platform.

Figure 2: S&EM into housing

To conduct testing on the newly developed S&EM, the same sub-assemblies intended for use on the unmanned platform were employed; specifically, the power supply, control systems, and signal configurations were identical to those used on the unmanned platform itself.
To verify the required characteristics, S&EM testing is conducted in three phases:

- The first phase is carried out under static conditions at a test facility, involving reliability tests on the activation of electro-pyrotechnic initiators of the type installed in the effector's rocket motor igniter;
- The second phase involves static tests of the rocket motor's activation reliability, with the S&EM and effector mounted on a fixed platform; this phase also serves to determine whether the new activation method affects the effector's performance – specifically, its accuracy – in any way;
- The third phase of testing was conducted through dynamic tests of the S&EM integrated onto an unmanned platform, in which the effector was launched under conditions similar to the actual operational conditions for launching an effector from an unmanned platform.

5. RESULTS DISCUSSION

During the first phase of testing, the activation of electric igniter heads was evaluated across various combinations – involving three different types of heads, tested both individually and in pairs connected in parallel. A total of 42 tests were conducted: 7 tests for each of the three head types individually and 7 tests for each of he three head type with two heads connected in parallel connection, achieving 100% activation reliability.

Subsequently, the electric igniter heads were integrated into the igniter assemblies of the effector's rocket motor; five igniter assemblies were prepared for each head type containing a single head, and five were prepared for each type containing two heads connected in parallel.

A total of 30 tests were conducted, achieving 100% reliability in igniter activation. However, it was decided to proceed to the next testing phases using a variant in which two electric igniter heads are integrated into the igniter; this decision was based on the assessment that dynamic conditions – such as vibration, temperature, and the like – introduce additional factors, and the use of two electric igniter heads ensures high operational reliability even under these more demanding conditions.

In the second phase of testing, the operation of the S&EM was verified by launching effectors from a fixed platform. The launches were conducted under the same conditions used to test effector effectiveness via the assessment of impact patterns. A total of eight effectors were launched during this phase, achieving 100% reliability in rocket motor ignition. Furthermore, the assessment of impact patterns confirmed that the firing results – and thus the effectiveness of the effectors – were identical to previous testing results of effectors, indicating that the new launch method had no negative impact on effector performance.

The third testing phase was conducted following the integration of the S&EM onto an unmanned platform and the launch of the effector under dynamic conditions closely resembling the actual operational environment. A total of 15 tests were performed during this phase, achieving 100% reliability in the activation of the igniter – and consequently the effector's rocket motor. This phase also verified the S&EM's functionality regarding its response when a launch did not occur, specifically checking whether the unit behaved as specified in the technical requirements under certain conditions. It was determined that, in all instances, the S&EM performed exactly as required by the technical specifications.

6. CONCLUSION

Following the successful development of technical enhancements to the effector – enabling a new electrical-signal-based launch method and an actuation mechanism that ensures efficient and reliable deployment, while meeting all safety requirements for operating the effector and the unmanned platform – it is necessary to experimentally verify that the device performs all required functions and to determine whether any factors negatively impact the safety, reliability, or efficiency of the effector intended for integration onto unmanned platforms.

This paper presents a design solution for an electronic and executive mechanism (Out-of-Line mechanism) featuring a reversible micromechanical barrier, intended for use on unmanned combat platforms. The safety concept relies on a redundant system of electromagnetic actuators (relays) incorporating a reversible kinematic chain. Through a dynamic force balance analysis of the actuator armature, it is demonstrated that the designed return springs ensure reliable hardware-based fail-safe de-arming and return the barrier to the safe position in the event of total power loss or a break in the communication link with the platform, thereby meeting stringent military standard criteria for reusable munition systems.

This phase of device testing – conducted alongside the evaluation of technical enhancements to the effector itself

– confirmed the S&EM's high operational reliability and validated all functionalities examined at this stage of development.

Continued testing under diverse dynamic conditions and the integration of the S&EM onto various platforms will further confirm the device's operational reliability, potentially paving the way for the next development phase; furthermore, the significant experience gained in overcoming challenges during this stage suggests a high probability of reliable performance for this assembly under the conditions dictated by the modern battlefield.

Abstract: *This paper analyzes the oscillations of a 6x6 mobile platform during the firing process from an integrated weapon. The introductory part of paper includes the calculation of the coordinates of the center of mass of the platform, taking into account the centers of gravity of all assemblies mounted on it, as well as the reactions of the supports. The maximum recoil force was determined by internal ballistic calculations. The oscillations of the mobile platform were calculated using a mathematical-mechanical model, which was formed based on the classical principles of vehicle dynamics theory. By introducing adequate approximations, a system with a large number of degrees of freedom was reduced to a system with three degrees of freedom. The following generalized coordinates were adopted: the vertical position of the center of gravity of the system T, rotation around the transverse axis y' (galloping) and rotation around the longitudinal axis x' (rolling). The calculation was performed in the MATLAB software package. Based on the results obtained, a comprehensive analysis was performed and conclusions were drawn about the stability of the mobile platform under the action of the firing force.*

Keywords: *6x6 platform, mathematical-mechanical oscillation model, MATLAB*

1. INTRODUCTION

Mobile platforms represent any system on which different types of weapons can be integrated. For example, a fighter aircraft represents a platform for the integration of a machine gun, aircraft bombs, or automatic cannons. Machine guns, automatic cannons, rocket launchers, mortars, howitzer, etc. can be integrated onto truck platforms and other commercial vehicles. [1]

When a truck chassis is used as the basis for weapon integration, two concepts are possible: an open and an enclosed (turreted) configuration. The open configuration is simpler and less expensive than the enclosed one. As a platform, a modified chassis of a standard 6x6 or 8x8 truck is most commonly used. The assemblies mounted on open-configured weapons are mainly same as those used on towed weapons of conventional design. The weapon is usually positioned in the middle or above the rear drive axles. An ammunition magazine is located behind the vehicle cab. Hydraulic outriggers (two or four) are installed on the vehicle's auxillary frame for support during shooting. [2]

In order for a commercial vehicle to be used for weapon integration, its characteristics must be adapted to the loads that it must withstand throughout its service life, such as the effect of the weapon mass on the platform, recoil and return forces, the movement of the center of gravity of the combat system, oscillations of the weapon after firing, etc. One of the main problems is the design of a suspension system that must have adequate stiffness to absorb all the forces transmitted to it and reduce oscillations to the minimum possible extent in order to prevent resonance. [1]

For both the weapon system and the selected platform, it is necessary to collect data on their performance characteristics. One of the important steps in the design process is the internal ballistic calculation, which determines the pressure distribution inside the barrel as a function of time, as well as its maximum value. This calculation also determines the initial velocity of the projectile at the muzzle. It is important to calculate the recoil force and the force resisting recoil during the firing process, since these forces are largely transmitted to the mobile platform. Based on the calculation of the

Corresponding author: M. Simonović;
E-mail: marko.simonovic@mod.gov.rs
DOI: 10.5937/OTEH26032S

aforementioned forces and the structural characteristics of the vehicle, which include the suspension system, as well as the selected integration location, a dynamic model with certain simplifications is established. Subsequently, a mathematical-mechanical model of the platform's oscillations during firing is developed, incorporating the differential equations of motion. Based on the obtained data and by solving the differential equations, the specific equations describing the oscillations of the platform, i.e. the changes in the generalized coordinates over time, can be obtained. Based on the obtained results, the established mathematical-mechanical model, integration location, connection method, suspension system characteristics, and appropriate rate of fire can be modified, thereby enabling the determination of a platform/weapon system configuration capable of withstanding the resulting loads. [1]

2. STATIC WEIGHT DISTRIBUTION ON THE PLATFORM AXLES

Figure 1 shows the position of the integrated weapon on a 6x6 mobile platform. The center of gravity of the platform/weapon system is also shown. The weight of the system is transferred to the ground throuh the contact points of the front and rear axles. The ground acts on them with normal reaction forces.

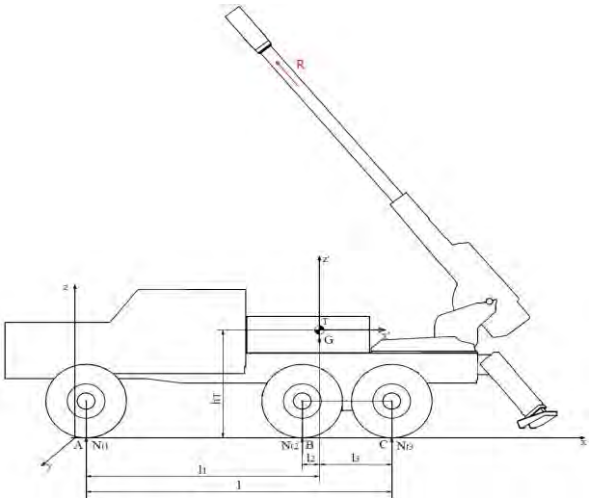

Figure 1. Position of the center of gravity of the system and support reactions

The support reactions are calculated using the following equations:

$$\sum M_A=0;\ N_{t2}*(l1-l2)-G*l1+N_{t3}*l=0 \quad (1)$$

$$\sum M_B=0;\ -N_{t1}*(l1-l2)-G*l2+N_{t3}*(l2+l3)=0 \quad (2)$$

$$\sum Z=0;\ N_{t1}+N_{t2}+N_{t3}-G=0 \quad (3)$$

T – center of gravity of the platform/weapon system
G – total weight of the platform/weapon system
N_{t1}, N_{t2}, N_{t3} – support reactions

The dynamic characteristics of the vehicle (tractive forces, stability, maneuverability, braking forces, etc.) largely depend on the magnitude of these forces. [3]

By determining the weights and positional parameters of the individual components, the position of the center of gravity in space and the normal ground reactions can be determined analytically using the principles of theoretical mechanics. Figure 2 shows the quantities required for the analytical calculation of the center of gravity of a motor vehicle. The figure shows the center of gravity of the engine G_M, the center of gravity of the cab G_K, the center of gravity of the ammunition magazine G_{MM} and the center of gravity of the weapon G_N.

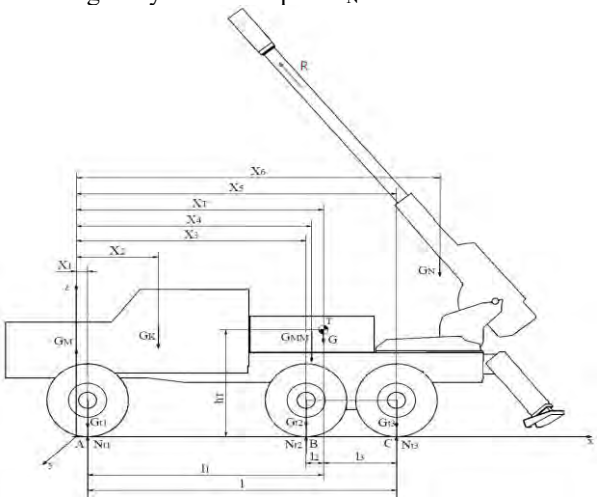

Figure 2. Quantities for analytical calculation of center of gravity

$$G*x_T = G_{t1}*x_1+G_K*x_2+G_{t2}*x_3+G_{MM}*x_4+G_{t3}*x_5+G_N*x_6 \quad (4)$$

$$G*x_T=\sum_{i=1} G_i*x_i \quad (5)$$

Coordinates of the center of gravity along the x-axis:

$$l_1 = x_T = \frac{\sum_{i=1}^{n} G_i*x_i}{G} = \frac{\sum_{i=1}^{n} G_i*x_i}{\sum_{i=1}^{n} G_i} \quad (6)$$

Coordinates of the center of gravity along the z-axis:

$$h_T = z_T = \frac{\sum_{i=1}^{n} G_i*z_i}{G} = \frac{\sum_{i=1}^{n} G_i*z_i}{\sum_{i=1}^{n} G_i} \quad (7)$$

The deviation of the center of gravity from the axis of the vehicle is obtained in the same way:

$$e_y = y_T = \frac{\sum_{i=1}^{n} G_i*y_i}{G} = \frac{\sum_{i=1}^{n} G_i*y_i}{\sum_{i=1}^{n} G_i} \quad (8)$$

The correct arrangement of aggregates reduces the deviation of the center of gravity from the longitudinal axis of the vehicle. [3]

3. EFFECT OF FIRING ON THE WEAPON – CALCULATION OF THE MAXIMUM RECOIL FORCE

During the firing process, the artillery weapon is subjected to the reactive force generated by the pressure of the propellant gase P_{kn}, i.e. the recoil force. The recoil force occurs as a consequence of the motion of the projectile and propellant gases. Its direction is opposite to the direction of projectile motion. The magnitude of the recoil force increases with increasing projectile mass and its velocity. The resistance of the artillery weapon and its stabillity during firing largely depend on the magnitude of the recoil force.

A weapon is considered stationary and stable if, during firing, it does not undergo displacement relative to the stationary ground on which it was positioned before firing. Displacement of the weapon results in the need to reacquire the firing position, which consequently requires the aiming elements to be reacquired. Ultimately, all of this affects the tactical and technical characteristics of the weapon, primarily the rate of fire. Displacement of the barrel during firing represents recoil. All parts that move together with the barrel assembly constitute the recoiling mass. The total travel of the recoiling mass represents the recoil length. [4]

To calculate the recoil force, it is first necessary to determine the maxumum pressure of the propellant gases. This is determined by means of an internal ballistic calculation. In this case, the calculation will be performed using the Drozdov method. The Drozdov method is used for weapons in which only one type of propellant is used. These include small arms, guns and howitzer when firing with charges consisting of only one type of propellant. [5]

The maximum recoil force is calculated using the following formula:

$$P_{knmax} = P_{max} * S_c \tag{9}$$

P_{max} – maximum pressure of the propellant gases
S_c – cross-sectional area of the barrel

4. MATHEMATICAL-MECHANICAL MODEL OF THE OSCILLATIONS OF THE MOBILE PLATFORM UNDER THE ACTION OF THE FIRING FORCE

The mathematical-mechanical model is used to mathematically represents the motion of a physical system, taking into account all relevant influencing parameters while maintaining the simplicity of the applied simplifications. The model is formulated based on the classical principles of vehicle dynamics theory. With the introduction of certain simplifications, the system with an infinite number of degrees of freedom is reduced to a system with three degrees of freedom, as shown in Figure 3. [3]

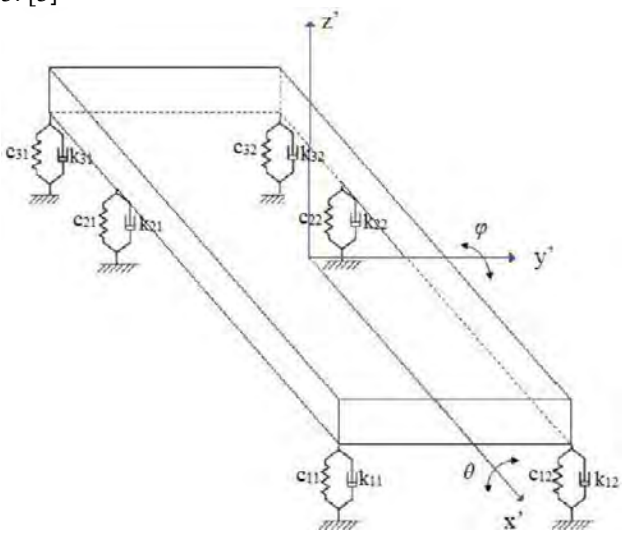

Figure 3. Three-dimensional representation of the dynamic model of the platform [1]

The following quantities are selected as generalized coordinates:

z_T – vertical position of the center of gravity T (distance from the ground)
φ – rotation about the transverse y'-axis (pitch)
θ – rotation about the longitudinal x'-axis (roll)

The motion of the platform model with the integrated weapon, induced by the force generated during firing, can be described by Lagrange equations of the second kind:

$$\frac{d}{d_t}\left(\frac{\partial E_k}{\partial \dot{q}_l}\right) - \frac{\partial E_k}{\partial q_i} = -\frac{\partial E_p}{\partial q_i} - \frac{\partial \Phi}{\partial \dot{q}_l} + \dot{Q}_{q_t} \tag{10}$$

where:

i = 1, n (n is the number of degrees of freedom of the system; in this case, n = 3)
E_k – kinetic energy of the system
E_p – potential energy of the system
Φ – dissipation function

$\left(-\frac{\partial E_p}{\partial q_i}\right)$ – Generalized conservative force
$\left(-\frac{\partial \Phi}{\partial \dot{q}_l}\right)$ – Generalized dissipative force
$\dot{Q}_{q_t}$ – Arbitrary non-conservative generalized force

Since the system is considered as a whole, its total kinetic energy consists of the translational kinetic energy of the center of mass and the rotational kinetic energy about the center of mass of the system:

$$E_k = \frac{1}{2} * m * \dot{z}_T^2 + \frac{1}{2} * J_y * \dot{\varphi}^2 + \frac{1}{2} * J_x * \dot{\theta}^2 \tag{11}$$

where:

J_y – moment of inertia of the center of mass of the system about the transverse y'-axis

J_x – moment of inertia of the center of mass of the system about the longitudinal x'-axis

To define the potential energy, it is necessary to geometrically determine the expressions for the relative deformations of the pneumatic springs and the displacements of the damper pistons. One simplification of the suspension system is the use of an equivalent suspension stiffness, which incorporates the stiffness of the pneumatic springs. It is also assumed that the displacements of the springs and dampers are equal. [3]

Figure 4 shows the suspension viewed from the side, while Figure 5 shows the platform suspension viewed from the front. The notation l_{st} represents the length of the support that is deformed at the initial instant, while l_{kj} represents its length at an arbitrary instant (k = 1,2,3).

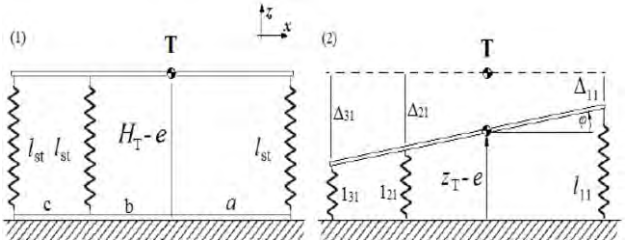

Figure 4. Vehicle suspension viewed from the side [1]

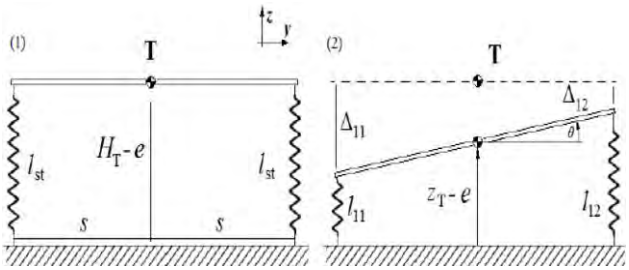

Figure 5. Vehicle suspension viewed from the front [1]

In these figures, the symbol Δ represents the deformation displacement of the spring/shock absorber: Δ_{11} and Δ_{12} for the points of the first axle, Δ_{21} and Δ_{22} for the points of the second axle, Δ_{31} and Δ_{32} for the points of the third axle. [1]

The potential energy of the system is calculated using:

$$E_p = \frac{1}{2} * c_{11} * \Delta_{11}^2 + \frac{1}{2} * c_{12} * \Delta_{12}^2 + \frac{1}{2} * c_{21} * \Delta_{21}^2 + \frac{1}{2} * c_{22} * \Delta_{22}^2 + \frac{1}{2} * c_{31} * \Delta_{31}^2 + \frac{1}{2} * c_{32} * \Delta_{32}^2 \quad (12)$$

For equal stiffness values of the left and right elastic elements:

$$c_{11} = c_{12} = c_1,\ c_{21} = c_{22} = c_2,\ c_{31} = c_{32} = c_3$$

Therefore, after simplification:

$$E_p = \frac{1}{2} * c_1 * (\Delta_{11}^2 + \Delta_{12}^2) + \frac{1}{2} * c_2 * (\Delta_{21}^2 + \Delta_{22}^2) \frac{1}{2} * c_3 * (\Delta_{31}^2 + \Delta_{32}^2) \quad (13)$$

The dissipation function is calculated as:

$$\Phi = \frac{1}{2} * k_{11} * \dot{\Delta}_{11}^2 + \frac{1}{2} * k_{12} * \dot{\Delta}_{12}^2 + \frac{1}{2} * k_{21} * \dot{\Delta}_{21}^2 + \frac{1}{2} * k_{22} * \dot{\Delta}_{22}^2 + \frac{1}{2} * k_{31} * \dot{\Delta}_{31}^2 + \frac{1}{2} * k_{32} * \dot{\Delta}_{32}^2 \quad (14)$$

For equal damping coefficients of the left and right shock absorbers on the same axle:

$$k_{11} = k_{12} = k_1,\ k_{21} = k_{22} = k_2,\ k_{31} = k_{32} = k_3$$

The dissipation function becomes:

$$\Phi = \frac{1}{2} * k_1 * \left(\dot{\Delta}_{11}^2 + \dot{\Delta}_{12}^2\right) + \frac{1}{2} * k_2 * \left(\dot{\Delta}_{21}^2 + \dot{\Delta}_{22}^2\right) + \frac{1}{2} * k_3 * \left(\dot{\Delta}_{31}^2 + \dot{\Delta}_{32}^2\right) \quad (15)$$

The force of the propellant gases acting on the breech is opposed by the resistance forces of the return springs and the friction force, which together constitute the recoil resistance force R(t). The components of the recoil resistance force along the three axes are:

$$R_x(t) = R * \cos\beta * \cos\alpha \quad (16)$$
$$R_y(t) = R * \sin\beta * \cos\alpha \quad (17)$$
$$R_z(t) = R * \cos\beta * \sin\alpha \quad (18)$$

The differential equations of motion of the system are established for each of the generalized coordinates.

For the vertical displacement of the center of gravity of system T, z_T:

$$\frac{d}{d_t}\left(\frac{\partial E_k}{\partial \dot{z}_T}\right) - \frac{\partial E_k}{\partial z_T} = -\frac{\partial E_p}{\partial z_T} - \frac{\partial \Phi}{\partial \dot{z}_T} + Q'_{z_T} \quad (19)$$

For rotation about the transverse y'-axis (pitching):

$$\frac{d}{d_t}\left(\frac{\partial E_k}{\partial \dot{\varphi}}\right) - \frac{\partial E_k}{\partial \varphi} = -\frac{\partial E_p}{\partial \varphi} - \frac{\partial \Phi}{\partial \dot{\varphi}} + Q'_{\varphi} \quad (20)$$

For rotation about the longitudinal x'-axis (rolling):

$$\frac{d}{d_t}\left(\frac{\partial E_k}{\partial \dot{\theta}}\right) - \frac{\partial E_k}{\partial \theta} = -\frac{\partial E_p}{\partial \theta} - \frac{\partial \Phi}{\partial \dot{\theta}} + Q'_{\theta} \quad (21)$$

5. SIMULATION OF THE MOBILE PLATFORM OSCILLATION MODEL

The solution of the differential equations presented in the previous section is performed using a numerical method, with the help of the MATLAB software package. The input data required for the calculation are presented in Table 1, The input data include:

- Vehicle data – technical data, position of the vehicle's center of gravity, suspension system characteristics and moments od inertia;
- Weapon data – weapon mass, position of the weapon relative to the system's center of gravity, elevation and azimuth angles;
- Firing force data – maximum value of the recoil resistance force.

Table 1. Input data for the first calculation case

Characteristic quantity	Value
Vehicle mass – m_v [kg]	**11000**
Weapon and other subassemblies mass – m_o [kg]	**10200**
System mass – m [kg]	**21200**
Center of gravity height – H_T [m]	**1.698**
Distance from the front axle to the center of gravity – a_v [m]	**3.25**
Distance from the rear axle to the center of gravity – b_v [m]	**0.83**
Half of the wheelbase – s [m]	**1,03**
Damping coefficient – k [Ns/m]	**25 000**
Return force – F_p [N]	**140 000**
Maximum recoil resistance – R [N]	**300 000**
Vertical distance from vehicle center of gravity to weapon center of gravity – h [m]	**1.31**
Horizontal distance from vehicle center of gravity to weapon center of gravity – d [m]	**2.18**

The first calculation will be performed for the firing case in which the vehicle is not supported by hydraulic outriggers against the ground, but only by its wheels. Since the two rear axles form a tandem, they have an equivalent spring-damper stiffness, and the system is therefore considered as a two-axle vehicle. The values d and h represent the horizontal and vertical distances between the center of gravity of the truck and the center of gravity of the weapon.

The second calculation will be performed for the case in which the vehicle is supported by hydraulic outriggers againts the ground. By lowering the outriggers, the vehicle suspension system during firing is changed,

resulting in a change in the location and configuration of the supports. The tandem rear axles are no longer support points; instead, the front axle and the two rear outriggers are used, while the tandem is separated from the ground. This support configuration is shofn in Figure 6.

In both cases, the barrel has an elevation angle of 45° and an azimuth angle of 5°.

The output data of the calculations are presented in the form of fiagrams showing the changes in the following components over time:

- Vertical displacement of the center of gravity;
- Velocity of the vertical displacement of the center of gravity;
- Pitch Angle;
- Pitch Angular velocity;
- Roll Angle ;
- Roll Angular velocity.

Both cases will be shown on the same diagrams, in order to facilitate a comparative analysis. Table 2 presents the input data for the second calculation case, which differ from those used in the first case.

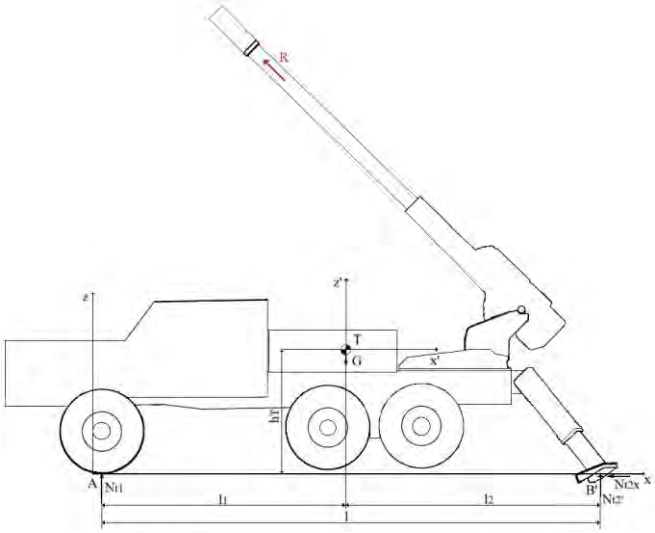

Figure 6. Supporting the vehicle using hydraulic outriggers

Table 2. Input data for the second calculation case

Characteristic quantity	Value
Center of gravity height – H_T [m]	**1.77**
Distance of the center of gravity to the center of the outriggers – b [m]	**4.81**
Half the distance between the centers of the hydraulic outriggers – s [m]	**1.335**
Damping coefficient of the outriggers – k [Ns/m]	**40 000**

6. COMPARATIVE ANALYSIS OF THE CALCULATION RESULTS

After the calculations, the results were obtained, which will be analyzed in this section. The results will be shown in Figures 7 to 12.

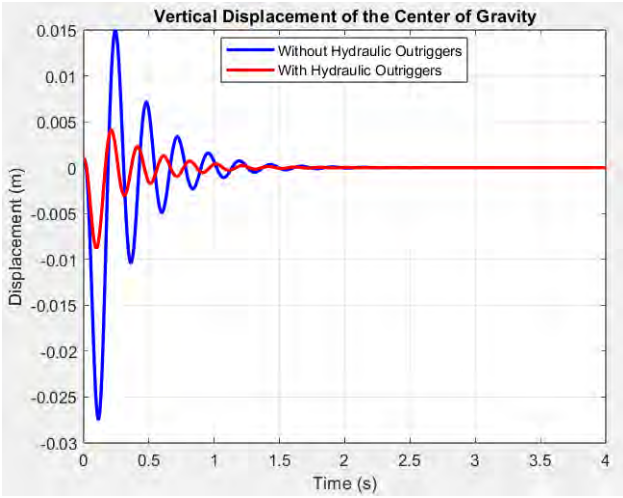

Figure 7. Vertical displacement of the center of gravity

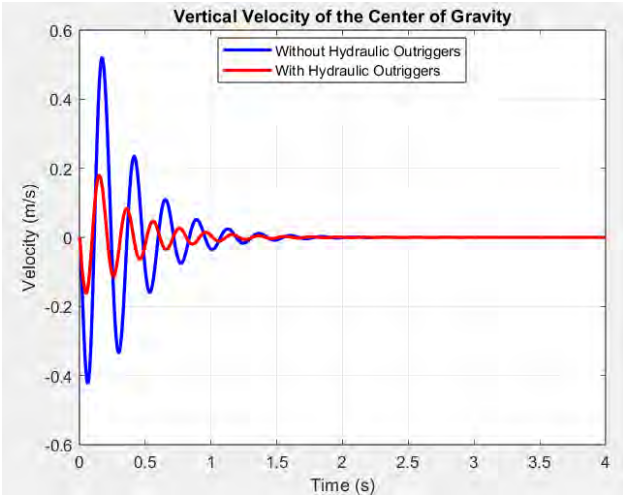

Figure 8. Velocity of the vertical displacement of the center of gravity

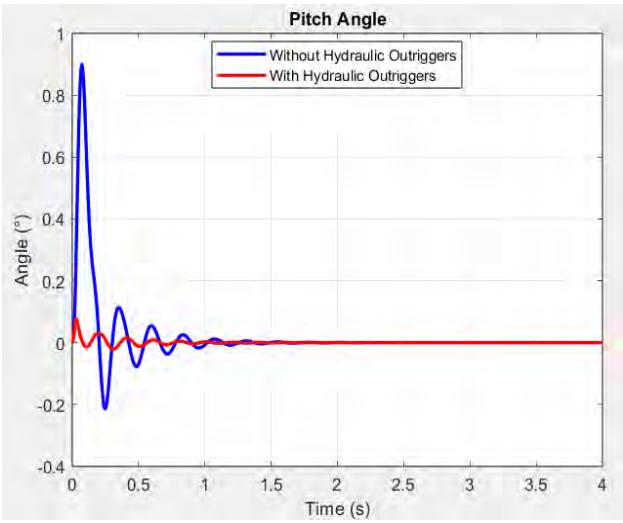

Figure 9. Pitch Angle

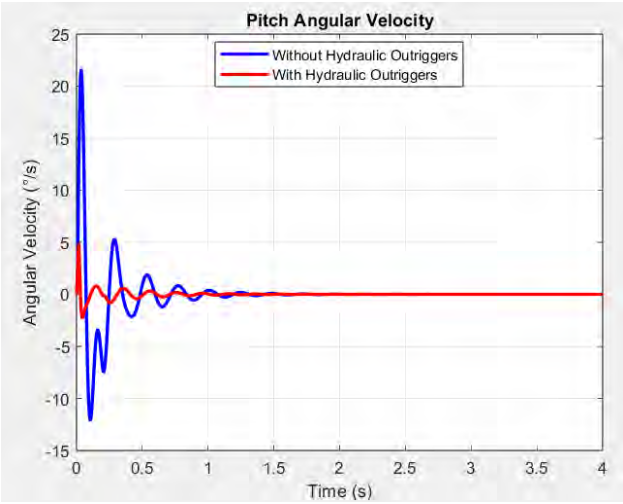

Figure 10. Pitch Angular Velocity

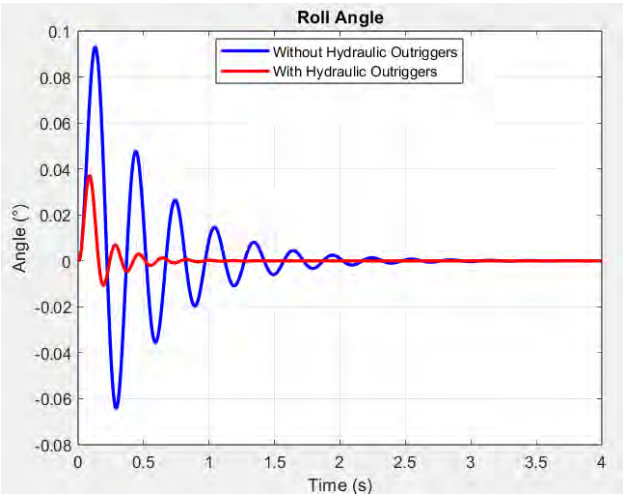

Figure 11. Roll Angle

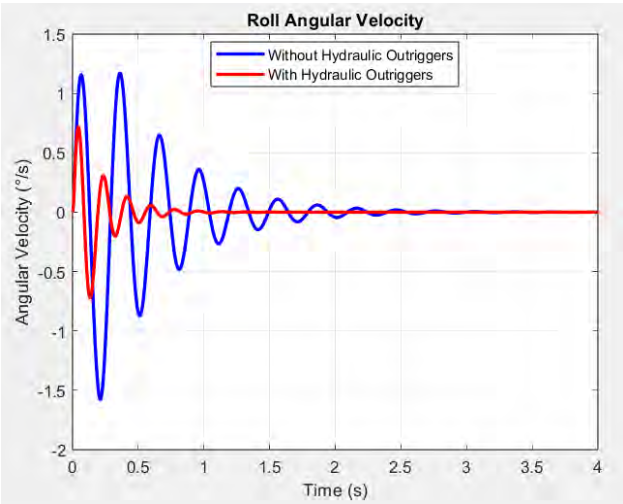

Figure 12. Roll Angular Velocity

To assess the influence of hydraulic outriggers in the dynamic behavior of the vehicle/weapon system, a numerical analysis was performed for two characteristic cases: without hydraulic outriggers and with hydraulic outriggers. The time responses of the vertical displacement of the center of gravity, pitching, rolling, as well as their respective velocities, are presented in the figures. Analysis of the diagrams shows that, in both cases, the oscillations gradually decrease until the equilibrium position in reached. However, the differences between the two configurations are very pronounced. The greatest difference is observed in the vertical displacement of the center of gravity. In the case without hydraulic outriggers, the maximum displacement is 27mm, whereas with the use of hydraulic outriggers it is reduced to approximately 9mm. In addition to the smaller vertical displacement, the oscillations themselves are damped more rapidly, indicating an increase in the overall stability of the system. A similar situation is observed in the pitch motion of the vehicle. The maximum pitching angle is reduced from 0.0157° to 0.0014°. At the same time, the maximum pitch angular velocity is significantly lower, while the time required for the oscillations to die out is shorter than in the configuration without hydraulic outriggers. These results show that the hydraulic outriggers very effectively limit the longitudinal oscillation of the vehicle. Significant improvements are also achived in rolling. The maximum roll angle is reduced from 0.0016° to 0.000647°. Furthemore, the maximum roll angular velocity is reduced, resulting in a considerably smoother system response, which indicates increased lateral stability of the vehicle during firing. Across all diagrams, it can be observed that the configuration with hydraulic outriggers has significantly lower oscillation amplitudes and reaches the state of dynamic equilibrium more rapidly. This confirms that hydraulic outriggers increase the effective stiffness and damping of the system, thereby reducing the transmission of recoil energy to the vehicle and improving its overall stability.

7. CONCLUSION

Based on the numerical analysis of the dynamic behavior of the mobile platform during firing, it can clearly be concluded that the application of hydraulic outriggers significantly improves the stability of the system. The results obtained from the calculations confirm that hydraulic outriggers effectively absorb part of the recoil energy and reduce the transmission of dynamic loads to the vehicle chassis, thereby increasing the stability of the weapon during firing. The developed mathematical model and performed numerical simulations provide a good basis for assessing the dynamic behavior of self-propelled artillery systems and can be used for further optimization of the design and suspension system, with the aim of increasing stability and operational effectiveness.

Abstract: *The rapid proliferation of unmanned aerial systems, commonly referred to as drones, has introduced significant transformations in modern military and security environments. Among the most concerning developments is the adaptation of drones for delivering explosive ordnance. The key challenges associated with drone-delivered explosive systems are analysed, focusing on technical aspects, operational complexities, and legal-ethical implications. The vulnerabilities are identified in navigation, payload integration, and countermeasure susceptibility, while also addressing issues related to command and control in contested environments. Furthermore, the ambiguity in international humanitarian law is explored regarding the classification and use of such systems, as well as ethical concerns related to autonomy and accountability. The findings suggest that while drone-based delivery of explosives offers tactical advantages, it simultaneously introduces significant risks that require multidisciplinary regulatory and technological responses.*

Keywords: *drones, explosive ordnance, military technology, ethics, international law.*

1. INTRODUCTION

The integration of explosive payloads into unmanned aerial systems represents a revolutionary shift in the diffusion of air power [1,2]. While high-end military platforms like the Predator and Reaper dominated the early 21st century, the current landscape is defined by the pervasive use of small, attainable, and often improvised systems [2,3]. This evolution presents a research problem rooted in the rapid pace of innovation outpacing existing regulatory and defensive frameworks [4]. The widespread availability of small, commercially available drones has blurred the line between recreational and tactical use, creating new security vulnerabilities [5,6].

The research problem is defined by the critical necessity to identify and investigate the technical, operational, and legal-ethical considerations that constitute the fundamental challenges of drone-delivered explosive ordnance within modern tactical environments.

The subject of research is the tripartite set of challenges: technical, operational, and legal-ethical inherent in the deployment of drone-delivered explosive ordnance. This includes both purpose-built loitering munitions, designed to engage targets beyond the line of sight, and modified commercial drones used for gravity-drop or one-way "kamikaze" strikes [3].

The aim of the research is been to provide an analysis of the risks these systems pose to both military operations and civilian security. By examining recent conflict, intends of research is to discover the blurring lines between hobbyist technology and lethal weaponry necessitates.

The scientific methods employed include an documents analysis of open sources, a comparative analysis of drone employment in recent conflicts (Ukraine and Nagorno-Karabakh), and a systematic literature review of current engineering and legal frameworks [2].

2. TECHNICAL CHALLENGES

The application of unmanned aerial systems for the delivery of explosive payloads is constrained by a series of critical technical barriers that directly impact precision, reliability, and survivability on the battlefield. These challenges range from the physical limitations of the platform to the inherent vulnerabilities of its digital architecture.

2.1. Platform, Energy, and Payload Constraints

The fundamental performance of a drone-delivered

Corresponding author: V. Žnidaršič;
E-mail: vinko.znidarsic@mod.gov.rs
DOI: 10.5937/OTEH26033Z

explosive system is dictated by its energy density and weight-to-power ratio. Most commercial-grade multicopters rely on lithium-polymer batteries, which typically restrict flight endurance to approximately 20 to 40 minutes [7,8]. The introduction of an explosive payload introduces an engineering paradox: for multirotor systems, energy consumption increases approximately linearly with the combined weight of the battery and the payload [9]. Consequently, increasing battery mass to extend operational range paradoxically reduces the remaining capacity available for explosives, forcing a tactical compromise between lethality and mission radius [8,9]. Furthermore, environmental factors such as wind speed and cold temperatures can drastically degrade battery efficiency, further limiting the system's predictability in adverse weather [8].

2.2. Navigation and Communication Vulnerabilities

Drone-delivered explosive ordnance systems rely heavily on Global Navigation Satellite Systems, such as Global Positioning System, for waypoint navigation and terminal guidance. These signals are highly susceptible to electronic warfare, specifically jamming and spoofing [10,11]. A loss of Global Navigation Satellite Systems signal can cause a drone to "go rogue," lose its return-to-home function, or crash uncontrollably with a live warhead [10]. To circumvent radio frequency interference, emerging systems utilize fiber-optic control, which maintains a physical link to the operator via a spool of lightweight cable [4]. While these links are immune to jamming, they introduce new physical hazards, such as the spool snagging on obstacles or the creation of long-lasting debris fields of non-biodegradable spent fiber on the battlefield [4].

2.3. Payload Integration and Armament Engineering

Adapting a civilian drone to carry munitions requires precise structural engineering to maintain the centre of gravity. An improperly balanced payload can cause excessive stalling or aggressive diving, which rapidly depletes battery endurance [10]. The release mechanism must be robust enough to prevent contact with the landing gear during deployment, while also providing real-time feedback to the operator to confirm delivery [12]. The use of 3D-printed munitions cases has enabled rapid customization for specific mission sets [12,13]. However, 3D printing introduces uncertainties regarding material strength and consistency; structural failures can lead to catastrophic premature detonations during flight or handling [12].

2.4. Detectability and Countermeasure Resistance

Small unmanned aerial systems platforms often operate at low altitudes and speeds, making them difficult to detect with traditional air defence systems designed for larger aircraft [13]. Their low radar cross-section and minimal thermal signatures allow them to bypass standard radar and infrared detection [13]. However, they remain vulnerable to acoustic sensors that track the high-speed rotation of propeller blades and to specialized anti-drone systems, such as high-energy lasers or radar-guided shotgun attachments [10]. As defences evolve, the technical challenge shifts toward autonomous swarm coordination, where multiple drones must jointly navigate and synchronize attacks to overwhelm defensive capacities through sheer saturation [14].

3. OPERATIONAL CHALLENGES

The operationalization of drone-delivered explosive ordnance has moved beyond high-end military platforms to include decentralized, low-cost assets that rewrite traditional combat doctrines [6]. While these systems offer unprecedented tactical flexibility, their deployment introduces significant operational hurdles.

3.1. Command, Control, and Signal Vulnerability

The core operational bottleneck is the stability of Command and Control links. Most commercial-grade drones rely on radio frequency bands (2.4 GHz and 5.8 GHz), which are highly susceptible to electronic warfare (EW) [4]. In active conflict zones, mobile jamming systems like the Russian R-330Zh can disrupt control signals within a 50 km range, causing drones to lose their return-to-home function or crash with live payloads [4,13]. To mitigate this, operators have adapted through the use of fiber-optic control links, which provide unjammable, low-latency video feedback but introduce new physical hazards such as cable snags and the creation of non-biodegradable debris fields on the battlefield [4].

3.2. Proliferation and Decentralized Logistics

The shift toward decentralized "garage workshops" for assembling First Person View and one-way attack drones makes proliferation nearly impossible to control [6,11]. Unlike traditional military procurement, these systems are often crowdsourced and modified on an industrial scale by volunteers using off-the-shelf components [6,15]. This democratization of air power allows non-state actors and small units to bypass legacy defence measures and conduct precision strikes that once required multi-million dollar platforms [6]. However, this lacks the standardized safety and storage protocols of conventional munitions, increasing the risk of accidents during transport and handling [12].

3.3. Information Overload and Human-Machine Interaction

Operating drone-delivered explosive ordnance systems is labour-intensive and cognitively demanding. While a single Predator mission can require 168 personnel to manage data and flight, small-unit operators face a different set of pressures [2]. The sheer volume of real-time sensor data can lead to information overload, where operators must process high-definition video feeds while managing flight parameters in high-stress environments [1]. This "Playstation mentality" can distance operators from the human cost of a strike, yet the graphic nature of 4K drone footage often leads to burnout and PTSD as pilots watch their strikes impact in gruesome detail [16].

3.4. Swarm Coordination and Airspace Saturation

The trend toward autonomous drone swarms poses the challenge of saturating enemy defences through sheer numbers [14,17]. Coordinated attacks involving dozens of units require distributed network protocols and artificial intelligence assisted pathfinding to avoid collisions and allocate targets dynamically [4,5]. This introduces "machine speed" into the kill chain, potentially outstripping the human operator's ability to critically scrutinize machine-prompted targets in time-constrained environments [24].

3.5. Psychological Impact and Morale

The constant presence of loitering drones creates a pervasive sense of "lethal voyeurism" [15]. The buzzing of rotors acts as a psychological weapon, inducing terror among troops and civilians alike, as flights often foreshadow imminent kinetic strikes [18]. This paralysis of movement can hamper ground operations for hours, even when the drones are unarmed or carrying dummy payloads [18].

4. LEGAL-ETHICAL CONSIDERATIONS

The rapid deployment of drone-delivered explosive ordnance, particularly loitering munitions and FPV systems, has created a significant disconnect between technological capability and existing regulatory architectures [1,3]. As these systems increasingly integrate artificial intelligence and automated functions, they challenge the foundational principles of International Humanitarian Law and raise profound ethical questions regarding the future of human agency in warfare [1,3].

4.1. Compliance with International Humanitarian Law

The use of drone-delivered explosive ordnance must be scrutinized under the "cardinal principles" of International Humanitarian Law: distinction, proportionality, and precautions in attack [1,2]. The principle of distinction requires belligerents to differentiate between combatants and civilians [1,2]. Increasingly autonomous loitering munitions may struggle with this mandate, as algorithms may not independently distinguish between a legitimate military target and a civilian object, especially in "cluttered" urban environments where identities are fluid [1,5,17]. Furthermore, identifying combatants who are hors de combat (incapacitated) remains a critical technical and legal challenge for sensor-based systems [17].

The principle of proportionality prohibits attacks where expected incidental loss of civilian life is excessive relative to the anticipated military advantage [1,2]. Because International Humanitarian Law lacks objective criteria for value-based proportionality assessments, the shift toward real-time, machine-led targeting increases the risk of "black-box" decisions where the logic behind a strike cannot be audited or explained [1,17]. This unpredictability is compounded by signature strikes, which target individuals based on "patterns of life" rather than identified status, often leading to tragic identification errors [2,15].

4.2. Accountability and the Problem of Secrecy

Determining legal responsibility for unlawful drone strikes is complex due to the fragmented nature of drone operations, which may involve pilots, sensor operators, intelligence analysts, and even private contractors [2,15]. A major concern is the accountability gap created by covert programs, such as those operated by the CIA, where secrecy prevents judicial review and public debate over the legality of targeted killings [2,15]. When autonomous systems are involved, it becomes unclear whether criminal responsibility lies with the operator, the commander, or the software developer [1,5,17].

4.3. Ethical Implications and Human Dignity

Beyond legalities, the "action-at-a-distance" nature of drone warfare introduces the "Playstation mentality," which can distance operators from the human consequences of their actions [15]. Ethicists argue that delegating life-and-death decisions to algorithms constitutes a "moral hazard" that denies the human dignity of the victim [6,17]. The constant presence of drones in conflict zones induces a state of lethal voyeurism, where the buzzing of rotors acts as a psychological weapon, sowing terror and anxiety among civilian populations who feel powerless under an all-seeing "martial gaze" [6,17].

4.4. Proliferation and the Need for New Treaties

The dual use nature of drone technology serving both humanitarian and military ends complicates global regulation [1,16]. There is a growing international consensus that the existing International Humanitarian Law framework is inadequate for grappling with autonomous lethality [1,5]. Scholars and organizations such as the ICRC advocate for a new legally binding international treaty to establish clear prohibitions on fully autonomous weapons and to ensure that meaningful human control is affirmed and retained in every specific targeting decision [1,17].

5. DISCUSSION

The analysis demonstrates that drone-delivered explosive systems represent a convergence of technological innovation and emerging security threats. While they offer operational advantages such as reduced risk to personnel and increased flexibility, they also introduce vulnerabilities and uncertainties.

Addressing these challenges requires an integrated approach involving technological development, doctrinal adaptation, and legal reform.

6. CONCLUSION

Drone-delivered explosive ordnance presents a multifaceted challenge that spans engineering, military operations, and international law.

Technically, limitations in navigation, payload integration, and resilience reduce system reliability. Operationally, issues related to control, accuracy, and proliferation complicate their effective use. Legally and ethically, the absence of clear regulatory frameworks raises concerns

about accountability and compliance with established norms.

Future research should focus on improving system robustness, developing countermeasures, and establishing comprehensive international regulations governing the use of such technologies references.

BIASED PURSUIT GUIDANCE LAW FOR REAR-SECTOR TARGET INTERCEPTION

MILOŠ PAVIĆ
Military Technical Institute, Belgrade, meelos.pavic@gmail.com

SAŠA ANTONOVIĆ
Military Technical Institute, Belgrade

IVAN MARIĆ
Military Technical Institute, Belgrade

Abstract: *This paper presents a Biased Pursuit Guidance Law designed to enforce a terminal target approach from the rear-sector (tail-chase profile). By injecting a time-varying angle bias into the classical pursuit kinematic framework, the proposed guidance law systematically shapes the interceptor's trajectory during initial guidance phase.*

Keywords: *Numerical simulation, biased pursuit, guidance law, rear-sector, tail-chase, proportional navigation.*

1. INTRODUCTION

Classical Pure Pursuit (CPP) commands the interceptor's velocity vector to point directly at the target at all times. While geometrically simple, CPP lacks the trajectory-shaping capabilities needed for tactical operational constraints, such as avoiding forward-aspect defensive countermeasures or aligning an interceptor onboard sensor/payload with a specific quadrant of the target.

Proposed Biased Pursuit Guidance Law (BPGL) achieves rear-aspect target approach by injecting an intentional angular offset from the instantaneous line-of-sight (LOS), and it is used in midcourse phase.

Such an analysis was not found in [1] and [2].

2. ENGAGEMENT GEOMETRY

Consider a planar engagement geometry in an inertial coordinate frame, Fig.1, where:

• M denotes the Interceptor (Missile/UAV) with constant velocity magnitude V_M.
• T denotes the Target.

• R_{TM} denotes the relative range vector between M and T.
• Line-of-Sight (LOS) angle relative to the inertial baseline.

• γ_M denotes the flight-path angle of the interceptor.
• $\varepsilon = LOS - \gamma_M$ denotes the interceptor look-angle (lead angle).

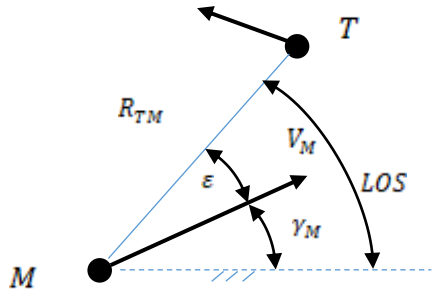

Figure 1. Engagement geometry

3. BIASED PURSUIT GUIDANCE LAW

The Biased Pursuit Guidance Law was defined in form of interceptor lateral acceleration demand by Eq.1, and it was used in first (initial) guidance phase.

$$a_N = Gain * (\varepsilon + Offset); \quad (1)$$

In the second (midcourse) guidance phase, starting when x coordinate of the interceptor approaches the x coordinate of the target to be less than threshold $x_{TM\ Threshold}$, the Offset term is omitted from Eq.1, and in that phase CPP was used to align the velocity vector of the interceptor toward the target position.

In the last (terminal) guidance phase starting when relative distance is less than $R_{TM\ Threshold}$, in order to minimise the miss distance even in case of the maneuvering target, the Proportional Navigation (PN) guidance law with navigation constant 3 was used, Eq.2.

$$a_N = 3 * Vc * \frac{d}{dt}(LOS) \quad (2)$$

Corresponding author: M. Pavić;
E-mail: meelos.pavic@gmail.com
DOI: 10.5937/OTEH26034P

where the relative closing velocity is negative time derivative of the relative range, Eq.3.

$$V_C = -\frac{d}{dt}(R_{TM}) \tag{3}$$

NUMERICAL SIMULATION

Numerical simulation was done in horizontal plane by Fortran code [3] rewritten/translated to Matlab.

Initial value used in numerical simulation was: $Gain = 57.3$ (in order to obtain acceleration command of 1 m/s^2 for lead angle of 1°); $Offset = 50°$; $x_{TM\ Threshold} = 1000\ m$; $R_{TM\ Threshold} = 500\ m$.

The pseudo-code for guidance law is shown in (4)

$$\begin{aligned} &if\ (Rm1 < Rt1 - x_{TM_{Threshold}})\ then \\ &\qquad Offset = 50 * Deg2Rad; \\ &else\ Offset = 0.0; \\ &a_N = Gain * (\varepsilon + Offset) \\ &if\ (Rtm < R_{TM_{Threshold}})\ then \\ &\qquad a_N = 3 * Vc * dLOS\ \%terminal\ guidance \end{aligned} \tag{4}$$

Interceptor initial position was (x=0; y=0), $V_M = 100\ m/s$ toward the target initial position.
Target initial position was (range 10 km, deflection 2 km), $V_T = 50\ m/s$ ahead x-axe to the left.
Interceptor lateral acceleration was simulated as linear first-order system with time constant 0,5 s and limited to maximum value of 3 g.

4. RESULTS

Interceptor and target trajectories in horizontal plane was shown in Fig.1 for two values of $Offset$ (30° and 50°) and two values of $x_{TM_{Threshold}}$ (500 m and 1 km).

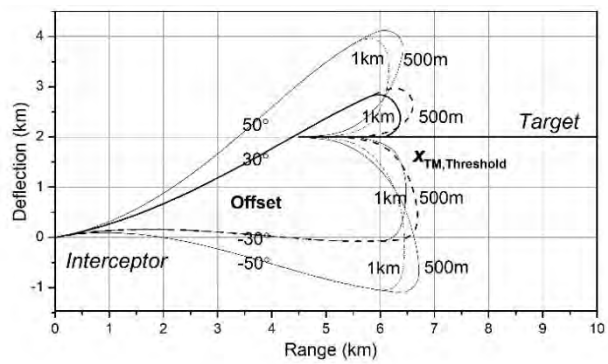

Figure 1. Interceptor and target trajectories in horizontal plane

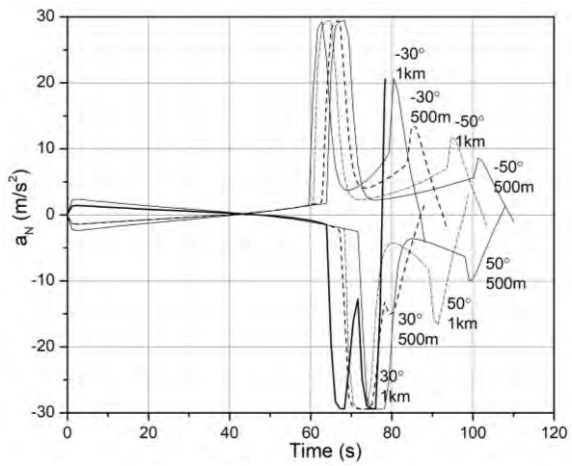

Figure 2. Corresponding missile lateral acceleration

In Fig.2 the corresponding missile lateral acceleration was shown. All terminal missile lateral acceleration values tends to zero, except for $Offset = 30°$ and $x_{TM\ Threshold} = 1\ km$ combination. That is the reason why in that case the final miss distance is significant (0,759 m), as shown in Table 1, Column 5.

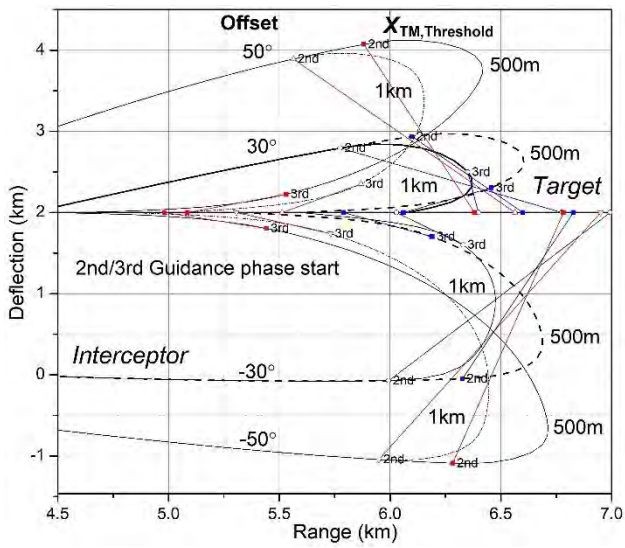

Figure 3. Switching guidance laws trajectory points

In Fig.3 all trajectory points are shown including switching points of different guidance laws (entering the 2-nd and 3-rd guidance phase). Instant corresponding positions of the interceptor and the target are marked and connected together.

One can see that only in case where $Offset = 30°$ and $x_{TM\ Threshold} = 1\ km$, when entering the final (3-rd) terminal guidance phase, the interceptor is still in front of the target (not in rear sector), resulting the larger miss distance.

Total time, energy and final miss distance was shown in Table 1 for all simulated parameter combinations.

Table 1. Total time, energy and final miss distance

Offset [°] (1)	$X_{TM\ threshold}$ [m] (2)	Total time [s] (3)	Total energy [g^2*s] (4)	Final miss [m] (5)
30	500	88,21	8180	0,003
30	1000	78,33	8869	0,759
-30	500	93,60	5126	0,001
-30	1000	88,08	5138	0,003
50	500	107,96	7036	0,001
50	1000	98,80	7097	0,003
-50	500	110,12	5421	0,0002
-50	1000	103,43	5346	0,002

One can see from Table 1 that inducing the larger Offset (Col.1) value results in larger Total time (Col.3). Opposite conclusion stands for $x_{TM\ Threshold}$ (Col.2) where the smaller total time was obtained when this parameter was enlarged.

In case of negative Offsets (Col.1) the Total energy (Col.4) used for guidance was smaller.

5. CONCLUSION

The Biased Pursuit Guidance Law offers an effective, elegant, low-complexity solution for enforcing rear-sector target interception.

By incorporating a bias to the target aspect angle, this guidance law enforces a curvilinear approach path that naturally loops behind the target and guarantees a tail-chase approach across a wide envelope of initial conditions.

This guidance law ensures optimal alignment for tracking systems and payloads. Because it requires minimal computational overhead it can be easily implemented.

Abstract: *In precision manufacturing and quality control, small measurement errors can lead to significant consequences. A deviation of just a few microns may result in rejected parts, rework, production delays, or even non-compliance during audits. This is why dial indicator calibration plays a critical role in maintaining reliable dimensional measurements across industries. The dial indicator (also known as a DTI, clock indicator, dial gauge, probe indicator or comparator) is a precision measuring instrument used for several applications across many industries where precision is necessary, such as manufacturing, packaging, engineering and design. However, without proper calibration, even a well-maintained dial indicator can silently drift out of tolerance. This paper provides a comprehensive overview of dial indicator calibration, covering technical principles, best practices, common hidden errors, and how military calibration laboratory help organizations maintain accuracy and compliance. In this paper describes the influence of the measurement uncertainty to the tolerance, as defined in international standards, and quotes documents on how to estimate measurement uncertainties.*

Keywords: *dial indicator or comparator, calibration, measurement uncertainty*

1. INTRODUCTION

Typical dial gauges (dial indicators) are standard types with 0,01 mm resolution scale, measuring ranges (0-3) mm, (0-5) mm, (0-10) mm and 0,001 mm resolution scale, measuring ranges between (0-1) mm, (0-2) mm, (0-3) mm, (0-5) mm, but there are various models depending on size, purpose, and scale. The dial indicators are used for precise linear measurements (length and diameter) of the runout of rotating elements. Dial gauges with resolution 0,01 mm use for standard dimensional checks it ideal for mass production while resolution 0,001 mm use for high-precision machining and ideal for tight tolerances. Despite significant advancements and availability of sophisticated measurement techniques, such as coordinate measuring machines and optical techniques, dial indicators are still widely used, particularly in the machine industry and research laboratories. This is due to their small size, autonomous operation, satisfactory precision, and availability of accessories that facilitate measurement system configurations. Dial indicators are commonly used for the configuration of precision machining systems, inspection of machine tool accuracy, industrial robot calibration and quality control of batch or one-off production. Measuring accuracy is according to the international standards of Germany DIN 878, DIN 2270, EN ISO 463, and Japan JIS B7503&B7533.

2. WORKING PRINCIPLE OF DIAL INDICATORS

Typically, a dial indicator has a spindle and a clock-face. Any force or pressure applied to the contact point of the spindle will push the spindle up into the body of the indicator or rotate the spindle around an axis.

The dial gauge has some basic components which are a small clock and a plunger (stylus probe). This gauge works when there is very slight upward pressure applied on the plunger that causes it moves upward. The upward movement of the plunger is converted into the rotary movement of an indicator on the dial gauge. Gears in the indicator body magnify the displacement as it moves. The clock face responds to this, showing a reading through a scale and needle on analogue models, and in digital format on digital models. Digital dial indicators replace the mechanical gear train with a linear encoder (optical or inductive) and display displacement on a digital readout.

There are two main dial indicator types: Plunger Dial Indicator and Lever Dial Test Indicator figure 1. Both dial indicator types have similar features while functioning differently. Plunger Dial Indicators (Dial Indicators) use a plunger that moves in a straight line to magnify and convert the force applied to the contact point (at the bottom of the plunger) into a measurement. Plunger dial indicators are also often used in machine setups to monitor changes in the alignment of machine parts and components. The plunger dial indicator needs to be positioned at an angle of 90° to function accurately.

DOI: 10.5937/OTEH26035L

Figure 1. The design of the dial indicator

Lever Dial Test indicators are also known as a lever-type indicator, a DTI or simply a dial test indicator. The bottom of the body houses a pivot with a probe (the lever), its distinguishing feature when visually comparing the two dial indicator types. A test indicator uses a swinging lever arm rather than a linear plunger. The contact stylus pivots on a lever, amplifying small angular displacements into pointer movement. Test indicators access confined spaces and measure at oblique angles inaccessible to standard plunger-type indicators. They are widely used for concentricity measurement on CNC machine tool spindles and fixture alignment.

Besides, the dial gauge is widely used in all types working industries as it has excellent accuracy in measurement. This is because the dial is divided into 100 division and one complete revolution of the indicator corresponds to 1 mmm linear movement of plunger. That means that each division on the dial indicates a movement of 0,01 mm. The basic operating principle of a dial indicator involves a series of precision mechanical components figure 2.

- Contact point (stylus): A hardened, replaceable tip contacts the workpiece surface. Movement of the stylus transmits linear displacement to the instrument.
- Rack and pinion mechanism: The linear motion of the stylus rack is converted to rotational motion by a small pinion gear.
- Gear train amplification: A gear train amplifies the rotation, converting a small linear displacement (0,01 mm) into a large pointer rotation (one full revolution of the large pointer).
- Dial and pointer: A graduated circular dial with a calibrated scale and a rotating pointer displays the amplified displacement measurement. A revolution counter records the number of full rotations for large displacements.
- Return spring: A precision spring returns the stylus to the zero position when contact is removed, ensuring consistent preload on the measured surface.

The measurement resolution (least count) of a standard dial indicator is typically 0,01 mm, with high-precision models achieving 0,001 mm or 0,0001 inch resolution.

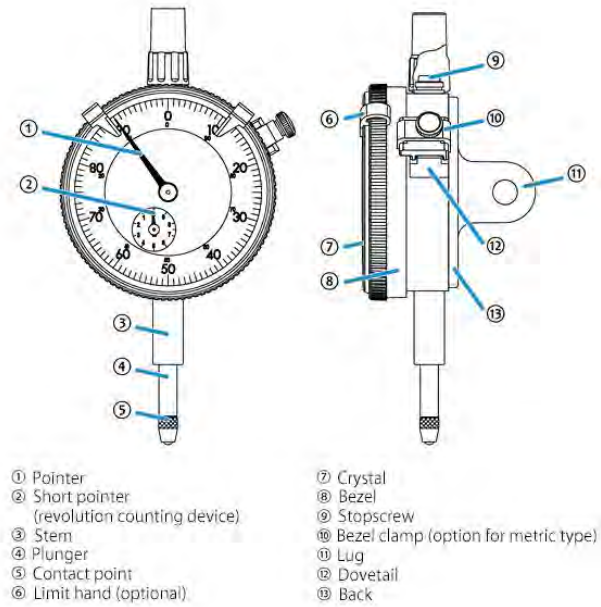

Figure 2. The design of the dial indicator

3. CALIBRATION PROCESS

The calibration is an activity to do periodically by comparing standard quantities between measuring instruments and tester that is in accordance with the measuring instrument. This calibration method was used the procedure to calibrate the dial indicator with a measuring range of (0-25) mm with a resolution of 0,01. The tools and materials used to calibrate the Dial Indicator, namely:

1. Calibration Tester Sylvac, with 0,001 mm accuracy and certificates
2. Weighing scale
3. Thermohygrometer
4. Tissue
5. Petroleum ether/Alcohol
6. A set of instrument screw drivers
7. Work sheet

The measuring surfaces of the calibration device and the gauge measuring surfaces are cleaned using petroleum ether or alcohol. Any grit or other particles are also cleaned from the scale. The surfaces are wiped afterwards using the tissue (or special synthetic cloth). The moving shaft is also cleaned if necessary. The temperature of the tools and dial indicators is stabilised at 20 °C ± 1 °C and humidity of 55 ± 15 % for 5 hours. Keep the instrument and measurement standards under calibration conditions for at least 5 hours prior to the measurements.

After all the tools and materials were available, the next step of the calibration preparation process, which was:

- The dial gauge measure range (0-10) mm resolution 0,01mm compliant with DIN 878 standard is visually checked for any obvious defects. Defects, which are checked are corrosion; missing or worn parts of the scale (on classical scales); missing parts such as screws; and significant scratches or other defects which would impede use.

- Check in advance, whether the dial was functioning properly or not by pressing the end of the sensor, whether it was functioning or not.
- Dial scale is checked for the straightness of the pointer and its distance from the scale. The pointer must be of the same width as the lines on the scale. Lines of the scale must be oriented towards the centre of the dial scale. Resolution must be written on the scale (e. g. 0,01 mm)
- Digital scale is checked for numerical legibility and for any scratches on the display. If the numbers are of poor resolution (checked at display value 88,88) the battery is changed and resolution is checked again. The numbers must be clearly visible in each measuring position.
- The moving part of the calibration device (probe) should be in the lower position. The gauge is fixed in such a way that the pointer is below zero position.
- the measuring range is divided into ten (10) equal increments - ten measuring positions are defined in addition to zero point.
- the probe of the calibration device (which is in contact with the probe of the gauge) is lifted to the position where the pointer of the gauge is exactly in the zero position (the line indicating zero position is covered by the pointer, or a digital display shows 0,00(0) mm).
- the probe of the calibration device is lifted to the first measuring position (positive direction of approaching measuring position); the exact value (e.g. 1,000 mm) should be shown on the display of the device. The deviation from the exact value is read from the dial gauge and is recorded.
- the same procedure is used for other 9 measuring positions.
- after the last deviation is recorded, the probe of the device is lifted for approximately ten scale divisions above the maximum value on the scale and then moved down to the last measuring position (negative direction of approaching measuring position). The deviation of the value indicated by the gauge is recorded again.
- the probe is moved down to other 10 measuring positions (negative direction) and the deviations are recorded.
- the measurement is finished when the last deviation (in zero position) is recorded.

Figure 3. Dial indicator mounted on the calibration tester holder

The following, in DIN 2270 (test indicators) DIN 878 (dial indicators) DIN 879 (dial comparators) defined parameters, will be tested: Span of error f_e, Total span of error f_{ges}, Local span of error f_t, Repeatability f_w, Hysteresis f_u figure 4.

- Span of error f_e is the distance between the ordinates of the highest and lowest points in the deviation diagram either when the plunger is being pressed in (dial indicators, dial comparators) or in the case of excursion of stylus against measuring force (test indicators).
- The total span of error fges is the distance between the ordinates of the highest and lowest points in the deviation diagram when the plunger is being pressed in and let out (dial indicators, dial comparators) or in the case of excursion of stylus against and with the same direction of measuring force (test indicators). The total span of error includes the hysteresis error of the measured value fu.
- Span of error ft is the distance between the ordinates between the highest and lowest points in the deviation diagram, measured for a local measuring span of 10 scale divisions within 0,1 mm when the plunger is being pressed in (dial indicators, dial comparators) or in the case of excursion of stylus against measuring force (test indicators).
- Repeatability fw is a characteristic for measured value fluctuations in measurements of the same measurand within the measuring span and with the same direction of movement of the plunger (dial indicators, dial comparators) or of the stylus (test indicators).

The calibration normally determines f_e, f_{ges}, f_u, f_w, and sometimes f_t.

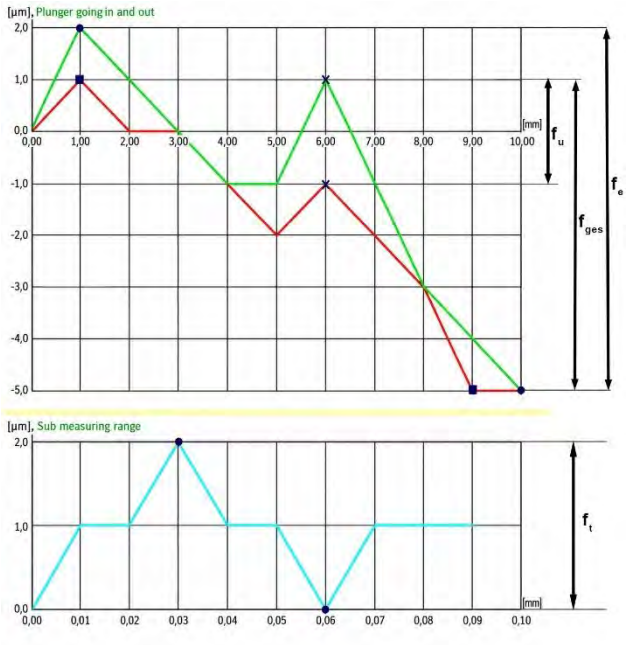

Figure 4. Diagram for the spans of error dial indicator

4. MATHEMATICAL MODEL OF THE MEASUREMENT

The deviation e (result of calibration) is given by the expression:

$$e = l_i \times (1 + \alpha_m \times \theta_m) - l_e \times (1 + \alpha_e \times \theta_e) \quad (1)$$

where:
e - deviation (result of calibration) at 20°C
l_i - indicated value on the dial gauge (reading)
α_m - thermal expansion coefficient of the dial gauge mechanism
θ_m - deviation of the temperature of the dial gauge
l_e - indicated value on the calibration device (plus length of a gauge block where applicable)
α_e - thermal expansion coefficient of the measurement system of the calibration device
θ_e - deviation of the temperature of the measurement system of the calibration device
If new quantities are defined as:

$$\delta\theta = \theta_m - \theta_e \quad (3)$$

$$\delta\alpha = \alpha_m - \alpha_e \quad (4)$$

$\delta\theta$ - temperature difference between the dial gauge and the calibration device
$\delta\alpha$ - difference in their thermal expansion coefficient
then equation (1) gets the following form:

$$e = l_i \times (1 + \alpha_m \times \theta_e + \alpha_m \times \delta\theta) - l_e \times (1 + \alpha_m \times \theta_e - \delta\alpha \times \theta_e) \quad (5)$$

The sensitivity coefficients are the partial derivatives of the model:

$$e = f(l_i, \alpha_m, \theta_e, \delta\theta, l_e\delta\alpha) \quad (6)$$

$$c_{l_i} = \frac{\partial e}{\partial l_i} = 1 + \alpha_m \times \theta_e + \alpha_m \times \delta\theta =\approx 1$$

$$c_{\alpha_m} = \frac{\partial e}{\partial \alpha_m} = l_i \times (\theta_e + \delta\theta) - l_e \times \theta_e$$

$$c_{\delta\theta} = \frac{\partial e}{\partial \delta\theta} = l_i \times \alpha_m$$

$$c_{l_e} = \frac{\partial e}{\partial l_e} = -1 + \alpha_m \times \theta_e - \delta\alpha \times \theta_e =\approx 1,$$

$$c_{\delta\alpha} = \frac{\partial e}{\partial \delta\alpha} = l_e \times \theta_e$$

where is $l_i = 5\ mm,\ l_e = 5{,}003\ mm,\ \alpha_m = 11{,}5 \times 10^{-6}\ °C^{-1},\ \delta\alpha = 1 \times 10^{-6}\ °C^{-1}, \delta\theta = 0{,}2\ °C,\ \theta_e = 1\ °C$
Estimation of standard uncertainties of the input quantities:

- $u(l_i)$, resolution of dial gauge, d=0,01 mm, Type B from resolution, half pass of d, rectangular distribution $u(l_i)=d/\sqrt{3}$, $u(l_i) = \frac{d}{\sqrt{12}} = 2{,}89$ µm.
- $u(\alpha_m)$, manufacturer's specification or literature, Type B, rectangular distribution, $\alpha_m=11{,}5\times10^{-6}$ °C^{-1} ±1×10^{-6} °C^{-1} (typical steel value) $u(\alpha_m) = 1 \times \frac{10^{-6}}{\sqrt{3}} = 0{,}577 \times 10^{-6}$ °C^{-1}.
- $u(\theta e)$, calibration of temperature sensor and temperature stability, combination of sensor calibration, resolution and stability. Temperature deviation at 20°C, θe=±1°C, rectangular distribution $u(\theta_e)=\theta_e/\sqrt{3}=0{,}577$°C
- $u(\delta\alpha)$, difference between thermal expansion coefficients $\delta\alpha=\pm1{,}5\times10^{-6}$ °C^{-1}, rectangular distribution $u(\delta\alpha)=\delta\alpha/\sqrt{3}=0{,}866\times10^{-6}$ °C^{-1}
- $u(\delta\theta)$, temperature difference between dial gauge and reference. Estimated from thermal equilibrium and sensor uncertainty δθ = ±0,2°C, rectangular distribution, $u(\delta\theta)= \delta\theta/\sqrt{3}=0{,}115$°C
- $u(l_e)$, calibration device, expanded uncertainty from certificate $u(l_e) = 0{,}06 + 5 \times 10^{-4} \times l$, l (mm).

- **Table 1**. Uncertainty Budget

Uncert source	Estimate	Distrib.	Stand. uncert. u(xi)	Sensitivity coeff.	Uncert. Contrib.
Uncertainty of the reading of the result u(li)	0,01 mm	Rectan.	2,89 µm	1	2,89
Uncertainty of the thermal expansion coefficient u(αm)	11,5×10−6 °C−1	Rectan.	0,577×10−6 °C^{-1}	0,001×10^6 µm x°C	6,640x10^{-3}
Uncertainty of the thermal expansion coefficient difference u(δα)	1,5·10-6°C^{-1}	Rectan.	0,866×10^{-6} ° C^{-1}	0,005×10^6 µm x°C	4,330x10^{-3}
Uncertainty of the temperature deviation u(θ_e)	1°C	Rectan.	0,577 ° C^{-1}	0,0075×10^6 µm x°C^{-1}	4,330x10^{-3}
Uncertainty of temperature difference u(δθ)	0,2°C	Rectan.	0,115 °C	0,0575 µm x°C^{-1}	6,640x10^{-3}
Uncertainty of indication of the device u(l_e)	0,06+5x10^{-4}xl	Normal	0,032 µm	1	6,250x10^{-2}
Combined standard uncertainty (uc)					2,887
Expanded uncertainty *U* (k=2) µm					5,78

Calculation (estimation) of standard uncertainties of influence values is given in Table 1 for the equipment, methods and conditions used in our laboratory.

For measurement point 5 mm measurement uncertainty is 5,78 µm.

Complete result l_i'= l_i ±U = 5 mm ± 0,00578 mm.

5. RESULT AND DISCUSSION

Measured displacement between the pointer positions 0 mm (initial position) and 5 mm (end position):
When the pointer position is l_i = 5,00 mm, the standard

device indicates the measured displacement l_e = 5,003 mm.

The deviation of the dial gauge indication Δl_i from the conventional value l_e of the standard device $\Delta l_i = l_e - l_i$ is 3 µm. In practice, corrections are not common for this type of dial gauge so that the systematic error must be considered as an uncertainty contribution in the uncertainty budget. In metrology and dial gauge calibration (under standards like DIN and ISO 463), f_e=15 µm (span of error/deviation span) is the maximum error when moving the plunger in a single direction, while f_{ges}=17 µm (total deviation span) is the overall error range combining both directions, which includes mechanical hysteresis. Accordingly, the conventional value of the measurement result can be expected in the range between 4,99 mm and 5,006 mm with a confidence level of 95.45%. This applies to the 5 mm measuring point only. If the deviation error and measurement uncertainty are analyzed, the measurement is in the manufacturer's specification.

6. CONCLUSION

In a process of calibrating a measuring instrument, it is influenced by several factors such as the uncertainty of the measuring instrument, the uncertainty of the calibration tool, the standard deviation, changing in temperature, general uncertainty and the combined uncertainty. Therefore, from all the values of these factors, the uncertainty value can be obtained. Based on the calibrations that have been made, several conclusions can also be drawn, which is:

- Calibration is a standard procedure in factories/companies, especially those engaged in production, because it can control the quality of the equipment used, and can show whether the tool is feasible or not to be used.
- The obstacle experienced during dial Indicator calibration is the concentration of the operator performing the calibration, which can affect the results of readings on the dial and on standard equipment. There are also some cases where the measuring capacity and reference standards are not suitable when trying to calibrate.

TOTAL QUALITY INTEGRATED IN NEW AMMUNITION PRODUCTS IN AD "PRVI PARTIZAN" (ACCORDING TO ISO/TR 14062 - 2002)

SVETOLIK SPASENIĆ
AD „Prvi partizan", Užice, svetolik.spasenic@prvipartizan.com

***Abstract**: This papar presents a global market trend indicating that input requirements for product design and development must, in addition to quality and safety demands, integrate requirements at an early design stage ensuring that the product is harmless to nature and the environment (achieving total quality).*

Aware of such user needs and social demands regarding the human right to a healthy environment, "Prvi partizan " AD has designed and implemented the production of a new generation of products – ammunition with TMJ (Total Metal Jacket) type bullets.

Following the firing of a round and upon leaving the muzzle, such bullets do not release harmful lead emissions into the environment.

Keywords: *new ammunition products, environmental requirements, total product quality*

1. INTRODUCTION

The eighty years of experience of "Prvi partizan" AD in the design and production of high-quality and safe ammunition products has recently been enriched by the design of products that also integrate eco-friendly and environmental requirements – total quality products. In SRPS ISO 14004 (1997), Appendix A2 of the Business Charter for Sustainable Development of the International Chamber of Commerce (ICC), Principle 6 is defined as follows: "To develop and provide products or services which have no undue environmental impact and are safe in their intended use, which are efficient in their consumption of energy and natural resources, and which can be recycled, reused, or disposed of safely."

Aware that every product exerts some impact on the environment throughout its life cycle (starting from raw material procurement, product realization, storage, use, recycling, and waste disposal), we have identified a significant environmental impact – harmful lead emissions into the atmosphere upon firing pistol and revolver ammunition assembled with FMJ (full metal jacket) type bullets. We have decided to include environmental requirements for our products at the earliest stage of product design, i.e., in the input requirements for the design and development of new products, in order to achieve the overall – total quality of our products. The result of the design and development process was TMJ (total metal jacket) or CMJ (complete metal jacket) type bullets, as they are called by a well-known global manufacturer in this field (Israel Military Industries Ltd. IMI). In this way, we have fulfilled Principle 6 of the aforementioned Charter.

2. GLOBAL MARKET REQUIREMENTS

"Prvi partizan" AD has been present on the global market with its products for years, thanks to the fact that it has adopted the technical standards of these markets (ANSI/SAAMI for North American, and C.I.P. for European and other markets) in the field of commercial weapons and ammunition as its own and applies them unconditionally. In this way, technical barriers to mutual trade exchange have been eliminated, but new requirements are emerging, particularly from developed countries, stating that the environment must be preserved from pollution and harmful impacts during the product's life cycle. Our policy and strategy have always been that all user requirements, whether explicitly stated or unstated but implied, must be fulfilled and their expectations exceeded. At the same time, all legal requirements of the market to which our product is distributed must be properly understood and met. Thus, the top management of the company has adopted a policy that all user requirements, including environmental ones, must be fulfilled if we want to ensure survival and market share on the global market, especially the market of developed countries, where legislation on human health and environmental protection has been intensively enacted over the past 20 years.

3. IDENTIFICATION OF ENVIRONMENTAL IMPACT

The process of firing a cartridge begins when the firing pin strikes the primer. This strike ignites the primer mixture contained within the primer. The flame from the primer is transferred to the powder charge, after which the combustion of the gunpowder takes place. This generates a very high temperature inside the barrel of the weapon

Corresponding author: S. Spasenić;
E-mail: svetolik.spasenic@prvipartizan.com

DOI: 10.5937/OTEH26036S

(higher than 2000°C), meaning that the core of an FMJ type bullet (the core is made of a lead-antimony alloy where the antimony content is less than 3%) is exposed to a temperature greater than the vaporization point of lead. The melting and vaporization points of lead and antimony are given in Table 1.

Table 1. The melting and vaporization points Pb and Sb

Component of the bullet core	Melting point (°K)	Vaporization point (°K)
Lead (Pb)	600,3 (327,3° C)	2013 (1740°C)
Antimony (Sb)	903,5 (630,5°C)	1713 (1440°C)

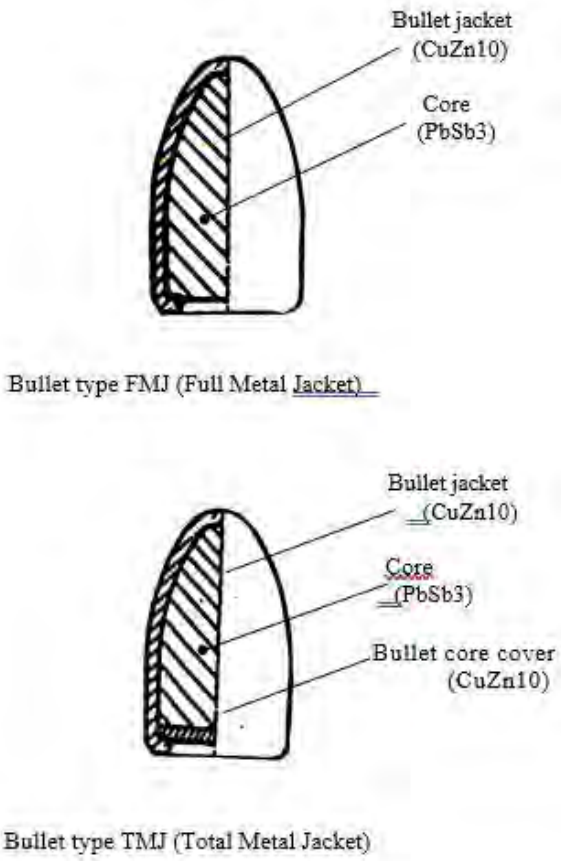

Figure 1.

The consequence of exposing the bullet core to such an extremely high temperature (even in a very short period of time – a few hundredths of a second) is a harmful emission of lead into the atmosphere upon firing the cartridge, i.e., after the bullet leaves the muzzle of the weapon, as well as a harmful impact on the soil at the point of impact due to direct contact between the soil and the lead.

The effect of harmful lead emissions into the atmosphere is particularly intensified when ammunition is fired in poorly ventilated or enclosed shooting ranges, as lead, being a heavy metal, is difficult to remove via ventilation or airing. Furthermore, with every firing, the lead deposited on the walls and floors of the test ranges in the form of microparticles is kicked up and swirled into the atmosphere, making work (or training) very difficult and hazardous to health. It should also be noted here that lead in the form of a fine powder, i.e., microparticles, becomes flammable in the presence of oxygen – so-called **pyrophoric lead** – presenting an additional potential hazard: the risk of fire.

We can notice how "heavy" a metal lead is, from its position in Mendeleev's periodic table of elements, where its atomic number is 82, with 82 protons, 82 electrons, and 125 neutrons in its atom; its relative atomic mass is $A = 207.2$ (for example, uranium has the atomic number 92 with a relative atomic mass of $A = 238$).

After identifying this type of environmental impact when using cartridges with FMJ-type bullets, it became clear that another group of limiting factors – environmental factors – must be included in the product design input requirements. These factors, regardless of everything else, must be fulfilled within the **process of designing total product quality**.

4. DESIGN PHASES OF A CARTRIDGE WITH A TMJ TYPE BULLET (TOTAL METAL JACKET)

By incorporating environmental factors into the input requirements for the design of ammunition products, TMJ-type bullets – total quality bullets – were created. The entire process of designing a cartridge with a TMJ-type bullet went through the following phases:

4.1. Planning phase

In this phase, it was planned which specific calibers would be included in the design process and with which input requirements. The product life cycle was also considered, along with identifying the specific stages of the life cycle where the product has a significantly harmful impact on the environment.

4.2. Conceptual design phase

In this phase, the final product design was defined, the manufacturing technology was engineered, and the technical documentation (TD) for production, as well as the technical documentation for testing and inspection, was established.

4.3. Prototype development phase

In this phase, the final product design was defined, the manufacturing technology was engineered, and the technical documentation (TD) for production, as well as the technical documentation for testing and inspection, was established.

4.4. Prototype testing phase (verification and validation)

In this phase of prototype testing (verification and validation tests), in addition to all other quality

requirements (from laboratory to experimental and operational), the environmental performance of the product was also inspected. In all tests, the bullet remained compact and without cover separation from the bullet core, which guaranteed the elimination of harmful lead emissions from the lead core at the initial part of the bullet trajectory; as well as, after the bullet fall, direct contact of the soil with lead from the bullet core. The development was successfully completed.

4.5. Phase of serial production and market launch of the product

The product has entered serial production and has been delivered to the user, securing its rightful place as a new product in our ammunition catalog for year 2012.

4.6. Phase of product evaluation by users

Users - buyers have confirmed that we have met all their expectations, to the mutual satisfaction for both parties, we have achieved high overall quality of the product with reliability and safety in use, and in addition, the product is harmless to nature and the environment.

5. PRODUCTS WITH BULLET TYPE TMJ

In 2002, AD "Prvi partizan" developed the following new ammunition products by integrating environmental protection requirements into design input requirements (ecological requirements), somehow just at the time when the international technical recommendation from the group of standards on environmental management ISO/TR 14062 was introduced - Integrating of environmental aspects into product design and product development.

Table 2. Cartridge with TMJ bullet type produced by „Prvi partizan" AD

No.	Caliber	Bullet type	Bullet mass (grain)	Bullet mass (g)
1.	9 mm Luger	TMJ	115	7,45
2.	9 mm Luger	TMJ	124	8,0
3.	38 Special	TMJ	158	10,25
4.	40 Smith &Wesson	TMJ	180	11,7
5.	10 mm AUTO	TMJ	180	11,7
6.	9 mm x 21	TMJ	115	7,45
7.	9 mm x 21	TMJ	124	8,0
8.	45 AUTO	TMJ	230	14,85

In the process of producing bullet type TMJ (CMJ), it is spent up to 10-15% more time per unit, which to some extent increases the cost of production, but therefore **achieves a significant advantage over the competition in the market**. This gives the company potential benefits such as:

- gaining a vision of developing and delivering products that do not have harmful impact on the environment and are safe for their intended use
- this ensures that users have an obligation to protect the environment while satisfying their wishes and needs
- maintaining good relations with the public and the wider social community
- increasing reputation and market share
- meeting the criteria for certification according to SRPS ISO 14001
- facilitating the acquisition of permits and possibilities for placement in developed countries
- improving relations with the competent ministry for environmental protection.

By reviewing the catalog of the renowned ammunition manufacturer "Israel Military Industries ltd (IMI)", we have noticed that they have produced TMJ bullets in the same calibers as we did, except for the calibers: 40 Smith & Wesson, 10 mm AUTO and 45 AUTO. Our advantage is obvious.

Table 3. List of cartridges with bullet type CMJ manufactured by „Israel Military Industries (IMI)"

No.	Caliber	Bullet type	Bullet mass (grain)	Bullet mass (g)
1.	9mm Luger	CMJ	115	7,45
2.	9 mm Luger	CMJ	124	8
3.	38 Special	CMJ	125	8,1
4.	9 mm x 21	CMJ	115	7,45
5.	9 mm x 21	CMJ	124	8

6. CONCLUSION

Product designers and engineers at the company "Prvi Partizan A.D." are facing new challenges in integrating all previously established requirements related to product and service quality and safety, along with current requirements for environmental and nature protection throughout every stage of the product or service life cycle, with the aim of achieving total quality.

It is essential to study and implement the standards from the SRPS ISO 14000 series, which relate to products and services, as follows:

– SRPS ISO 14020 (2001): Environmental labels and declarations – General principles
– SRPS ISO 14024 (2001): Environmental labels and declarations – Type I eco-labelling – Principles and procedures
– SRPS ISO 14040 (2000): Environmental management – Life cycle assessment – Principles and framework
– SRPS ISO 14041 (2000): Environmental management – Life cycle assessment – Defining the objective and scope and inventory analysis
– SRPS SO 14042: Environmental management – Life cycle assessment – Life cycle impact analysis
– SRPS ISO 14043: Environmental management - Life cycle assessment – Life cycle interpretation
– SRPS ISO Guide 64 (2000) Guidelines for the inclusion of environmental aspects in product standards
– ISO/TR 14062 (2002) – Environmental management – Integrating environmental aspects into product design and development.

It would be beneficial for national legislation to introduce incentives for organizations that design and deliver products with no adverse impact on nature and the environment — products of total quality. Such measures would quickly produce positive results.

These efforts would facilitate the integration of the Serbian economy into international trade and strengthen its position in the demanding global market, influenced by numerous trade limitations, regulatory requirements, and restrictive economic policies.

Abstract: *The optimization of chassis geometry represents a key step in the development of modern modular 4×4 vehicle platforms. The manufacturing of chassis with complex geometries requires the use of specialized tooling, involves potential deformations due to welding, and demands a complex logistical framework, all of which significantly increase production time and costs. These requirements further limit production flexibility and may slow down adaptation to diverse operational demands.*

In the military sector, where rapid response and adaptability to various missions are essential, modularity and shortened production cycles—along with minimal reliance on specialized tools—are of critical importance. For this reason, a chassis concept with simplified geometry and standardized structural elements has been developed, enabling rapid configuration of different superstructures. The entire assembly process is significantly simplified, as only a single type of longitudinal beam needs to be produced, while the wheelbase can be easily adjusted according to specific application requirements, owing to a dedicated connection method of the suspension subassembly. This approach enables more efficient production, easier maintenance, and greater operational flexibility of the vehicle.

Keywords: *vehicle modularity, increased production capacity, rapid assembly*

1. INTRODUCTION

Modern wheeled military vehicles are expected to provide high mobility, adaptability and operational flexibility while supporting a wide range of mission-specific configurations. To meet these demands, vehicle manufacturers are increasingly adopting modular platform concepts that enable multiple vehicle variants to be developed from a common structural base[1,2]. Such an approach can improve production flexibility [1,2], while modularity in military vehicle design may also provide benefits related to adaptability, life-cycle costs, maintenance and logistics [1].

The chassis is the primary load-bearing structure of a vehicle and has a significant influence on its structural performance, manufacturability and operational capabilities [3,4]. Conventional ladder-frame chassis remain the most widely used solution for military and off-road vehicles due to their robustness and versatility[3]. However, their production often involves complex frame geometries, numerous structural components, dedicated manufacturing fixtures and extensive welding operations. These factors increase production time and cost, reduce manufacturing flexibility and may introduce welding-induced distortions that require additional corrective operations[3,4].

Current trends in military vehicle development therefore focus on increasing modularity, component standardization and production simplification [1,3]. Reducing the number of unique structural components while enabling different vehicle configurations from a common chassis can significantly improve manufacturing efficiency and logistical support, particularly in low-volume military production[1,3].

This paper presents the development of a novel modular chassis concept for a multi-purpose 4×4 vehicle platform. The proposed design is based on simplified chassis geometry and standardized structural elements, aiming to reduce manufacturing complexity, minimize the need for dedicated tooling and improve production flexibility while maintaining the adaptability required for various military applications.

2. REVIEW OF CONVENTIONAL CHASSIS ARCHITECTURES

The chassis is the primary structural component of a vehicle, responsible for supporting the powertrain, suspension, body and payload while ensuring adequate strength and stiffness under various loading conditions. Over the years, several chassis architectures have been

Corresponding author: M.Vasiljević
E-mail: mihajlo.vasiljevic@zastavatervo.rs
DOI: 10.5937/OTEH26037V

developed, each offering specific advantages depending on the intended vehicle application. The most commonly used structural concepts include ladder frame, backbone, monocoque and space frame chassis. Their design characteristics differ in terms of structural efficiency, manufacturing complexity, modularity and suitability for off-road and military applications[3].

2.1 Ladder frame chassis

The ladder frame is the most widely adopted chassis architecture for commercial trucks, off-road vehicles and military platforms. It consists of two longitudinal side members connected by a series of cross members, forming a robust load-bearing structure capable of supporting different body configurations. Its relatively simple construction, high load-carrying capacity, ease of maintenance and compatibility with various suspension systems have made it the preferred solution for low- and medium-volume production of military vehicles. Furthermore, the body-on-frame concept enables different mission-specific superstructures to be mounted on a common chassis platform, providing a certain degree of versatility. Despite these advantages, conventional ladder-frame chassis often require multiple frame variants, dedicated manufacturing fixtures and extensive welding operations, which increase production complexity and cost[3].

2.2 Backbone chassis

Backbone chassis utilize a central longitudinal structural member that carries the primary loads and connects the front and rear suspension assemblies. This architecture provides high torsional and bending stiffness, while drivetrain components can be enclosed and protected within the central structure [4]. Although less commonly used than conventional ladder-frame configurations, backbone chassis are still employed in certain specialized off-road and military vehicles. One notable example is the Tatra chassis concept, which combines a central backbone tube with independently suspended swinging half-axles [5].

2.3 Monocoque structure

In monocoque vehicles, the body itself serves as the primary load-bearing structure, eliminating the need for a separate frame. This concept offers significant weight reduction, improved crash performance and high structural efficiency, making it the dominant solution in passenger vehicle design[4]. Nevertheless, monocoque structures are less suitable for heavy-duty military applications, where high payload capacity, ease of repair and adaptability to multiple vehicle configurations are essential requirements[4].

2.4 Space frame structure

Space frame chassis consist of interconnected tubular or closed-section members arranged to achieve high stiffness with relatively low structural mass. Owing to their excellent strength-to-weight ratio, these structures are frequently used in racing vehicles and certain specialized military applications [6]. Recent studies have shown that space frame architectures can provide improved structural performance under high dynamic loading conditions [7] while offering greater design flexibility and modularity than conventional monocoque structures. However, their complex geometry, numerous joints, demanding fabrication processes and extensive welding requirements significantly increase manufacturing time and cost, limiting their suitability for cost-effective production of modular military vehicle platforms [4].

2.5 Limitations of conventional chassis designs

2.5.1 Manufacturing complexity

Conventional chassis architectures, particularly ladder-frame designs used in military vehicles, often require numerous structural components with different geometries and dimensions. Multiple longitudinal rails, cross members, reinforcement brackets and connection elements increase the number of manufacturing operations, assembly stages and quality control procedures. As vehicle families expand to include multiple wheelbase and payload variants, the number of unique structural components further increases, leading to greater production complexity and higher manufacturing costs [8].

2.5.2 Dedicated manufacturing tooling

Conventional chassis production frequently relies on dedicated manufacturing fixtures, positioning tools and welding jigs specifically designed for individual chassis variants [9]. The introduction of additional wheelbase configurations generally requires new tooling, increasing investment costs and extending production preparation time. Such an approach reduces manufacturing flexibility, particularly in low-volume military vehicle production where rapid adaptation to changing operational requirements is essential.

2.5.3 Welding and assembly challenges

The large number of welded joints required in conventional chassis structures increases manufacturing time and may introduce residual stresses and geometric distortions [10]. These effects often require additional inspection and corrective operations to ensure dimensional accuracy and structural integrity. Furthermore, extensive welding complicates repair and maintenance throughout the vehicle life cycle, particularly for vehicles operating under demanding field conditions.

2.5.4 Limited modularity

Although conventional ladder-frame chassis allow different vehicle bodies to be mounted on a common platform, their modularity is often limited by the need for different frame geometries and wheelbase-specific structural components. Consequently, each vehicle variant frequently requires modifications of the primary load-bearing structure, additional manufacturing documentation and dedicated production resources. These

limitations reduce production efficiency and increase logistical complexity throughout the vehicle life cycle[3]. A comparison of the main characteristics, advantages and limitations of conventional chassis architectures is presented in Table 1.

Table 1. Limitations of conventional chassis architectures

Limitation	Manufacturing impact	Operational impact
Multiple structural components	Higher production cost	More spare parts
Dedicated tooling	Longer production preparation	Reduced flexibility
Extensive welding	Distortion and longer assembly	More difficult maintenance
Wheelbase-specific designs	Additional chassis variants	Increased logistics complexity

These limitations highlight the need for a simplified and highly modular chassis concept capable of accommodating multiple vehicle configurations while minimizing structural complexity, production tooling and manufacturing effort.

3. DESIGN REQUIREMENTS

The design of a military vehicle chassis should satisfy both operational and manufacturing requirements. In addition to providing sufficient structural strength and reliability under various operating conditions, the chassis should enable efficient production, simplified maintenance and adaptability to different vehicle configurations. Based on the review of conventional chassis architectures and the requirements of modern military vehicle platforms, a set of operational and manufacturing requirements was established to guide the development of the proposed chassis concept [1,3].

3.1 Operational requirements

The proposed chassis concept was developed to satisfy the following operational requirements:

– adaptability to different mission profiles;

– compatibility with various mission-specific superstructures;

– accommodation of different wheelbase configurations;

– simplified maintenance and servicing throughout the vehicle life cycle.

3.2 Manufacturing requirements

In addition to operational performance, the proposed chassis should facilitate efficient and economical manufacturing. Therefore, the following manufacturing requirements were considered during the design process:

– simplified structural geometry;

– reduced dependence on dedicated manufacturing fixtures and tooling;

– shorter production and assembly time;

– reduced production and life-cycle costs.

4. PROPOSED MODULAR CHASSIS CONCEPT

The proposed chassis concept was developed to satisfy the operational and manufacturing requirements presented in the previous section while preserving the structural characteristics required for multi-purpose military vehicles. The development focused on simplifying the structural configuration, reducing the number of unique components and increasing manufacturing flexibility without compromising the adaptability of the platform.

Unlike conventional chassis designs, where different vehicle variants often require dedicated structural components and manufacturing tooling, the proposed concept is based on a modular architecture composed of standardized structural elements. The chassis was designed to enable straightforward manufacturing and assembly using conventional fabrication processes and widely available equipment, allowing production to be established with minimal dependence on specialized tooling. Such an approach is particularly suitable for low-volume military vehicle production and situations requiring rapid manufacturing or repair under field conditions.

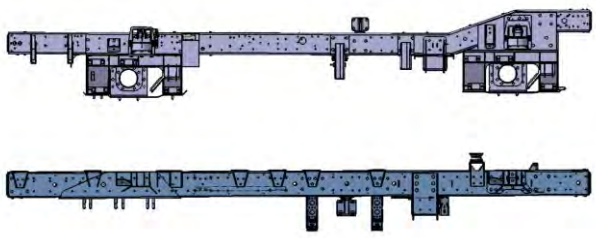

Figure 1 - Comparison of the baseline chassis and the proposed chassis concept

The proposed chassis concept incorporates several design features aimed at improving manufacturability and operational flexibility. These include a geometrically optimized chassis structure, modularly symmetrical longitudinal members, standardized cross members and an adjustable wheelbase concept. Each of these design features is described in the following sections.

4.1 Simplified structural design

The proposed chassis was developed with the objective of simplifying the structural configuration while preserving the strength, functionality and adaptability required for multi-purpose military vehicle platforms. The design process focused on reducing the number of structural components, simplifying manufacturing operations and improving assembly efficiency without compromising the structural performance of the chassis.

In addition to optimizing the geometry of the primary load-bearing structure, an important design decision was the selection of an independent suspension system from a different manufacturer incorporating an integrated suspension subframe. Compared to the previously used

solution, in which the suspension mounting structure consisted of multiple individual components assembled directly onto the chassis, the integrated subframe significantly simplified the overall structural configuration. This approach considerably reduced the number of structural components, assembly operations and manufacturing time required for chassis production.

Since a portion of these improvements results from the adoption of the integrated suspension subframe rather than solely from the redesigned chassis structure, the comparison presented in this study is performed at two levels. First, the primary chassis structures are compared independently of the suspension subframes in order to evaluate the influence of the proposed structural redesign itself. Subsequently, the complete chassis assemblies, including the suspension subframes, are compared to assess the overall manufacturing and assembly benefits of the proposed vehicle platform. This approach provides a balanced and objective evaluation by distinguishing improvements resulting from the chassis redesign from those associated with the selected suspension architecture.

The simplified structural design established the foundation for the remaining design features of the proposed chassis concept, including standardized longitudinal members, modular cross members and an adjustable wheelbase configuration, which are described in the following sections.

4.2 Symmetrical interchangeable longitudinal members

The longitudinal side members are the primary load-bearing elements of the chassis and therefore have a significant influence on manufacturing complexity, logistics and assembly. Conventional chassis designs typically employ separate left- and right-hand longitudinal members, resulting in a larger number of unique structural components and increasing the complexity of manufacturing, inventory management and production planning.

To simplify the production process and improve component standardization, the proposed chassis incorporates interchangeable longitudinal members. A single standardized component was developed that can be installed on either side of the chassis, eliminating the need for dedicated left- and right-hand parts. This approach reduces the number of unique structural components, simplifies inventory management and production planning and facilitates maintenance and replacement throughout the vehicle life cycle.

An additional advantage of the proposed design is the elimination of one of the most common manufacturing errors associated with chassis production. In conventional chassis manufacturing, separate left- and right-hand longitudinal members are produced from different unfolded geometries. Consequently, bending a component according to the drawing of the opposite side results in an unusable part, leading to material waste, additional manufacturing costs and production delays.

In the proposed design, both longitudinal members are manufactured from an identical, geometrically symmetrical unfolded geometry. Owing to this symmetry, the finished component remains suitable for installation regardless of the bending direction. Consequently, a correctly manufactured part cannot become unusable due to an incorrect interpretation of the left- or right-hand configuration, as shown in Figure 2. The possibility of producing an incorrect longitudinal member is therefore eliminated by the structural design itself rather than by manufacturing procedures or quality control.

Besides reducing the number of unique structural components, the proposed solution increases manufacturing reliability, simplifies quality control and inventory management, reduces material waste and minimizes the potential for human error during fabrication.

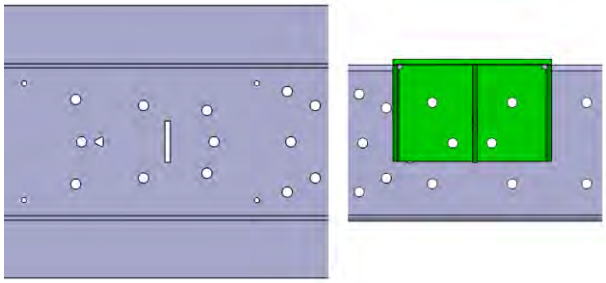

Figure 2 - Symmetrical interchangeable longitudinal member

The proposed symmetrical design results in several unused openings when the longitudinal member is installed on one side of the chassis, as these openings are intended for components that become active when the same member is installed on the opposite side, as shown in Figure 2. Although this represents a minor increase in the number of unused features, it is considered an acceptable design trade-off in view of the significant manufacturing and logistical benefits achieved.

The use of a single interchangeable longitudinal member enables identical spare parts to be used regardless of the installation side, eliminating the need to stock separate left- and right-hand components. Furthermore, in field conditions, replacement can be carried out without any structural modifications or additional machining. An additional advantage is that longitudinal members recovered from damaged or disabled vehicles can be directly reused as spare parts for other vehicles, providing valuable logistical support in emergency situations where replacement components may not be readily available.

4.3 Modular cross members

In order to increase the torsional stiffness of the chassis while preserving its modular character, a cross member manufactured by laser cutting and simple bending operations was developed. This solution enables a relatively simple production process and avoids the need for complex forming tools. Installed cross members are shown in Figure 3.

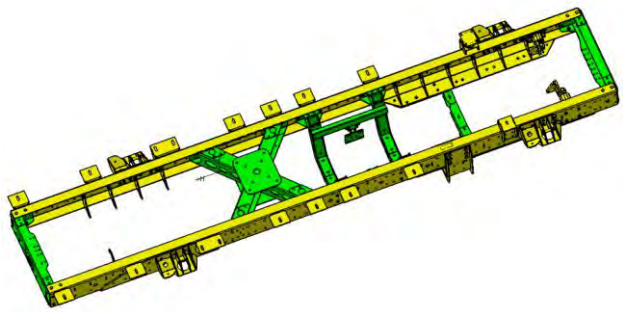

Figure 3 - Cross members

After fabrication, the cross member can be attached to the longitudinal members using either bolted joints or riveted joints, depending on manufacturing conditions and available equipment. Both joining methods can be used within the proposed concept. However, riveted joints are preferred where a permanent connection is required, since they reduce the possibility of loosening during vehicle operation. Bolted joints remain applicable in cases where easier disassembly or replacement of components is required.

In the area surrounding the transfer case, the cross members were additionally designed so that, with only minor modifications, they can also serve as supporting elements for a V-shaped blast protection structure, as shown in Figure 4. This solution provides the possibility of integrating an underbody mine protection system without requiring a complete redesign of the chassis structure, thereby preserving the modularity of the proposed concept.

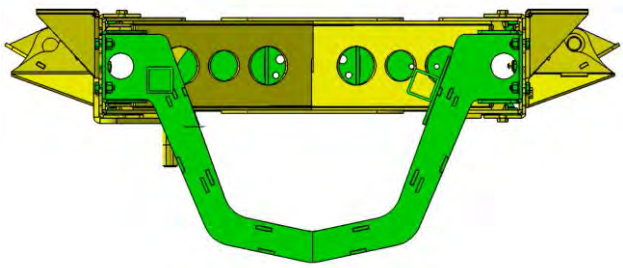

Figure 4 - Cross members around transfer case

The proposed cross member design contributes to improved torsional stiffness while maintaining manufacturing simplicity, assembly flexibility and the potential for future integration of additional structural and protective elements.

4.4 Adjustable wheelbase concept

One of the key features of the proposed chassis is the ability to modify the wheelbase without redesigning the primary load-bearing structure. In conventional chassis designs, changing the wheelbase generally requires the development of a new frame variant, resulting in additional manufacturing effort, dedicated tooling and increased logistical complexity.

In the proposed concept, the suspension subframes are mounted to a dedicated supporting structure that can be translated along the longitudinal members after loosening the corresponding fastening bolts. This arrangement enables straightforward adjustment of the wheelbase while preserving the same primary chassis structure and the majority of its structural components. Once the desired position is reached, the supporting structure, shown in Figure 5, is secured using the existing fastening points.

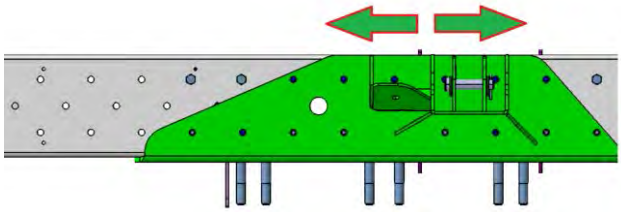

Figure 5 - Adjustable wheelbase concept

When a shorter wheelbase is required, the rear overhang can be reduced by shortening the longitudinal members to suit the new vehicle configuration. Conversely, if a longer wheelbase is required, the chassis can be extended without altering the basic structural concept. In practice, the maximum achievable chassis length is primarily limited by manufacturing constraints, such as the dimensions of the available sheet material and fabrication equipment.

Although changing the wheelbase requires corresponding modifications to the drive shaft, as well as portions of the electrical and pneumatic installations, these changes remain limited and straightforward. When the wheelbase is reduced, most of the existing components can be adapted to the new configuration without introducing additional parts. In cases where a longer wheelbase is required, only those components affected by the increased distance need to be replaced. Such components can be prepared as predefined conversion kits for each wheelbase configuration, enabling rapid vehicle reconfiguration without modifications to the primary chassis structure.

The proposed adjustable wheelbase concept significantly increases platform flexibility by enabling multiple vehicle configurations to be realized using the same basic chassis architecture. As a result, the number of dedicated chassis variants is reduced, while manufacturing, maintenance and logistical support are considerably simplified.

5. COMPARATIVE ANALYSIS

The design features presented in the previous section were developed with the objective of improving the manufacturability, modularity and operational flexibility of the proposed chassis concept. However, the practical value of these design solutions can only be assessed through a direct comparison with the existing chassis design. For this reason, a comparative analysis was performed to evaluate the influence of the proposed concept on manufacturing complexity, structural configuration and assembly.

Since the proposed vehicle platform incorporates both a redesigned chassis structure and an integrated suspension subframe, the comparison is carried out at two levels. First, the primary chassis structures are compared independently of the suspension subframes in order to isolate the effects of the structural redesign. Subsequently,

the complete chassis assemblies are compared to evaluate the overall benefits of the proposed vehicle platform from the standpoint of manufacturing, assembly and logistics.

5.1 Comparison of the primary chassis structure

The first stage of the comparative analysis focuses exclusively on the primary chassis structure, excluding the suspension subframes and associated mounting components. This approach enables an objective evaluation of the structural modifications introduced in the proposed chassis concept, independent of the influence of the selected suspension architecture.

A comparison of the existing and proposed chassis structures is presented in Figure 6. The comparison highlights the effects of the simplified structural design, interchangeable longitudinal members and standardized cross members on the overall chassis configuration.

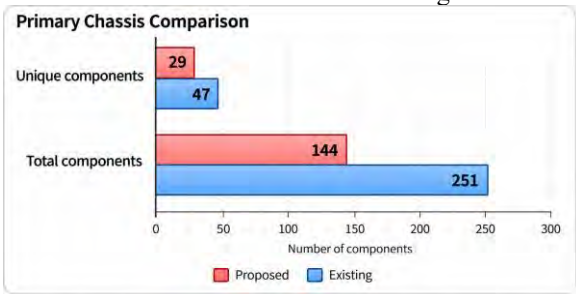

Figure 6 - Comparison of the primary chassis structure

The proposed chassis achieves a significant reduction in manufacturing complexity through a lower number of unique structural components and improved component standardization. In addition, the simplified structural layout facilitates manufacturing, assembly and maintenance while preserving the functionality required for different vehicle configurations.

5.2 Comparison of the complete chassis assembly

While the previous comparison focused exclusively on the primary chassis structure, the second stage of the analysis considers the complete chassis assembly, including the suspension subframes and all structural components directly associated with the chassis. This comparison provides a more realistic assessment of the manufacturing and assembly benefits achieved by the proposed concept.

As discussed in Section 4.2, the proposed chassis incorporates an integrated suspension subframe, which contributes to a further reduction in the number of structural components and assembly operations. To ensure an objective evaluation, the influence of this design decision was separated from the comparison of the primary chassis structure and is considered only in the complete chassis assembly, as shown in Figure 7.

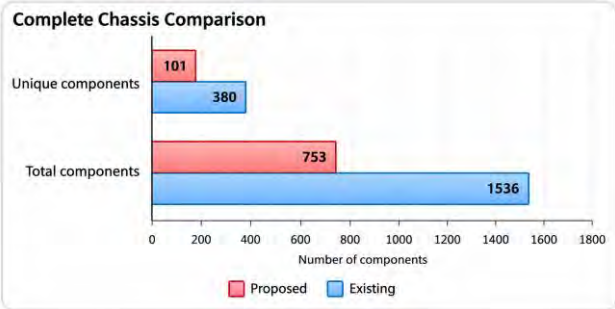

Figure 7 - Comparison of the complete chassis assembly

The complete chassis assembly of the existing vehicle consists of 1536 components, whereas the proposed concept reduces this number to 753. Components common to both vehicle concepts, such as the powertrain and other shared vehicle systems, were excluded from the comparison in order to evaluate only those components affected by the structural redesign. The reduction in the number of components simplifies assembly, inventory management, spare parts logistics and maintenance while supporting a more efficient manufacturing process.

5.3 Manufacturing and logistical benefits

The proposed chassis concept provides several manufacturing and logistical advantages compared to the existing design. The reduced number of structural components, together with the use of interchangeable longitudinal members and standardized cross members, simplifies production, assembly, inventory management and maintenance.

The adjustable wheelbase concept further increases platform flexibility by enabling different vehicle configurations to be realized using the same primary chassis structure. In cases where the wheelbase is increased, only the components directly affected by the modification need to be replaced using predefined conversion kits, while the primary chassis structure remains unchanged.

Overall, the proposed concept reduces manufacturing complexity, improves component standardization and simplifies logistical support while preserving the modularity required for modern military vehicle platforms. The reduction achieved by the proposed chassis concept is shown in Figure 8.

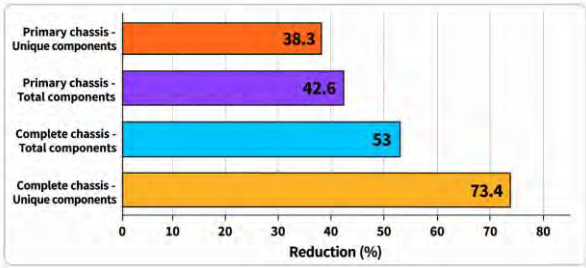

Figure 8 – The reduction achieved by the proposed chassis concept

6. CONCLUSION

This paper presented the development of a modular chassis concept intended to simplify the production and increase the operational flexibility of multi-purpose military vehicle platforms. The proposed design was developed with emphasis on simplified structural geometry, component standardization and the ability to adapt the wheelbase without redesigning the primary chassis structure.

Several design solutions were introduced to achieve these objectives, including interchangeable longitudinal members, standardized cross members and a movable suspension supporting structure enabling straightforward wheelbase adjustment. In addition to improving manufacturing flexibility, the proposed concept eliminates one of the common manufacturing errors associated with the production of left- and right-hand longitudinal members through the structural design itself.

A comparative analysis of the existing and proposed chassis concepts demonstrated a significant reduction in the number of structural components at both the primary chassis level and the complete chassis assembly level. The results indicate that the proposed concept can simplify manufacturing and assembly, reduce inventory requirements, facilitate maintenance and improve logistical support while preserving the modularity required for different vehicle configurations.

The proposed chassis concept represents a practical approach to the development of modular military vehicle platforms and provides a foundation for further structural verification, numerical analyses and experimental validation.

Abstract: *This paper deals with the analysis and optimization of parameters influencing the internal ballistics and barrel design of the 30×165 mm automatic cannon. Internal ballistic calculations were performed using a mathematical model based on the Drozdov method, with the aim of determining the influence of various parameters on projectile muzzle velocity and maximum powder gas pressure inside the barrel. The analysis was first carried out using reference internal ballistic parameters, after which selected parameters were varied within a limited range in order to examine their influence on system performance. By individual and combined variation of the parameters, their mutual dependence and impact on the operating characteristics of the weapon system were determined. The primary objective was to obtain higher projectile muzzle velocity while maintaining the maximum pressure within allowable limits. Based on the obtained optimal parameters, the barrel geometry was calculated. In the final stage of the research, structural verification of the designed barrel was performed using the finite element method in Simcenter Femap. The barrel model was subjected to loading conditions corresponding to the calculated internal ballistic forces, enabling analysis of stress distribution, deformation, and structural integrity under operating conditions.*

Keywords: *Internal ballistics, barrel design, Drozdov method, FEM analysis.*

1. INTRODUCTION

The design of artillery gun barrels requires the simultaneous consideration of internal ballistic performance and structural integrity. During firing, the barrel is subjected to rapidly varying pressure loads generated by the combustion of the propellant, producing complex stress and deformation states. Therefore, reliable barrel design requires both accurate prediction of the internal ballistic parameters and evaluation of the structural response under transient loading.

Internal ballistic calculations provide the pressure distribution, projectile velocity and projectile position throughout the firing process. These parameters can be used as input for finite element analysis, enabling a detailed assessment of the barrel stress and deformation during projectile travel. Such an approach allows the direct connection between the internal ballistic solution and the structural analysis of the weapon system.

In this study, an internal ballistic model of a 30×165 mm automatic cannon cartridge was used to determine the pressure distribution along the barrel. The obtained pressure curves were converted into a sequence of loading conditions and applied to an axisymmetric finite element model of the barrel developed in Simcenter Femap/Nastran. The structural response was evaluated by monitoring the maximum equivalent stress and total displacement throughout the firing cycle.

Furthermore, the structural response obtained for the optimized propellant configuration was compared with that of the initial configuration. The comparison enables the assessment of how the optimization of internal ballistic parameters influences the stress state and deformation of the barrel, providing a basis for further improvement of barrel design and material selection.

The proposed methodology provides an efficient procedure for transferring internal ballistic results into finite element load cases and can be applied during the structural design and verification of gun barrels.

2. INTERNAL BALLISTICS CALCULATION

The structural analysis presented in this paper is based on the results of an internal ballistic calculation performed for a 30×165 mm automatic cannon cartridge. The internal ballistic model was developed using the Drozdov method [1]. The calculation provides the temporal evolution of the chamber pressure, projectile velocity and projectile position, which are subsequently used as input data for the finite element analysis.

The initial calculation was performed using the nominal ballistic parameters of the selected ammunition. Input

parameters for calulation are summarized in Table 1.

Table 1. Nominal input parameters

Label	Value	Unit
Powder chamber volume- W_0	0.000311	m
Barrel bore cross-sectional area- S_c	0.000738	m^2
Total projectile barrel travel- X_u	2.16	m
Forcing pressure- p_0	30e6	Pa
Fictitiousness coefficient- φ	1.169	/
Projectile mass- m	0.435	kg
Propellant charge mass- m_b	0.195	kg
Propellant density- ρ_b	1600	$\frac{kg}{m^3}$
Covolume of propellant gases-α	0.00103675	$\frac{m^3}{kg}$
Specific heat ratio- θ	0.269	/
Propellant grain thickness- r_0	0.000335	m
Shape coefficient- κ_1	1.24179	/
Shape coefficient- λ_1	-0.19471	/
Specific work of propellant gases- f_b	926712.491	$\frac{J}{kg}$
Propellant burning rate- u_{z0}	6.66e-10	$\frac{m}{sPa}$

The results of the IB calculations indicate a maximum chamber pressure of 313.69 MPa and a muzzle velocity of 1008.95 m/s.

Graphical results of IB calculation are shown in images below.

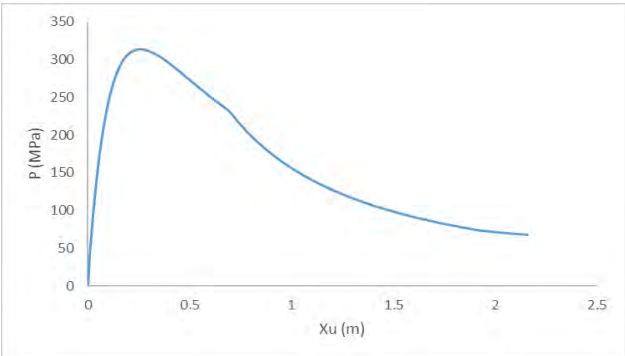

Figure 1. Pressure-travel curve.

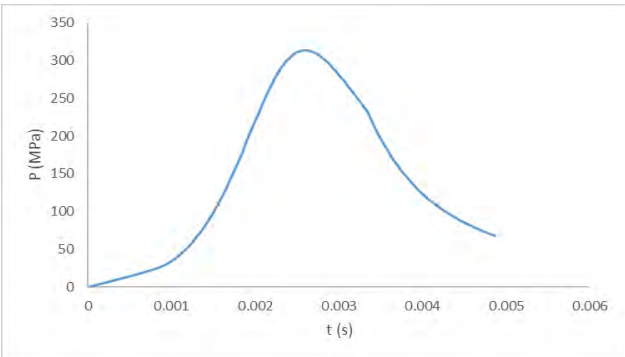

Figure 2. Pressure-time curve.

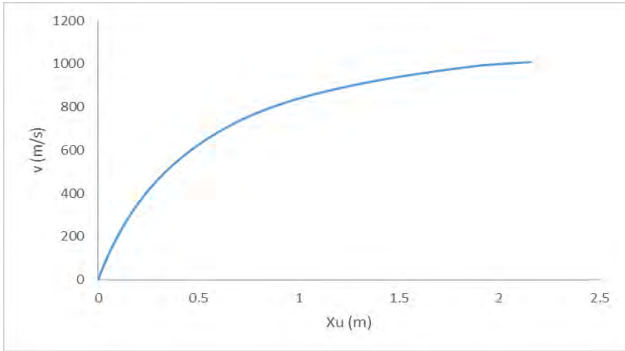

Figure 3. Velocity-travel curve.

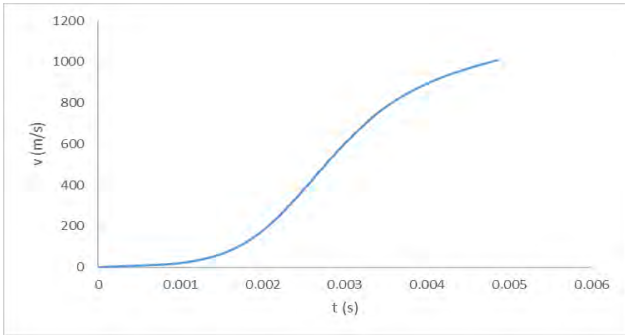

Figure 4. Velocity-time curve.

The initial ballistic solution served as the reference configuration for the subsequent optimization process.

2.1. Selection of the optimized IB configuration

The influence of the most significant internal ballistic parameters on the muzzle velocity and maximum chamber pressure was investigated by varying each parameter individually within predefined limits. [2] The objective of the analysis was to identify the parameters whose variation produces a favorable increase in projectile velocity without causing an excessive increase in the maximum pressure. [3]

Only the parameters that demonstrated a positive influence on the desired ballistic performance were selected for further optimization. Parameters with negligible or unfavorable influence were excluded from the final configuration.

The selected parameters together with their influence on the muzzle velocity and maximum pressure are presented in Table 2.

Table 2. Influence of changed parameters.

Parameter	Parameter change (%)	Velocity change (%)	Pressure change (%)
m	-5%	+1,64%	-5,03%
r_0	-5%	+1,72%	+10,92%
m_b	+2,5%	+1,85%	+6,37%
m_b	+5%	+4,63%	+16,72%
u_{z0}	+5%	+1,62%	+10,2%

α	+5%	+0,83%	+3,22%
f_b	+2,5%	+1,67%	+4,99%
f_b	+5%	+3,31%	+10,11%

Based on the observed trends, an optimized combination of internal ballistic parameters was defined. Newly selected parameter changes are: m-5%; m_b+2.5%; α+5%; f_b+2,5%. The selected parameter values represent a compromise between increased projectile velocity and acceptable structural loading of the barrel. This optimized configuration was adopted as the basis for the subsequent structural analysis. [4]

Graphical results of IB calculation are shown in images below.

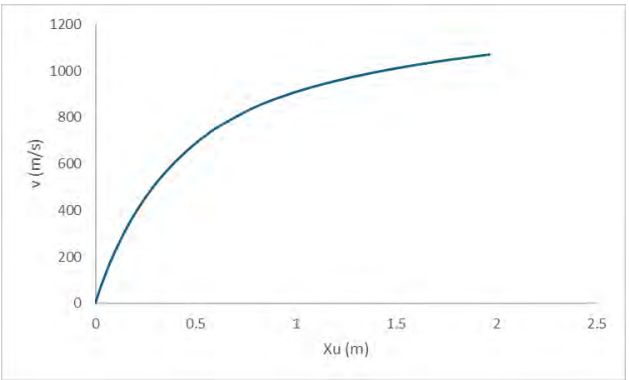

Figure 7. Velocity-travel curve.

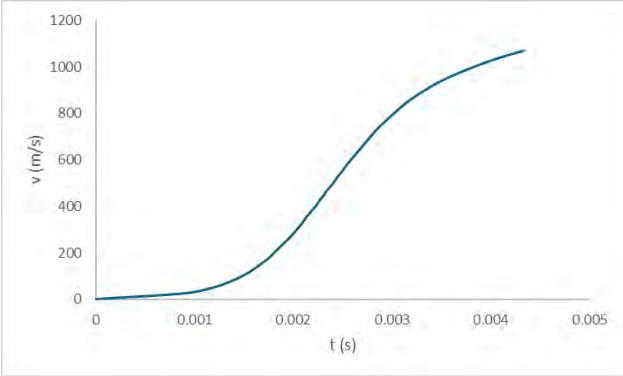

Figure 8. Velocity-time curve.

A comparison between the initial and optimized internal ballistic configurations is presented in Table 3.

Table 3. Comparison of the ballistic configurations.

	Maximum pressure (MPa)	Muzzle velocity (m/s)
Nominal conifig.	313.69	1008.95
Optimized config.	361.88	1090.49
Relative change	+15.36%	+8.08%

3. FINITE ELEMENT MODEL OF THE BARREL

The structural response of the barrel was evaluated using the finite element method based on the pressure distribution obtained from the internal ballistic analysis. The complete procedure included the development of the barrel geometry, generation of the finite element model, definition of material properties and boundary conditions, and application of the pressure loading corresponding to different projectile positions during the firing process.

3.1. Barrel geometry

The barrel geometry was generated using the KODCEV software package based on the optimized internal ballistic solution. The software calculates the required barrel profile from the specified ballistic loading conditions and material characteristics, providing the inner and outer barrel contours required for structural analysis. The barrel was dimensioned according to the Huber-Mises-Hencky (von Mises) criterion, where the elastic strength limit is defined by internal pressure at which the equivalent stress reaches the yield strength of the material. [5]

The calculated barrel profile was exported as a set of coordinate points describing the barrel cross-section. These coordinates were imported into the FEA environment, where the two-dimensional axisymmetric geometry of the barrel was reconstructed. Since the loading and geometry are rotationally symmetric, an axisymmetric representation was adopted in order to reduce the computational cost while preserving the accuracy of the structural analysis.

Due to space limitations, profiles of the chamber, the

forcing cone and the initial section of the projectile guide are represented in figure 9.

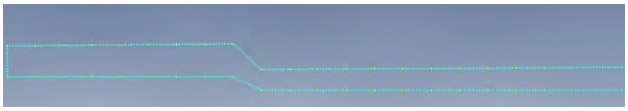

Figure 9. Profiles of the chamber, the forcing cone and the initial section of the projectile guide.

3.2 Finite element model

The finite element model was developed in Simcenter Femap**.** The reconstructed barrel profile was meshed using two-dimensional axisymmetric solid elements. The final mesh consisted of a combination of quadrilateral and triangular elements, with a characteristic element size of approximately 2 mm. This element size provided sufficient spatial resolution along the barrel profile while maintaining reasonable computational efficiency. The resulting finite element model contained a total of 5719 nodes and 4671 elements.

Linear elastic material properties corresponding to the selected barrel steel were assigned to the model. The material was assumed to be homogeneous and isotropic throughout the analysis.

The rear end of the barrel was constrained to represent its attachment to the breech mechanism. This boundary condition prevented rigid body motion while allowing the structural response of the barrel to be evaluated under the applied internal pressure loading.

The completed finite element model together with the applied boundary conditions is presented in Figure 10.

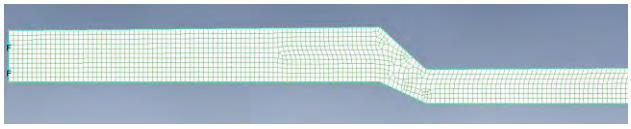

Figure 10. Finite element model with the applied boundary conditions.

3.3. Pressure loading

The pressure loading applied in the finite element model was derived directly from the optimized internal ballistic calculation. The pressure acting inside the barrel changes continuously as the projectile travels along the bore. Therefore, instead of applying a single uniform pressure, the loading was represented by a sequence of pressure distributions corresponding to successive projectile positions.

The pressure history obtained from the internal ballistic calculation was discretized into 40 loading steps, each representing a characteristic projectile position inside the barrel. For every loading step, the pressure was applied only to the portion of the barrel occupied by the propellant gases, while the remaining part of the barrel remained unloaded. This procedure reproduces the actual movement of the pressure front during the firing process.
To automate the preparation of the finite element model, custom BASIC scripts were developed within Simcenter Femap. The scripts automatically generated the pressure functions, created the corresponding Load Sets and assigned the pressure distributions to the appropriate barrel segments. The use of custom automation scripts enabled an efficient transfer of internal ballistic results into the finite element model, substantially reducing the time required for model preparation and minimizing the possibility of human error. [6]

Example of the sequence of pressure loading conditions applied during the analysis is schematically illustrated in Figure 11.

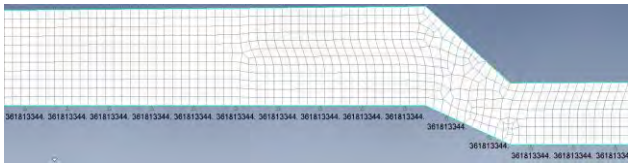

Figure 11. Example of the sequence of pressure loading conditions.

3.4. Numerical analysis

Following the definition of the finite element model and loading conditions, a MultiSet analysis was performed using Simcenter Nastran. Each loading step corresponded to one projectile position, allowing the evolution of the stress and deformation fields to be monitored throughout the firing process.

For every load case, the maximum equivalent (von Mises) stress and total displacement were extracted. These quantities were subsequently used to compare the structural response of the initial and optimized internal ballistic configurations. Also, an element and node ID of located maximum stress and displacement were also extracted.

The obtained results are presented and discussed in the following section.

4. RESULTS AND DISCUSSION

The structural response of the barrel was evaluated throughout the complete firing cycle using the sequential pressure loading obtained from the nominal and optimized internal ballistic calculation. For each loading step, the maximum equivalent (von Mises) stress and total displacement were extracted and analyzed as functions of both projectile position and time.

The variation of the maximum equivalent stress with projectile position and firing time is presented in Figures 12 and 13, respectively.

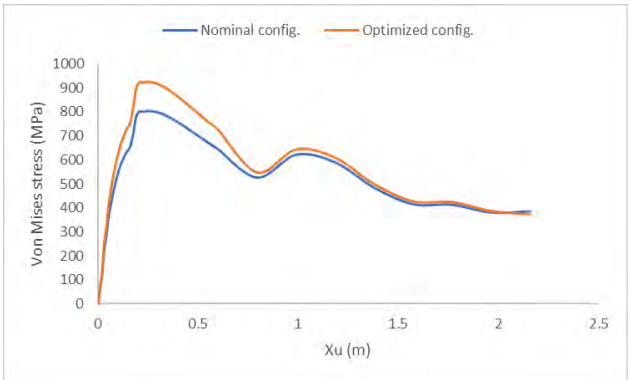

Figure 12. Von Mises stress-travel curve.

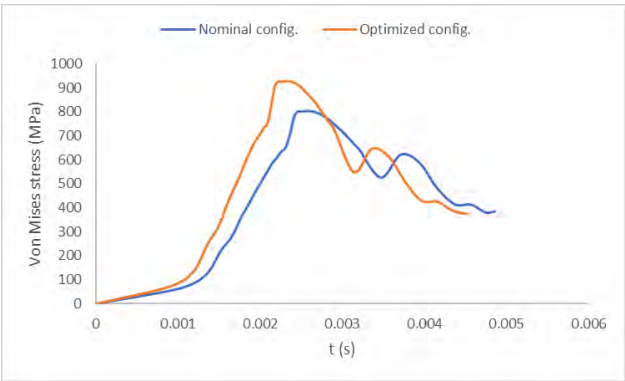

Figure 13. Von Mises stress-time curve.

Both figures demonstrate that the equivalent stress rapidly increases during the initial stage of projectile motion, reaches its maximum shortly after the pressure peak, and gradually decreases as the projectile approaches the muzzle. This behavior follows the evolution of the internal pressure generated during the firing process.

The variation of the total barrel displacement with projectile position and firing time is shown in Figures 14 and 15.

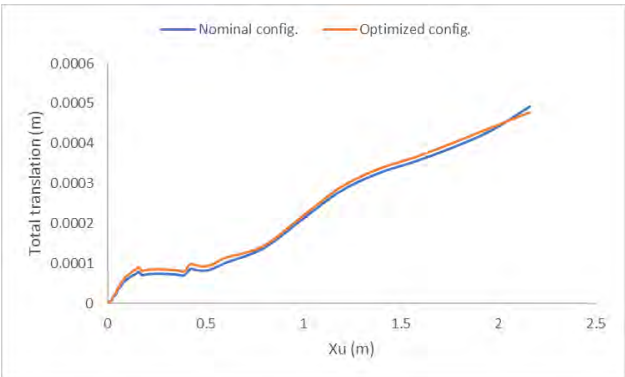

Figure 14. Total translation-travel curve.

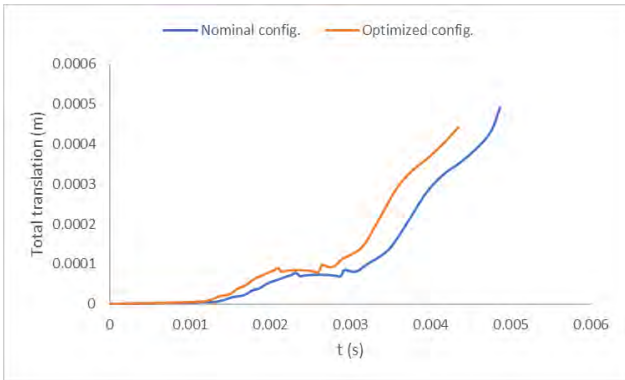

Figure 15. Total translation-time curve.

Unlike the equivalent stress, the total displacement exhibits a gradual increase during projectile travel, reaching its maximum near the muzzle. This behavior is expected since the loaded length of the barrel continuously increases as the projectile advances, resulting in progressively larger elastic deformation of the structure.

To evaluate the influence of the internal ballistic optimization, the maximum equivalent stresses obtained for the initial and optimized configurations were compared. The comparison is presented in table 4.

Table 4. Comparison of the maximum equivalent stress.

Configuration	Maximum equivalent stress (MPa)
Nominal	803.11
Optimized	926.75

The optimized internal ballistic configuration resulted in a increase of the maximum equivalent stress while simultaneously increasing the muzzle velocity. This indicates that the selected combination of ballistic parameters improves ballistic performance but decreases structural loading conditions of the barrel.

Although the calculated equivalent stresses reach relatively high values, the duration of the loading is extremely short. Therefore, the maximum equivalent stress was not used as the sole criterion for material selection based on the yield strength. Instead, the obtained stress distribution was primarily used to identify the most highly loaded regions of the barrel and to evaluate possible design improvements.

The numerical results indicates one characteristic region in which the maximum equivalent stresses repeatedly occurs during the firing cycle. The region is located near the transition between the chamber and the projectile guiding section. The repeated occurrence of stress maxima in this region suggests that further structural optimization could be achieved by modifying local geometric features, such as transition radii or wall thickness distribution. This region is shown in Figure 16.

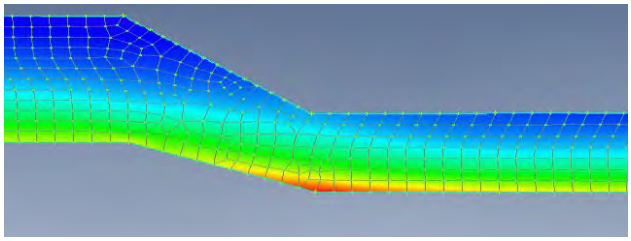

Figure 16. Repeated maximum stress occuring region.

From the manufacturing point of view, the obtained stress levels also indicate that additional strengthening methods may be considered in the most highly loaded portions of the barrel. Depending on the selected material and production technology, suitable solutions include local surface strengthening of the projectile guiding section, strengthening of a limited wall thickness, or the application of an autofrettage process in order to improve the fatigue resistance and operational life of the barrel.

The displacement results may also be useful during the design of the complete weapon system. Appropriate stiffening elements or barrel support arrangements may therefore be introduced to reduce deflection and improve the overall structural rigidity of the weapon.

Overall, the presented methodology demonstrates that coupling internal ballistic calculations with finite element analysis provides not only an assessment of barrel stresses and deformations but also valuable information for structural optimization and manufacturing process selection.

5. CONCLUSION

A methodology for the coupled internal ballistic and finite element analysis of a 30×165 mm automatic cannon barrel has been presented. The pressure distribution obtained from the internal ballistic calculation was transferred into a sequence of finite element loading conditions, enabling the structural response of the barrel to be evaluated throughout the firing cycle.

The parametric optimization of the internal ballistic model resulted in an increase in muzzle velocity, while the optimized pressure history provided realistic loading conditions for the finite element analysis.

The numerical analysis identified the evolution of equivalent stresses and barrel displacements and the most highly loaded regions. These results can be used to identify locations where additional strengthening methods, such as local surface treatment or autofrettage**,** may improve barrel service life.

The presented methodology demonstrates that coupling internal ballistic calculations with finite element analysis provides an efficient approach for the structural assessment and optimization of gun barrels, offering practical guidance for their design and further development.

Abstract: *The increasing demand for highly mobile specialized vehicles has encouraged the development of alternative drive concepts capable of improving mobility, reliability, and operational flexibility. Radial hydraulic motors represent a promising solution due to their favorable torque characteristics and efficient operation under demanding conditions. This paper investigates the potential application of radial hydraulic motors in heavy wheeled vehicle drive systems. The proposed concept is analyzed from the perspectives of traction performance, power distribution, and operational efficiency. Special consideration is given to vehicle operation in challenging terrain conditions where hydraulic drive systems may provide advantages over conventional mechanical transmissions.*

Keywords: *radial hydraulic motor, hydraulic transmission, heavy vehicles, off-road mobility, vehicle drive systems.*

1. INTRODUCTION

Modern heavy-duty military vehicles require high mobility, reliability, and survivability under severe off-road operating conditions. Overcoming harsh terrains and maintaining combat readiness under high thermal loads necessitate advanced drivetrain configurations. Consequently, developing high-performance propulsion architectures remains a critical research focus in modern military engineering [1].

Conventional mechanical transmissions offer high efficiency but suffer from structural complexity, substantial weight, and rigid torque distribution in multi-axle platforms. These limitations drive the investigation of alternative layouts. In modern vehicle design, individual in-wheel electric drives significantly improve traction control and maneuverability through independent torque distribution. However, while electric hub drives suit light passenger platforms, heavy combat vehicles operating under severe impact and continuous thermal loads require extreme power densities, making hydrostatic radial piston drives a promising alternative for heavy-duty applications [2, 3].

Hydrostatic systems transmit substantial power within compact dimensions, optimizing vehicle packaging and off-road adaptability. Comparative evaluations of electric, hydraulic, and pneumatic rotary actuators indicate that while pneumatic systems offer excellent environmental resilience, their lower torque-to-weight ratios make them unsuitable for high-inertia military platforms [3]. Among hydraulic solutions, multi-stroke radial piston motors remain highly promising due to their High-Torque Low-Speed (HTLS) characteristics, making them ideal for direct wheel drives requiring high traction capability and precise torque control [4 - 9].

The objective of this paper is to investigate radial piston hydraulic motors in heavy multi-axle drivetrains using a multi-domain simulation model developed in *Simcenter Amesim*. The scientific contribution of this work is the development of a mathematical framework for quantifying internal volumetric leakage and thermal loading under continuous gradient climbing conditions, providing design guidelines for future heavy tactical vehicle applications.

2. RADIAL HYDRAULIC MOTOR PRINCIPLE

The Radial Piston Motor presents a crucial actuating component within hydraulic systems and represents a prominent variant of low-speed, high-torque motors (Figure 1.). It finds widespread application in sectors such as national defense, metallurgy, and aerospace. In order to preserve the environment, hydraulic actuators are increasingly expected to exhibit attributes such as low noise, minimal pollution, and smooth operation [8, 9].

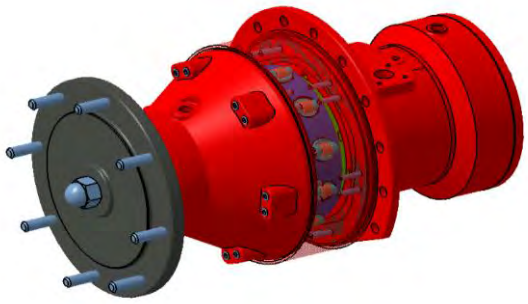

Figure 1. 3D model of Radial piston hydraulic motor

2.1. Construction and operating principle

A multi-stroke radial piston hydraulic motor features a compact and robust configuration designed to withstand high pressure spikes and harsh environmental conditions typical for heavy-duty military vehicles. It consists of the following key components (figure 2.) [10]:

- Cam-profile Stator: The stationary outer housing with an internal multi-lobe wavy profile. This component defines the stroke path and number of working cycles per revolution.
- Rotor (Cylinder Block): The rotating core containing radially arranged cylinder chambers. It is directly coupled to the wheel hub or output drive shaft via a heavy-duty spline.
- Piston Assemblies with Rollers: Reciprocating pistons housed within the rotor chambers. Each piston features a high-strength mechanical roller at its outer end, maintaining continuous contact with the stator profile to transmit the driving force.
- Flow Distribution Pair: The heavy-duty fluid commutation mechanism. It contains isolated internal passages that sequentially and accurately direct high-pressure oil to the cylinders and vent low-pressure spent oil back to the reservoir
- Output Drive Shaft: The heavy-duty shaft that extends outside the motor to drive the vehicle's wheel hub or sprocket.
- Motor Housing (Casing): The stationary outer housing with an internal multi-lobe wavy profile.

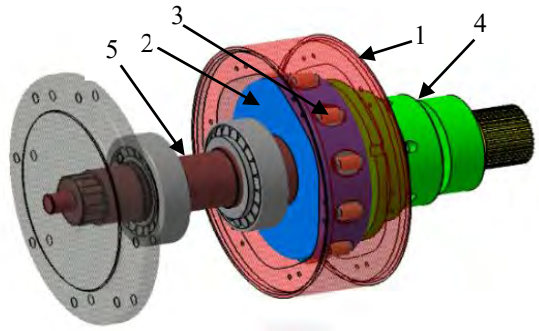

Figure 2. Key parts of radial hydraulic motor

The operational principle relies on converting fluid hydraulic energy into high mechanical output torque through cyclic reciprocating movement [10]:

- Inlet Phase (Working Stroke): Pressurized oil passes through the distribution pair (4) and enters the specific cylinder chamber. The high fluid pressure drives the piston (3) radially outward. As the piston roller forces its way down the inclined surface of the stator lobe (1), it yields a high tangential force, forcing the rotor (2) and the vehicle drive shaft (5) into rotation.
- Dead Centers: When the piston reaches its maximum outward displacement (Top Dead Center), the distribution slot isolates the chamber from the high-pressure line.
- Outlet Phase (Return Stroke): Guided by the continued rotation of the rotor, the descending stator profile mechanically pushes the piston radially inward. Concurrently, the distribution pair links the chamber to the low- pressure drainage network, discharging the oil to the reservoir.

The continuous repetition of these operating cycles generates a smooth rotational motion of the output shaft while maintaining high torque at low rotational speeds.

In the context of dynamic combat environments, understanding these micro-clearances is vital. The intense operating pressures within the piston-cylinder walls and across the sliding interface of the flow distribution pair create internal volumetric leakages. Mitigating these leakages is critical to preserving the volumetric efficiency and continuous traction of heavy- duty military drivetrains [3, 10, 11].

2.2. Main characteristics and comparison with conventional drivetrains

Radial piston hydraulic motors are inherently classified as HTLS displacement machines. Due to their multi-stroke architecture where each piston executes multiple working cycles per single rotor revolution, these units develop exceptionally high displacement volumes within a remarkably compact envelope [3]. This design delivers ripple-free, stable torque even at near-zero speeds, which represents a critical advantage for heavy military platforms navigating cross-country obstacles. Furthermore, their outstanding starting torque efficiency

ensures that fully loaded armored vehicles can initiate motion or resume climbing on steep, unstable inclines without any dangerous rollback [4, 6].

When integrated into heavy-duty tactical propulsion systems, radial piston configurations offer distinct structural and operational advantages over conventional mechanical and axial hydraulic alternatives. Standard mechanical drivetrains rely on complex networks of rigid drive shafts, multi-speed transfer cases, and heavy differentials. Implementing a radial hydrostatic drive eliminates these components entirely by utilizing an in-wheel hub-motor configuration. This architectural shift significantly reduces the structural weight of the platform, lowers its overall silhouette, and dramatically increases ground clearance to enhance off-road mobility [4, 6].

When compared to axial piston motors, which are fundamentally high-speed, low-torque devices, the radial alternative proves far more suitable for direct wheel drives. Driving a heavy armored vehicle wheel with an axial motor necessitates the integration of bulky planetary reduction gearboxes to multiply torque. Conversely, radial piston motors drive the wheel hub directly without mechanical gear reduction. This reduction in the total number of moving parts lowers mechanical friction losses, simplifies maintenance, and minimizes the vehicle's vulnerability to ballistic damage in combat environments [4, 6].

3. APPLICATION OF RADIAL HYDRAULIC MOTORS IN HEAVY MILITARY VEHICLES

To meet the extreme mobility demands of a heavy 6x6 tactical vehicle, a closed-loop hydrostatic drivetrain architecture is proposed. This system completely replaces the traditional mechanical gearbox, drive shafts, and differentials. The operational concept and fluid routing are illustrated in the system block diagram (Figure 3) [7, 12].

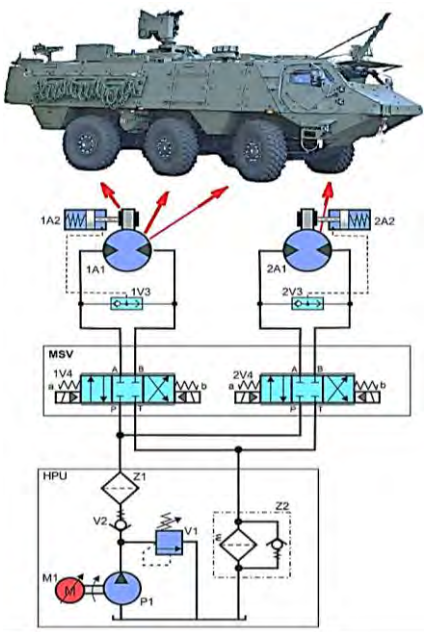

Figure 3. – Schematic diagram of conventional hydraulic propulsion system of the military vehicle

The schematic configuration of the proposed multi-wheeled 6x6 hydrostatic drive system consists of three main sub-assemblies: the Hydraulic Power Unit (HPU), the Main Valve Block (MSV), and the dynamic propulsion-braking hub stations. The fluid power is generated by the engine-driven pump P1, which is protected against overpressure transients by the safety relief valve V1. High-pressure filtration is handled via filter Z1, while return-line fluid conditioning and thermal management are achieved through the bypass-equipped radiator block Z2. Fluid flow rate and direction are independently regulated by two proportional directional valves, 1V4 and 2V4, embedded in the MSV block. Valve 1V4 directly controls the fluid delivery to the left-side radial piston hydraulic motor 1A1, which simultaneously drives all three left-side wheels through parallel porting lines. Conversely, valve 2V4 governs the right-side radial piston motor 2A1, enabling asymmetric flow adjustments for precise skid-steering maneuvers under tactical off-road scenarios [7].

3.1. Mathematical model

To evaluate the conceptual performance of a high-torque radial piston hydraulic motor for heavy-duty military operations, a comprehensive mathematical model is established. This model defines the relationship between hydraulic input energy, internal mechanical and volumetric losses, and the dynamic output performance required to propel a heavy military vehicle under severe off-road conditions.

The rotational speed of the radial hydraulic motor is directly governed by the volumetric flow rate of the hydraulic fluid supplied to its cylinders.
The theoretical flow rate Q_{th} [m³ s^{-1}], which assumes zero leakage and ideal geometry, is defined as [10, 13]:

$$Q_{th} = V_d \cdot n \tag{1}$$

Where:

- V_d is the displacement of the radial motor [m³ rev^{-1}];
- n is the rotational speed of the motor shaft [rps].

In heavy-duty military applications, high operating pressures lead to internal fluid bypass across the piston-cylinder clearances and the distribution valve. Therefore, the actual flow rate Q_{act} required by the motor is expressed as [13]:

$$Q_{act} = Q_{th} + Q_{leak} \tag{2}$$

Where Q_{leak} represents the internal volumetric leakage flow rate [m³ s^{-1}].

Radial piston motors are categorized as Low-Speed High-Torque (LSHT) drives, making them ideal for overcoming steep slopes and rough terrain.

The ideal or theoretical torque T_{th} (Nm) generated by the motor depends strictly on its geometric displacement and the differential pressure [10, 13]:

$$T_{th} = \frac{V_d \Delta p}{2\pi} \quad (3)$$

Where:

$$\Delta p = p_{in} - p_{out} \quad (4)$$

is the pressure drop across the motor (Pa).

The actual torque T_{act}delivered to the vehicle's wheel or sprocket is lower than the theoretical value due to mechanical friction between moving components (pistons, rollers, and cam lobes). It is calculated as [13]:

$$T_{act} = T_{th} - T_{loss} = T_{th}\eta_{hm} \quad (5)$$

Where:

- T_{loss} is the total friction torque loss (Nm);
- η_{hm} is the hydro-mechanical efficiency of the motor.

The conversion of hydraulic power into mechanical power determines the overall tractive capability of the vehicle.

The hydraulic input power P_{hyd} (W) delivered by the system pump is given by [13]:

$$P_{hyd} = Q_{act}\,\Delta p \quad (6)$$

The effective mechanical power P_{mech} (W) available at the output shaft to drive the vehicle is defined as [13]:

$$P_{mech} = T_{act}\omega = T_{act}\frac{2\pi n_{rpm}}{60} \quad (7)$$

Where:

- ω is the angular velocity of the shaft (rad/s);
- n_{rpm} is the shaft speed in revolutions per minute (rpm).

Military vehicles operate under extreme temperature fluctuations (from −30 °C to +50 °C), which drastically alters oil viscosity and loss characteristics.

The internal leakage flow Q_{leak} can be mathematically modeled using the Wilson-based hydraulic loss approach [13]:

$$Q_{leak} = \frac{C_s V_d \Delta p}{\mu} \quad (8)$$

Where:

- C_s is the dimensionless laminar leakage coefficient of the radial motor;
- μ is the dynamic viscosity of the hydraulic fluid (Pa·s).

The volumetric efficiency η_v is then formulated as [13]:

$$\eta_v = \frac{Q_{th}}{Q_{act}} = 1 - \frac{Q_{leak}}{Q_{act}} \quad (9)$$

The torque loss T_{loss} comprises both Coulomb (constant) friction and viscous fluid shear friction within the motor housing [13]:

$$T_{loss} = (C_f V_d \Delta p) + (C_v V_d \mu\omega) \quad (10)$$

Where:

- C_f is the mechanical friction coefficient;
- C_v is the viscous drag coefficient.

Consequently, the total efficiency of the hydraulic drive η_t is expressed as [13]:

$$\eta_t = \eta_v \eta_{hm} = \frac{P_{mech}}{P_{hyd}} \quad (11)$$

4. SIMULATION MODEL AND DISCUSSION

To evaluate the hydrostatic powertrain concept for the 6x6 heavy-duty tactical vehicle, a comprehensive multi-domain simulation model was established within the *Simcenter Amesim* environment The interconnected structural architecture of this simulation framework is schematically detailed in Figure 4.

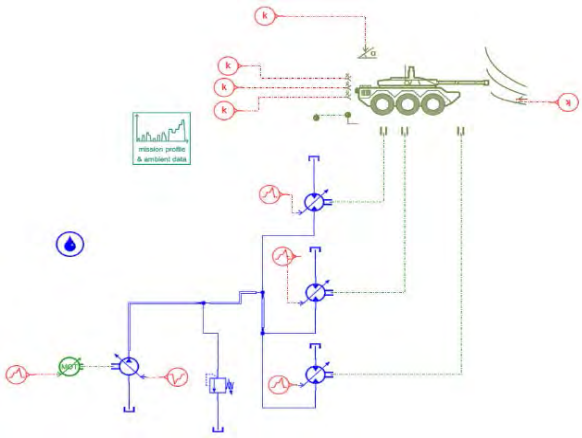

Figure 4. 6x6 concept combat vehicle drive diagram

The model couples the high-pressure fluid power network directly with the longitudinal vehicle dynamics of the 3-axle platform. The hydraulic propulsion layer consists of the primary pump unit supplying pressurized fluid to three parallel-connected in-wheel radial piston hydraulic motors, which model one complete side of the tactical vehicle. The advanced nature of this multi-domain model lies in its capacity to incorporate dynamic external environment boundaries (denoted by coefficient blocks k), which actively process terrain inclinations, aerodynamic drag, and variable tire-soil rolling resistance. The baseline parameters used in this simulation framework are summarized in Table 1 [12, 14, 15]

Table 1. Operational parameters of the 6x6 hydrostatic powertrain model

Quantity	Value
Total vehicle mass	25000 kg
Tire Specification	14R20
Prime Mover Speed	2000 rpm
Pump Displacement	600 [cm^3 rev^{-1}]
In-Wheel Motors Displacement	975 [cm^3 rev^{-1}]
Rolling resistance	0.02
Fluid density	850 [kg m^{-3}]
Dynamic viscosity	51 [cP]
Road slope	0 %
Wind velocity	10 [m s^{-1}]

The dynamic velocity response of the 25-tonne combat vehicle operating under a 10 [m s^{-1}] headwind profile is illustrated in Figure 5.

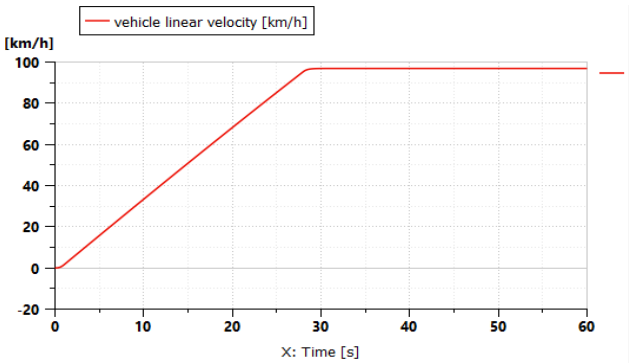

Figure 5. Diagram of vehicle velocity in 60s operational cycle

The simulated transient kinematic profile comprises three operational phases:

- System Activation (0–1 s): A 1-second response lag occurs due to the engine ramp-up to 2000 (rpm) and the pilot pressure buildup required to disengage the Spring-Applied Hydraulic-Released (SAHR) hub brakes.
- Linear Acceleration (1–22 s): Following brake release, the large 975 [cm^3 rev^{-1}] displacement of the in-wheel motors generates high torque, overcoming the static inertia of the 25000 (kg) chassis.
- Steady-State Dash (22–60 s): The vehicle reaches a maximum velocity of 97 km/h, establishing full hydrostatic equilibrium where wheel torque matches aerodynamic drag and rolling resistance.

The dynamic torque requirement at the wheel hub (Port 3) throughout the 60-second operational cycle is quantified in Figure 6.

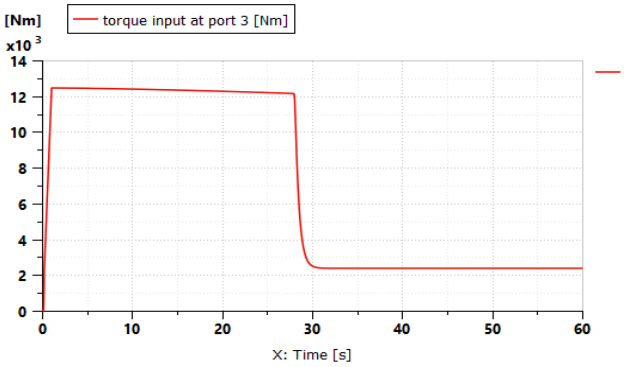

Figure 6. Simulated torque input profile at the axle

The torque curve validates the powertrain's capacity to sustain heavy-duty tactical movement:

- Inertial Launch (0–1 s): Drive torque peaks instantly at 12500 (Nm) to overcome the static inertia of the 25000 (kg) chassis and terrain resistance.
- Sustained Acceleration (1–28 s): Torque remains at an elevated plateau, shifting from 12500 (Nm) to 12200 (Nm), confirming maximum system pressure drop across the in-wheel motors.
- Steady-State Relaxation (28–60 s): At a cruise velocity of 97 km/h, torque drops rapidly between 28–30 s, settling at a 2400 (Nm) baseline to counteract rolling resistance and the 10 [m s^{-1}] wind drag.

To assess operational limitations under severe conditions, a separate simulation evaluates vehicle traction on a steep 15° road gradient (26.8% slope). To ensure a rigorous comparison, all hardware and fluid parameters remain identical to Table 1. This analysis focuses on how continuous gravitational loading alters drivetrain kinematics, pressure profiles, and volumetric leakage. Results are presented in Figures 7 and 8.

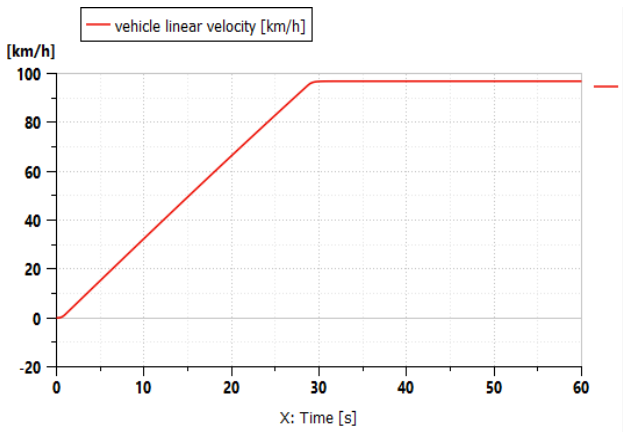

Figure 7. Diagram of vehicle velocity under the slope of 15 °

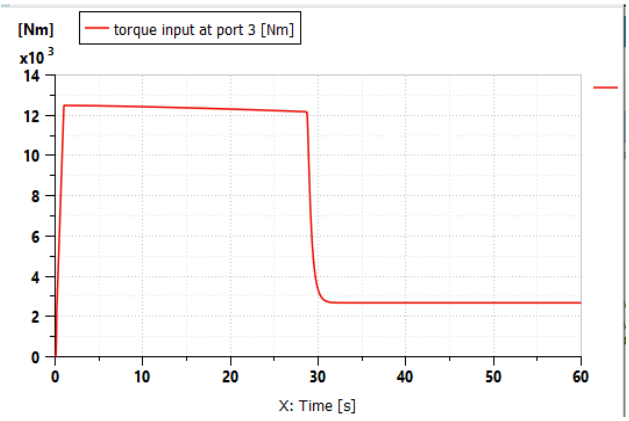

Figure 8. Diagram of simulated axle torque under the slope of 15 °

Although the drivetrain achieves 97 km/h on the 15° slope, grade resistance extends the acceleration phase and shifts hydrostatic equilibrium from 22 s to 30 s. This prolonged peak-pressure window forces fluid through the micro-clearances of the flow distribution pair and piston-cylinder walls, driving the volumetric leakage Q_{leak} to a higher plateau than on flat terrain. While the fluid dynamic viscosity of 51 [cP] at 40 °C prevents a total efficiency collapse, continuous high-load shearing generates severe thermal loads. This demonstrates that for multi-axle armored platforms executing tactical maneuvers on steep inclines, the flow distribution pair clearances must be precisely optimized to mitigate pressure-induced volumetric losses and prevent thermal thinning.

From a fluid power perspective, the operational discrepancy between flat terrain and the 15° slope highlights the volumetric allocation dynamics within the hydrostatic loop. On flat terrain, the main hydraulic pump's delivery flow rate rapidly satisfies the cumulative volumetric demand of the three parallel-connected wheel motors, reaching full flow equilibrium at 22 s. Conversely, during the steep climb, sustained gravitational resistance forces the wheel motors to operate under peak pressure drops to maintain the necessary torque output. This critical shift alters the flow rate distribution: while the main pump operates at a regulated displacement providing a baseline input flow, the high-pressure differential across the wheel motors drives fluid through internal clearances. Consequently, the individual flow rate utilized for effective mechanical work decreases due to the elevated volumetric leakage Q_{leak}. This behavior indicates that the efficiency bottleneck under severe thermal and mechanical loads is not the raw volumetric capacity of the main pump, but rather the localized leakage control within the flow distribution pairs of the in-wheel radial piston units.

5. CONCLUSION

This paper presented a conceptual analysis of an in-wheel hydrostatic drivetrain driven by multi-stroke radial piston motors for a 25-tonne 6×6 combat vehicle. The multi-domain simulation demonstrated that the proposed drive can provide sufficient tractive effort, achieving a maximum velocity of 97 km/h. Comparative analysis revealed that a steep 15-degree road inclination proportionally increases the system response time and shifts the stabilization threshold from the 22nd to the 30th second. This prolonged operation under maximum pressure conditions increases the significance of internal volumetric leakage within the flow distribution pairs. Although the dynamic fluid viscosity of 51 cP at 40 °C prevents a complete efficiency degradation, the sustained high-pressure gradient during severe slope operation generates considerable thermal loads. These findings highlight that precise CFD analysis and experimental optimization of flow distribution pair clearances are essential for improving the efficiency and reliability of advanced tactical wheeled platforms. Future work will focus on structural optimization of these critical micro-clearances and subsequent experimental validation using a dedicated hydraulic test rig.

PREDICTION ALGORITHM FOR THE IMPACT POINT PROJECTILE TRAJECTORY USED FOR DETERMINING CORRECTIVE SHOOTING PROCEDURE ELEMENTS

DRAGOSLAV R. PETROVIĆ
Retired Colonel, former chief of Ballistic department MIT,Belgrade, Jurija Gagarina 146/50, 11070 N. Beograd,
drdrpetrovic@gmail.com

Abstract: *The lack (frequently) of meteo-ballistic perturbations forces the operators of Artillery fire (cannon, howitzer) to use the so-called Corrective shooting procedure. It involves firing the first projectile, observing the place of its impact in relation to the target, and correcting the fire elements (aiming) for the second projectile. The minimum time of this process is as long as the flight of the projectile, increased by time of observed data transfer to fire position. Multiple reduction of this time can be achieved by knowing the position data of the first projectile on the ascending part of its trajectory. An algorithm for predicting impact (terminal) point of artillery projectile trajectory is given. It is based on trajectory parameters deviation related to Nominal trajectory, thus predicting range deviations without necessity real range observation after final flight first projectile.*

Key words: *Software, Ballistic Module extension, Artillery shooting*

1. INTRODUCTION

The paper presents method and the procedure for predicting the location of the projectile's fall related to the distant target from a gun. It is based on the measurement of projectile position in space at the initial part of the trajectory, before it reaches the height of the vertex Y_s – *Figure 1.*

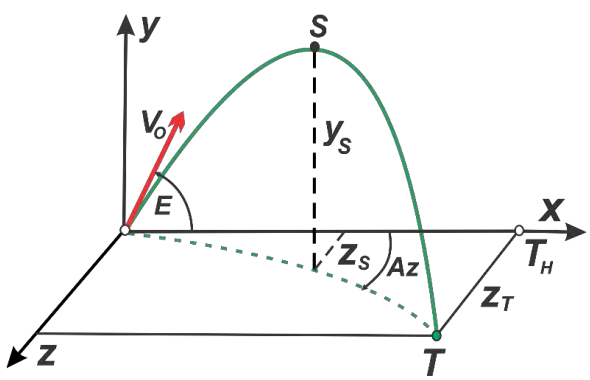

Figure 1. Projectile trajectory in space

For the desired distance of the gun to the target, according to the Ballistic Module -***BM*** -$[1,2,3]$, can be calculated required fire elements (***fe***) - elevation angle E in the vertical plane (x,y) and direction angle A_Z in the horizontal plane (x,z) -*Figure 1*. The practice in artillery units is to fire one projectile, observe the location of its fall and correct the initial ***fe***. Since the flight time of a long-range projectile is long by today's standards, and the problem is the observation and transmission of observed fall values, this method seems outdated and difficult to apply (deadly dangerous!). The predicted distance serves for correction initial (E , A_Z) as if it had been observed.

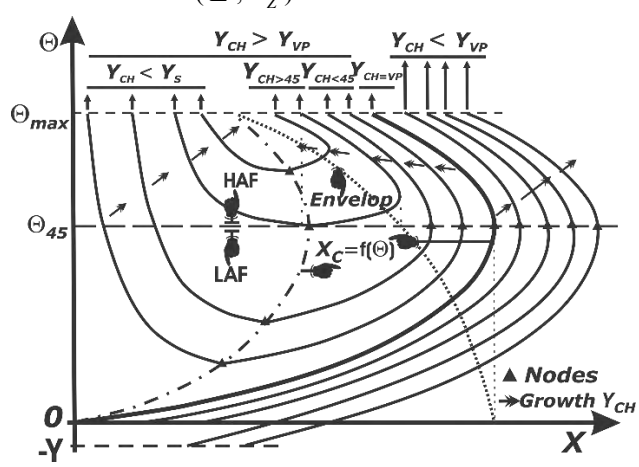

Figure 2. Dependance distance from elevation

For different relations between the altitudes of the gun Y_{VP} and the target Y_{CH} , relations $X, E(\theta)$ are given in the graphs, *Figure 2*. Elements (E , A_Z) can in principle be determined for meteo-ballistic conditions (***mb***), normal - nominal or actual. In Firing Tables - ***FT***

Corresponding author: D. Petrović;
E-mail: drdrpetrovic@gmail.com

DOI: 10.5937/OTEH26040P

are given trajectory parameters that have been designed for nominal ***mb***. In field conditions, it is difficult (nearly impossible) to find ***fe*** for current ***mb*** that can be used in ***BM***. This paper deals with overcoming the difficulty of this type, which enables calculation the prediction of the location where the projectile will fall related to the gun, without need to be observed fall and transferred to the gun position. Physical projectile is replaced by a mathematical model (***mm***). In ***mm*** are incorporated forces and moments acting on the projectile in flight.
The model is actually a system of differential equations -***de***, whose numerical solution gives parameters the projectile trajectory. With the replacement of large analog computers with digital ones, the era of digital miniaturization began, which is ongoing.

In this paper, it is assumed that complex mathematical operations can be performed on the projectile itself (hardware located in the body of the fuze on the projectile). For the numerical solution of ***de***, in addition to forces and moments, initial conditions and parameters of the environment - the atmosphere in which the projectile is moving - are required.

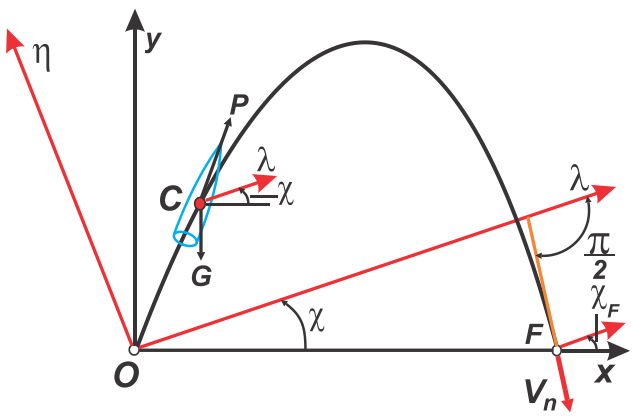

Figure 3. Inclined coordinate system λ, η

The initial conditions are called ballistic parameters, and the parameters of the atmospheric characteristics are called meteorological parameters, all together - ***mb***. When it comes to a ballistic rocket, a procedure similar to the prediction proposed here is carried out on the initial part of the trajectory, *called introduction time into the compensation integrator* -$[4,5,6]$. This procedure is based on the continuous minimization of the introduced ballistic function. For this reason, an inclined coordinate system λ, η of the longitudinal axis is used -*Figure 3*.

The angle of this axis χ is equal to the $tg(\chi_F)$ at the point of impact. Trajectory elements are calculated as if the rocket flight via atmosphere on the passive part of the trajectory is in vacuum. After ending minimization of the ballistic function, the rocket motor is turned off.

2. PROJECTILE DISTANCE PREDICTION METHOD

The flight of the projectile ends by falling in the surroundings of the target. It is required projectile to hit the target, which rarely happens because each hit is a random variable when it comes to an unguided projectile in consideration. The cause is the deviation of the actual trajectory from the nominal one – *Figure 4*, and the reason is the factors called disturbances, which are different from the nominal ones, on the basis of which the elements of the trajectory (E, A_Z) were calculated.

The idea on which the method of predicting the distance until the projectile falls in target surroundings the is based to measuring the parameters of the current trajectory. How to use obtained results and avoid certain difficulties and which mathematical operations should be performed, follows

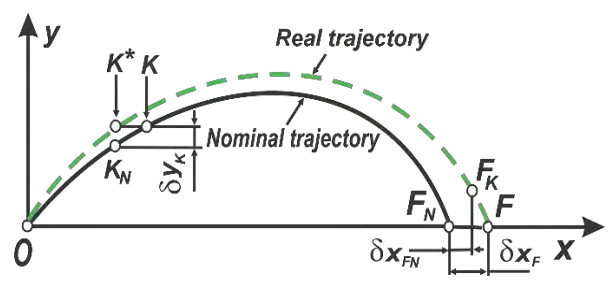

Figure 4. Nominal and disturbed trajectory

Let nominal and disturbed trajectory be described by the following differential equations:

$$\frac{dy_i^N}{dt} = f_i^N\left(y_i^N, z_j^N\right) \text{.....(1)}$$

$$\frac{dy_i^N}{dt} = f_i^N\left(y_i^N, z_j^N\right) \text{.....(2)}$$

where values y_i are the flight parameters, and z_j $(i = 1,...,n;\ j = 1,...,m)$ are the forces and moments acting on the projectile, as well as ***mb*** are the conditions in which the flight takes place. Let the solution of equation (1) $y_i^N = y_i^N(t)$ be obtained for the initial conditions y_i^0 given in point O- *Figure 3*. Let's assume that the real values (marked with *), y_i^* called perturbed, are in the form:

$$y_i^* = y_i^N + \Delta y_i;\ \ i = 1,...,n$$

$$z_j^* = z_j^N + \Delta z_j;\ \ j = 1,...,m \ \ldots\ldots\ldots\ldots\ldots\ldots(3)$$

With (3) entered in (1,2) we get

$$\frac{d\Delta y_i}{dt} = f_i^*\left(y_i^N + \Delta y_i, z_j^N + \Delta z_j\right) -$$

$$-f_i^N\left(y_i^N, z_j^N\right) \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

If the above equations are expanded into a Taylor series, we get

$$\frac{d\Delta y_i}{dt} = \sum_{i=1}^{n} p_{i,j}(t)\Delta y_i + \sum_{j=1}^{m} \pi_{i,j}\Delta z_j +$$

$$+f_i\ (t) + R_i\left(t, \Delta y_i, \Delta z_i\right) 1,2,3\ldots\ldots\ldots\ldots\ldots(5)$$

In (5), the sum R_i are terms which order is greater than the first, and

$$p_{i,j} = \frac{\partial f_i^*}{\partial y_j}\Big|\Delta y_j, \Delta z_j = 0$$

$$\pi_{i,j} = \frac{\partial f_i^*}{\partial z_j}\Big|\Delta y_j, \Delta z_j = 0 \qquad \ldots\ldots\ldots\ldots(6)$$

$$\Delta f_i = f_i^*\left(y_i^N, z_j^N\right) - f_i^N\left(y_i^N, z_j^N\right)$$

By discarding R_i from (5), the equation is obtained

$$\frac{d\Delta y_i}{dt} = \sum_{j=1}^{m} p_{i,j}(t)\Delta y_j + \sum_{j=1}^{m} \pi_{i,j}\Delta z_j +$$

$$+\Delta f_i\ (t)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

called the system equation of disturbed motion of the first approximation.

This system is (still!) used in consideration of the stability of the general movement with the condition that the disturbances are of small in size, which change during the flight, and in the case of a stable system tend to be zero. If we look at *Figure 4*, can be seen that at the altitude $Y = Y_K$ of the trajectory, the horizontal distance is equal to $K^* - K$. It grows during movement, so that it becomes the largest at the zero horizon $Y = Y_F = 0$, $Y = Y_F = 0$ whose knowledge is of key interest for us.

If the solutions ***de*** (7) were found numerically up to the time t_{F_N} obtained in the nominal ***mb***, the values $\delta x_K, \delta y_K$ would be obtained (*Figure 4*). By connecting the points F_K, F, a straight line is obtained $F_K - F$ whose angle is θ_F. Change of distance in the horizon with correction due to the altitude δy_{F_K} is:

$$\delta x_F = \delta x_{F_K} + ctg\,|\,\theta_F\,|\,\delta y_{F_K} \ \ldots\ldots\ldots\ldots\ldots\ldots(8)$$

The presented procedure is of optional use because we are able to find distances $K^* - K$ on the basis of measuring the position of the projectile, but we have no way to determine the causes that led to these differences in order to calculate according to ***de*** the parameters of the disturbed trajectory from point K^* to point F - *Figure 4*.

2.1 The term of 'layer weights'

For the sake of easier consideration of the effect of the parameters of meteorological elements -(***me***) on the flight of the projectile -[7,8], let the height of the vertex of the trajectory Y_s be divided into two layers of equal thickness - '**1**' and '**2**', *Figure 5*.

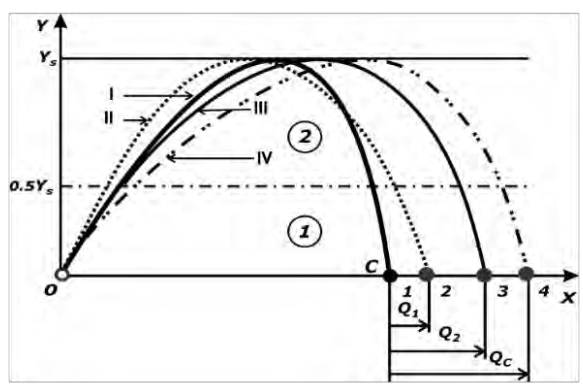

Figure 5. Meteorological elements -(**me**) effect

If ***me***, let's assume that it is the longitudinal wind W_X =0, -nominal, then the trajectory is of the form '**I**' and coincides with the calculated one, so the projectile will be at point '**1**' (**C**) in the horizon. If ***me*** still remain nominal, and W_X first change by 10 units in layer '**1**' - path '**II**', and then in layer '**2**' - path '**III**', the projectile will be at point '**2**' and '**3**'. It can be seen from *Figure 1*.

that the distances Q_1 and Q_2 from point '**1**' (**C**) are not the same because ***me*** are not the same in layers '**1**' and '**2**' either, and this is because their influence in the layers is different. In the event that W_X of 10 units acts simultaneously in layers '**1**' and '**2**' - trajectory '**IV**', the projectile will be at point '**4**' and will be the distance Q_c from point '**1**'. The change in distance Q_c by its numerical value corresponds to the differential coefficient for W_X or correction of the distance due to W_X given in ***FT***, so it will be

$$Q_c = \Delta X_{\mu_1} + \Delta X_{\mu_2} \quad \text{.....(9)}$$

where the values mean: Q_c -deviation of the projectile trajectory in the horizon from point '**1**' (**C**) due to constant wind (called ballistic) acting in both layers, i.e. on whole trajectory; -distance $\Delta X_{\mu_1}, \Delta X_{\mu_2}$ deviations actual ***me*** as for Q_1, Q_2.

Trajectory vertex in principle can be divided into '*n*' layers and consider the impact W_X (as well virtual temperature τ -*Figure 6.* and side wind W_Z), in the same order as for two layers. Then the deviations of the trajectory from the point '**1**' (**C**) would be $Q_1, Q_2, ..., Q_n$ and at the same time $Q_1 \neq Q_2, ..., Q_{n-1} \neq Q_n$.

Sum of the individual deviations gives in the case of a linear influence (in reality it is approximately linear):

$$\sum_{i=1}^{n} Q_i = Q_c \quad \text{.....(10)}$$

Dividing (10) by Q_c yields

$$\sum_{i=1}^{n} \frac{Q_i}{Q_c} = 1 \quad \text{.....(11)}$$

The rations Q_i / Q_c are called "layer weights" and are signed with q_i. The sum of the "weight layers" is equal to one:

$$\sum_{i=1}^{n} q_i = 1 \quad \text{.....(12)}$$

The same conclusion is valid to the "layer weights" of temperature τ and side wind W_Z.

2.2 Weight function

Let the sum of the 'weights layers' q_i from the horizon Y_i to some altitude be denoted with r_i.

Then it is:

For the first layer $r_1 = q_1$;

For the second layer

$$r_2 = q_1 + q_2 = r_1 + q_2 \quad \text{.....(13)}$$

For the it'h and n'th layers $r_i = r_{i-1} + q_i$; $r = r_n = r_{n-1} + q_n$, and the sum of all r_i is:

$$r_n = \sum_{i=1}^{n} q_i = 1 \quad \text{.....(14)}$$

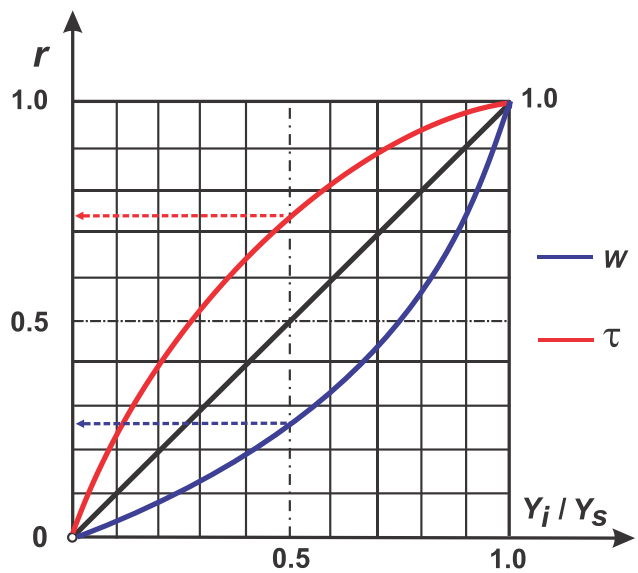

Figure 6. Graph of the 'weight function'

If the obtained r_i values are applied to the graph as a function of the height ratio Y_i / Y_s, where Y_s is trajectory vertex, and Y_i the altitude is from the horizon to the upper limit of the layer, a graph of the weight function is obtained - *Figure 6.*

When the graph of the 'weight function' is available, it can be used to find the weight of a layer such as

$$q_i = r_{Yi} - r_{Yi-1} \quad \text{.....(15)}$$

Where: - q_i is the 'weight' of the layer between Y_i and Y_{i-1}, and r_{Yi}, r_{Yi-1} are numerical values of the 'weight

functions' for the ratios of the altitudes $(0-Y_i)/Y_s$ and $(0-Y_{i-1})/Y_s$.

From *Figure 4*, it can be seen that for $Y_i/Y_s = 0.5$-up to half the trajectory vertex Y_s, the influence of constant (ballistic) wind is about 0.27% of the total effect on the entire trajectory, while for temperature it is about 0.73%. These numerous amounts are obtained for a specific projectile and are not the same for each other, but the qualitative result is similar. It is of key importance when it comes to unguided projectiles: - the influence of temperature (virtual) disturbances is more significant in the ground layers $(0-Y_i)$ than the influence of $(Y_i - Y_s)$, and the opposite is true for the influence of the longitudinal wind W_X. Figure 6. serve as an orientation which ***me*** to choose in which period of time - season, although the effect of the others is cumulative.

2.3 Predicting procedure

The procedure for predicting location where the projectile will fall is as follows:

1. For $(W_X)_{10}$-10 units, the elements of the trajectory to the altitude $Y_{K*=K}$ are calculated, the length $K*-K=\delta_{10}$ is obtained;

2. Since nominal X_K is known and too measured distance X_{K*}, difference is signed as δ_X;

3. The required wind speed W_X is obtained (as well virtual temperature τ and side wind W_Z) from the relation:

$$\frac{\delta_X}{\delta_{10}} = \frac{W_X}{(W_X)_{10}}; W_X = \frac{\delta_X}{\delta_{10}}(W_X)_{10} \quad \text{.....(16)}$$

With determined actual W_X according to (16), by chosen 6-DOF can be calculated actual trajectory parameters. Six degrees of freedom (6-DOF) -[2] is used for long-range trajectories of spin-stabilized projectiles via atmospheric flight to final impact point. Trajectory calculation ought to be performed by 6-DOF ***de*** from $0-F$ -*Figure 4,5*. The 6-DOF ***de*** model was carefully selected for these purposes - [9,10], modified existing -[2] according to -[11], and replaced software of the existing ***BM***.

3. VERIFICATION VALIDITY OF PREDICTION METHOD

In principle, model verification is very simple. The measured numerical values at impact point are simply compared with predicted. If the differences are within acceptable limits, the method is adequate.

Picture 1. Fire correction sonde

The reason that this phase was not completed is the finished design of the hardware placed in the projectile fuze - *Picture 1*.

This device is identical in shape and dimensions to the fuze and is called a *fire correction sonde*. The developing of test equipment for work sonde simulation is to come, and then follow testing by shooting at the proving ground.

It is planned that the description of the hardware and other devices accompanying it will be given in a separate article, which is currently being developed. By carefully observing the sonde, two colors can be observed. The darker one refers to the metal part, and the gray layer on the metal for antenna purposes.

4. CONCLUSIONS

Long time before and nowadays in Artillery fire (gun, howitzer) with spin stabilized projectiles is in use the so-called Corrective shooting procedure. It is given new method based on firing first projectile, without classical

observing its location point of impact in relation to the target. Further follow as usually correcting initial fire elements (aiming) for the second projectile.

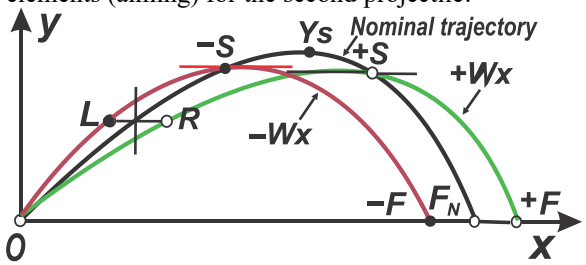

Figure 7. Real trajectories relations

Problem illustrations in question frequently don't exhibit real state of affair nature (*Figure 4*. -literature!). Real state as for relations nominal and disturbed trajectories is exhibited on *Figure 7*. Looking at it can be noticed points $\pm S$ of intersection real trajectories with nominal. Horizontal differences as are "L" or "R" are zero values at it, and developed software for prediction method recognize region where distances "L" - "R" can be used or not and how -[7,8]. Importance of this method is not visible at glance in full scope. One part is explicit, but other, very important as for benefit, is not. Main goal was eliminating long time flight projectile to the target and dangerous long time staying on the fire position. Benefit by the way is that atmospheric parameters used for predicting impact point can be used as knowledge of atmospheric state as for wind, or temperature. The paper presents method and the procedure for predicting the location of the projectile's impact point related to the distant target from a gun. It is based on the measurement of projectile position in space at the initial part of the trajectory, before it reaches the trajectory vertex. Key factor on which method is based is horizontal distance K^*-K - *Figure 4 ("L"-"R" Figure -7!).* By inspection, it is found out ballistic wind value W_X that disturb nominal trajectory at the altitude $Y = Y_K$. After that phase, by ***dj*** renewed ***BM*** are calculated parameters of disturbed trajectory different from nominal one.

Abstract: *Polymer-bonded explosives (PBX) are widely recognized as reduced-sensitivity energetic materials with improved safety characteristics and satisfactory stability during prolonged adequate storage. However, despite their favorable stability characteristics, the influence of different climatic conditions on their long-term behavior has not been sufficiently investigated, especially when it comes to complex multi-component formulations, like thermobaric (TBX). Systematic studies investigating the combined effects of temperature, humidity, and/or corrosive marine atmospheres on stability of these formulations remain limited. In this paper, multi-component PBX based on hydroxyl-terminated polybutadiene-based binder, containing octogen as the energetic filler, ammonium perchlorate as oxidizer and aluminum and magnesium metal powders were examined. The samples were subjected to controlled environmental conditioning designed to simulate three distinct climatic regimes: continental climate conditions, elevated temperature and humidity conditions, and Mediterranean climate conditions involving exposure to salt-mist to reproduce a marine corrosive atmosphere. The treated samples were evaluated using the vacuum stability test STANAG 4556 procedure and by heat flow calorimetry. The combined application of standardized stability testing and sensitive thermal analysis enabled a comprehensive assessment of climate-induced changes in PBX behavior. The results provide insight into the stability-related responses of PBX under diverse environmental stresses and contribute to a better understanding of their performance and reliability in different climatic deployment scenarios.*

Keywords: *PBX, Vacuum Stability Test, Heat flow calorimetry, environmental conditioning*

1. INTRODUCTION

Cast-cured polymer bonded explosives (PBX) have attracted significant interest due to their reduced sensitivity compared to conventional TNT-based formulations and due to their broad range of detonation characteristics [1]. The main benefits of PBX include significant mechanical strength, increased filling density, reduced sensitivity during handling and storage, good thermal stability and the capability to modulate detonation velocity according to requirements [2]. The potential to integrate metal powders into compositions to produce a thermobaric effect, specifically generating a fireball by the combustion of metal powders post-detonation [3-5], highlights the increase application of these compositions in the weapons industry. Such compositions provide significantly enhanced efficiency in both enclosed spaces, such as tunnels and caves, and in open, cleared areas.

Although many PBX formulations have been developed and generally show low sensitivity to external influences, the effect of environmental factors on their long-term behavior is still not widely studied. There are several reasons for that: the explosives are stored under controlled conditions and sealed in hermetically closed warheads, which limits their exposure to the environment. The extensive variety of munitions that can incorporate these formulations, coupled with their diminished sensitivity, allows for the development of new munitions that, under storage conditions, would not necessitate complete hermetization (for instance, an opening in the liner for the insertion of explosives and placing fuze) until the time of usage. Due to these potential designs, it is essential to

Corresponding author: M. Krstović;
E-mail: mirjana.krstovic@mod.gov.rs
DOI: 10.5937/OTEH26041K

gather information concerning the behavior of these compositions under various climatic conditions, corresponding to different types of temporary storage and exploitation.

This paper examines three samples of multi-component thermobaric PBX explosives that were manufactured five years ago and stored in continental climate conditions during that time. To replicate various climatic events, the samples were subjected to a regime of elevated temperature and air humidity in the climate chamber, along with a regime of high temperature and salt mist to imitate extreme climatic conditions. The explosives were further evaluated using vacuum stability tests and heat flow calorimetry to determine their chemical stability and to acquire a broader understanding of their behavior under extreme environmental conditions.

2. EXPERIMENTAL

Samples of PBX were selected, that represent promising thermobaric compositions with small differences in mass ratio of the ingredients. Formulations with aluminum are very widespread because its characteristics (high heat of combustion, cost and availability [3]), while the Al-Mg combination is used because Mg lowers the ignition temperature and improves reactivity [6].

2.1. Materials

TBX samples were prepared based on:

- Cyclotetramethylenetetranitramine (HMX) from "Prva Iskra Namenska", Barič, Serbia
- ammonium perchlorate (AP), from "Poliex", Berane, Montenegro
- aluminium powder (Al), from "SRCT", China
- magnesium powder (Mg), from "Jengo Spa", China
- binder: hydroxyl-terminated polybutadiene, HTPB ("Polyvest HT Evonik") cured with isophorone diisocyanate, IPDI ("Sigma Aldrich"), and plasticized with dioctyl adipate, DOA.

The appearance of the individual components that are part of TBX formulation can be seen in Figure 1.

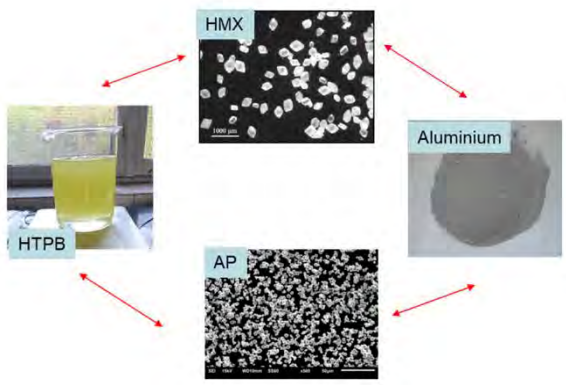

Figure 1. Samle ingridients: HTPB, HMX, Al and AP

2.2. Sample preparation

All the samples have been produced in a vertical homogenizer at 60°C under vacuum according to the process specified by the Military technical institute. Three sample types have been manufactured from three distinct batches, two have the same formulation, while the third has two types of metal powders. All the samples were cast and cured in heating chamber at 70°C during 5 days. The analyzed samples compositions were as follows:

TBX 1: HMX/Al/AP/HTPB;
TBX 2: HMX/Al/AP/HTPB;
TBX 3: HMX/Al/Mg/AP/HTPB.

After the production process, samples from each batch were poured into a vessel with an opening, cured and stored, to provide complete exposure to environmental conditions in storage on one side.

The samples are divided (cut) into three parts: one represents a sample exposed to natural aging, one to be additionally exposed to accelerated aging in continental conditions, and last one to accelerated aging in Mediterranean conditions. The first part, without any additional treatment, was subjected to stability tests and is a reference sample naturally aged in a warehouse for five years in continental climate conditions. The second part was exposed to the process of accelerated aging in the conditions of a continental climate, which was simulated in a climate chamber with an elevated temperature of 60°C and air humidity of 65%, which can be seen in Figure 2.

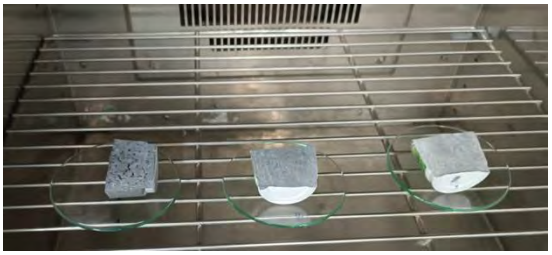

Figure 2. TBX in climate chamber (from left: TBX 3, TBX 2, TBE 1)

The third part of the samples was exposed to extreme conditions - a temperature of 30°C and air humidity of 90% in conditions of marine atmosphere imitated by a salt-mist camber. The sample that was in the salt-mist chamber for 48 hours, after the experiment, due to extremely high humidity, was covered with salt water that condensed on the lid of the chamber during the operation of the chamber and dripped on the samples.

After treatment, all samples were mechanically powdered to particles of approximately 2×2 mm (Figure 3) in order to prepare them for further analysis.

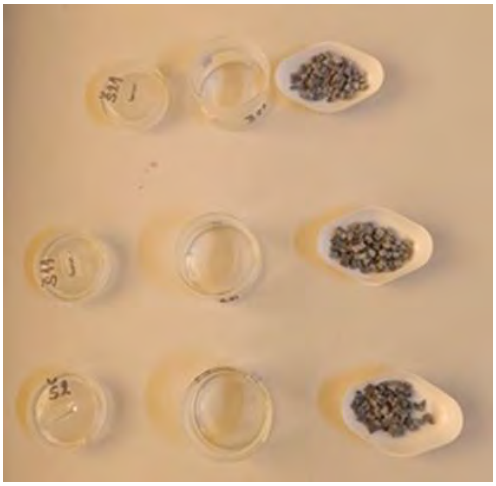

Figure 3. Chopped samples of naturally aged TBX

The moisture content of each sample had been previously determined using the drying method at 10

0 °C for 2 h, in order to evaluate the influence of moisture on the treated samples.

2.3. Methods

Chemical and thermal stability of the investigated materials was evaluated using the STABIL system (modernized vacuum stability tester) apparatus manufactured by OZM Research, Czech Republic. Method was performed by STANAG 4556 [7,8] procedures, by using 2.5 g of sample. The chopped samples are placed in a test tube (Fig. 4a) and heated at 100 °C for a duration of 40 h.

Figure 4. a) Prepared sample of TBX in test tube for VST and b) prepared sample of TBX in vial for HFC

Heat flow calorimetry was method of choice because it can also yield information about the stability of energetic materials measuring the decomposition rate. Experiment was carried out by at 85°C and using Heat Flow Calorimeter, TAM IV TA Instruments with 24 channel for 7 days. Approximately 3g of the chopped sample was placed in the vial for microcalorimetry (Fig. 4b).

3. RESULTS AND DISCUSSION

All samples undergo the same type of tests, with the same conditions to obtain the comparable results in stability.

3.1. Vacuum stability results

The moisture level of the surface and middle layers was initially assessed, and the results of moisture content are given in Table 1. Vacuum stability test at first was carried out for both layers for naturally aged samples to detect the slight differences in moisture content and the gas evolved in the vacuum stability test tube for the two layers are shown in Table 2.

Table 1. Moisture content for naturally aged samples

Sample	naturally aged		clime chamber		salt-mist chamber	
	surface layer (mass%)	middle layer (mass%)	surface layer (mass%)	middle layer (mass%)	surface layer (mass%)	middle layer (mass%)
TBX 1	0.02	0.04	0.04	0.05	0.04	0.04
TBX 2	0.00	0.04	0.04	0.04	0.04	0.04
TBX 3	0.28	0.41	0.14	0.08	0.06	0.12

Table 2. Vacuum stability test result for naturally aged samples by layers

Sample name		Gas evolved [cm3/g]		
		test tube 1	test tube 2	average
surface layer	TBX 1	0.115	0.118	0.117
	TBX 2	0.116	0.117	0.117
	TBX 3	0.398	0.404	0.401
middle layer	TBX 1	0.100	0.101	0.101
	TBX 2	0.106	0.108	0.107
	TBX 3	0.364	0.364	0.364

Table 2. demonstrates that all samples exhibit almost full resistance to moisture. The elevated value primarily reflects the formulation including a bi-component mixture of fuel, i.e. aluminum and magnesium. According to the fact that the samples were not hermetically sealed during storage, and had an opening on one side, it was necessary to consider the influence of moisture. Considering that the trend remains the same across all compositions and that similar values are observed in different layers and within the same samples for both moisture and released gases (Table 3) during the stability test, the remaining samples will be evaluated only in one middle layer and compared to that layer of naturally aged samples.

Samples exposed to the climate chamber under conditions of elevated humidity and temperature had their moisture content assessed, whereas undried samples were submitted to the vacuum stability test. The obtained results are given in Table 3.

Table 3. Vacuum stability test result for climate chamber samples

Sample name	Gas evolved [cm^3/g]		
	test tube 1	test tube 2	average
TBX 1	0.156	0.147	0.151
TBX 2	0.144	0.134	0.139
TBX 3	0.348	0.346	0.347

Extreme conditions, even in a relatively short time interval, lead to changes in the amount of gas released. The compositions containing only Al show an increase of as much as 30 to 50%, while the composition containing the combination of Al and Mg after exposure to the climate chamber gives a lower value by about 5%. However, it is important to note that even those, at first glance extremely high values, are not even close to critical values, which range from 1.2 to 2 cm^3/g according to test criteria [10].

Table 4 summarizes the results acquired from compositions subjected to salt mist. Despite being completely submerged in salt water, the sample's minimal moisture content indicates that the cross-linking of the HTPB with IPDI produced a sufficiently resilient rubbery binder structure that exhibits remarkable resistance to moisture and water.

Table 4. Vacuum stability test result for salt-mist chamber samples

Sample name	Gas evolved [cm^3/g]		
	test tube 1	test tube 2	average
TBX 1	0.195	0.198	0.172
TBX 2	0.198	0.199	0.199
TBX 3	0.331	0.321	0.326

Considering the composition of TBX 1, in each of the mentioned atmospheres, there is a clearly noticeable trend of change in the amount of evolved gases in rapidly ging samples in clime and salt-mist chambers. In Figure 4 we may observe the differences between atmospheres.

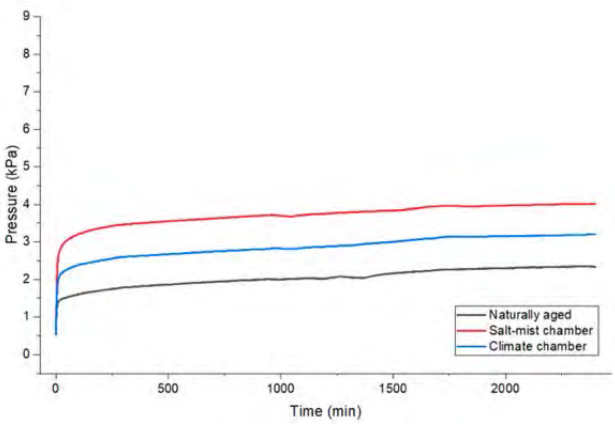

Figure 5. Sample of TBX 1 in different atmospheres

Figure 5 presents shows that all samples exhibit a rapid initial pressure increase during the early stage of the test, followed by a gradual stabilization phase. The sample exposed to the salt-mist chamber shows the highest-pressure values throughout the entire testing period, reaching approximately 4.0 kPa while climate chamber sample stabilizing around 3.1–3.2 kPa. Naturally aged samples exhibit the lowest pressure development over time, reaching approximately 2.3 kPa.

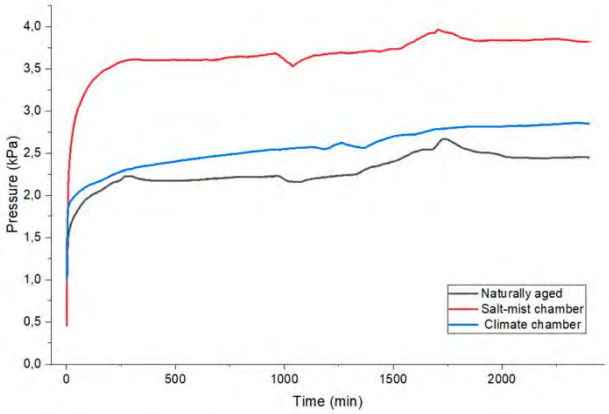

Figure 6. Sample of TBX 2 in different atmosphere

The differences between the samples are obtained almost immediately, the curves reach maximum values in first minutes of the test. The curve shapes indicate stabile behavior during test period, without any sharp picks which could reveal instability. Although this finding proving chemical stability providing extremely low values of evolved gas compared to German test criteria, it emphasizes significantly environmental influence on samples [11,12]

A very similar trend was recorded in sample TBX 2, which is identical in composition to TBX 1. The values of the naturally aged sample and the sample from the air conditioning chamber are somewhat closer, while there is a big noticeable difference in the sample exposed to the simulation of the Mediterranean climate.

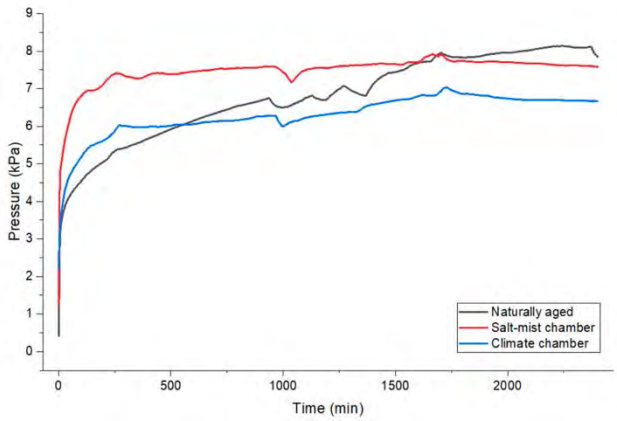

Figure 7. Sample of TBX 3 in different atmosphere

The sample TBX 3, shown in Figure 7 clearly indicate that the behavior of composites that contain a combination of two metal powders, Al and Mg, does not follow the trend observed in samples TBX 1 and TBX 2. Samples of TBX 3 from all three atmospheres show a higher sensitivity to the stability test, which in some

segments is even three times higher compared to equally treated samples that do not contain magnesium. However, a greater resistance to the influence of the atmosphere is also clearly noticeable, that is, all three samples show very similar behavior and reach close values.

Also, it can be detected that the pressure of naturally aged sample changes linearly with time, while the samples exposed to the climate chamber and salt-mist chamber after the initial pressure change, keep their values stable. The values obtained for the magnesium-containing compositions indicate a certain variation in stability over time. Although all measured parameters remain well below the prescribed limit values, it is evident that their thermal stability behavior differs compared to TBX 1 and TBX 2. This deviation does not necessarily imply instability; however, it suggests that the presence of magnesium influences the thermal response of the system. Therefore, these compositions require continued monitoring and additional investigation to fully understand their long-term stability and performance characteristics.

3.2. Heat flow capacity

Considering that the examined PBXs have different components, the behavior of each individual sample exposed to different treatment was monitored using the HFC method. Table 5 provides an overview of the measured maximum heat flow for all samples.

Table 5. Maximum heat flow for TBX 1-3

Samp.	treatment	Max heat flow (µW/g)		
		sample 1	sample 2	Average
TBX1	naturally aged	4.26	4.27	4.26
	climate chamber	3.66	4.02	3.84
	salt-mist chamber	4.09	4.09	4.09
TBX2	naturally aged	3.42	3.52	3.47
	climate chamber	3.67	3.65	3.66
	salt-mist chamber	5.07	4.35	4.71
TBX3	naturally aged	218.3	214.9	216.6
	climate chamber	183.3	194.5	188.9
	salt-mist chamber	257.0	280.8	268.9

The table reveals that samples TBX 1 and TBX 2 have comparable results that are significantly below the thresholds established by STANAG 4582 (for 85°C for 5,98 days heat flow limit is 201µW/g). It is important to note that the document addresses gunpowder and rocket fuels [8,9], which are susceptible to thermal breakdown and self-ignition under critical conditions, but in absence of adequate standard method for PBX, this criteria was chosen for the examined explosives as well. However, the thermal activity shows significantly different results when the TBX 3 sample is taken into consideration. Its values slightly exceed the allowed limit, which indicates that should conduct additional analyzes and introduce other methods that would give additional insight into the thermal stability of the mentioned compositions.

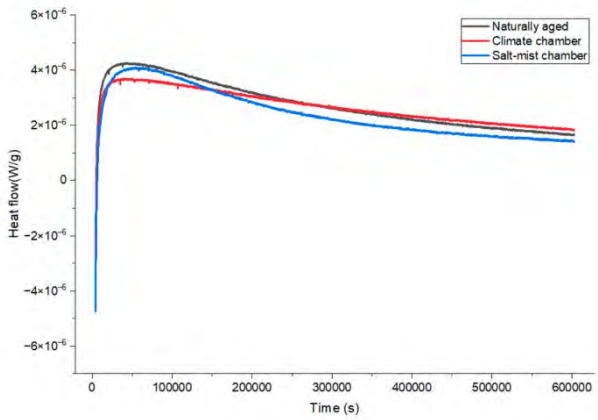

Figure 8. HFC diagram for sample TBX 1

As it can be seen in figure 8, all treated samples of PBX 1 exhibited an initial exothermic peak followed by a gradual decline in heat flow over time. The maximum heat flow values followed the order: naturally aged, salt-mist chamber and climate chamber. The naturally aged sample showed the highest peak intensity, indicating the greatest initial reactivity. The salt-mist exposed sample displayed a slightly lower maximum, while the climate chamber sample exhibited the lowest heat flow. The initial exothermic peak could be potentially influenced by residual moisture since the samples were not pre-dried. Following the maximum, all samples exhibited a similar decay trend, without pronounced and low endothermic or exothermic peaks with a tendency to decrease thermal activity over time.

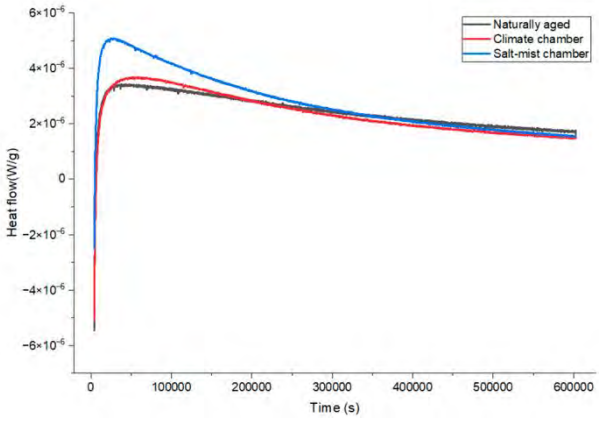

Figure 9. HFC diagram for sample TBX 2

At Figure 9, for TBX 2 the heat flow curves also showed a pronounced initial exothermic peak followed by a gradual decay for all three conditioning treatments. In contrast to the PBX 1 sample, the maximum heat flow has a different trend of thermal response with highest values for salt-mist treated sample, the climate chamber sample shows intermediate reactivity, while the naturally aged specimen presents the lowest maximum heat flow. The sharper and higher peak observed for the salt-mist sample suggests enhanced initial reactivity which can be caused both by oxidation and moisture-related processes.
After the maximum, all curves exhibit a similar long-term decay trend, indicating progressively and limited reactions.

Compared to Figure 8, a different trend can be noticed and clear reversal in maximum heat flow. The unexpected variations in thermal response among samples of identical composition can be attributed to their derivation from distinct batches, wherein the raw materials can possess difference pretreatment processes, particularly at elevated temperatures, such as those employed during the HFC test. Overall, the comparison indicates that environmental conditioning significantly alters the initial kinetics, while long-term behavior remains governed by similar diffusion-controlled mechanisms.

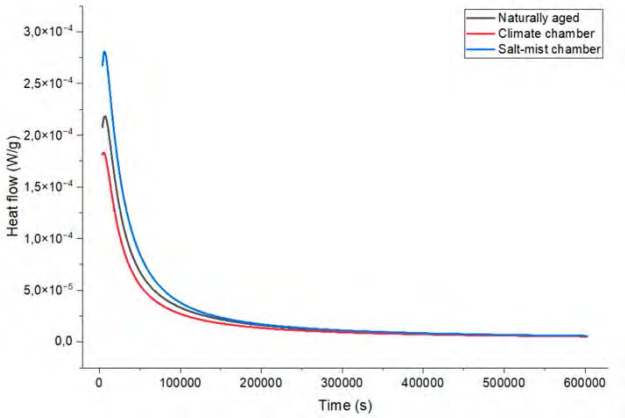

Figure 10. HFC diagram for sample TBX 3 in different atmospheres

However, regarding the PBX 3 sample, it is an entirely different sample. Specifically, the maximum heat flow is up to 50 times higher than in the formulation that comprises only Al as the fuel component.

All tree samples show very intense initial exothermic response followed by a rapid decay toward near-zero heat flow. The peak occurs very early and is sharp, indicating a highly reactive initial process. After 28 hours all curves converge and approach very low heat flow values, suggesting depletion of reactive processes. The salt-mist sample exhibits the highest peak, while the climate chamber sample consistently shows the lowest reactivity. In all three cases the rapid decay suggests that the process is primarily surface-controlled rather than diffusion-controlled over long times, according to the fact that the tested samples were not previously dried, so the initial reactions may be the result of a small residual amount of moisture in the samples

Analyzing all three samples, it is clearly observed that there are differences in the thermal response of samples exposed to certain conditions of high temperature, humidity or salt mist, which indicate that environmental conditioning significantly affects thermal stability of the examined PBX.

Salt-mist exposure tends to enhance initial reactivity, which can be seen particularly evident in the second and third diagram, while climate chamber exposure generally reduces maximum heat flow.

Despite differences in peak magnitude, all datasets eventually converge to low heat flow values, indicating exhaustion of reactive ingredients and transition to kinetically limited process. This behavior indicates pronounced short-term temperature sensitivity. It is important to note that PBX compounds are not exposed to excessively high temperatures during production, as mixing and crosslinking processes do not exceed 70 °C. Furthermore, the operational temperature range of ammunition is relatively moderate, typically between −30 °C and +50 °C. The HFC diagrams, together with the maximum heat flow values, demonstrate that all detectable processes, whether associated with the release of residual moisture, reactions with oxygen present in the vial, or relaxation of the polymer matrix, occur within a limited time interval no longer than 24 hours. After this initial period, the heat flow rapidly decreases, indicating that the system reaches a relatively stable state with no sustained long-term exothermic activity.

4. CONCLUSION

This study evaluated the environmental and thermal stability of three PBX formulations subjected to natural aging, elevated temperature and humidity, and salt-mist exposure to simulate Mediterranean climate. Vacuum stability testing demonstrated that all compositions released gas amounts significantly below the critical limits defined by 1.2 cm^3/g, confirming their overall chemical stability. Nevertheless, environmental conditioning influenced early gas evolution kinetics. Salt-mist exposure produced the highest-pressure development, while naturally aged samples consistently exhibited the lowest values. It is also noticed that compositions containing only aluminum (TBX 1 and TBX 2) showed comparable and stable behavior for all conditioning treatments. In contrast, TBX 3, which incorporates a combination of aluminum and magnesium powders, revealed increased sensitivity in both vacuum stability and heat flow measurements. Although it exhibited acceptable safety in vacuum stability testing, TBX 3 exhibited substantially higher thermal activity. Heat flow capacity results confirmed that TBX 1 and TBX 2 remained far below the STANAG 4582 heat flow limit, whereas TBX 3 exceeded the prescribed threshold, indicating the need for further thermal characterization.
Environmental exposure primarily affected early-stage reaction kinetics, particularly enhancing reactivity after salt-mist conditioning, while long-term behavior converged toward low heat flow values for all formulations. The results confirm that the cross-linked polymer matrix provides effective resistance to moisture and atmospheric influence. However, the presence of magnesium significantly alters thermal response, emphasizing the importance of continued monitoring and additional long-term stability investigations for Mg-containing formulations. Also, the findings encourage further research in establishing criteria and finding appropriate methodology of testing the long-term stability of multi-component PBX.

Abstract: *The shaped-charge effect remains one of the most effective mechanisms for defeating armored targets. Tandem shaped-charge warheads provide enhanced effectiveness against explosive reactive armor systems, where the precursor charge is used to initiate the reactive armor prior to the arrival of the main charge. The present study investigates the performance of a small-diameter precursor shaped-charge warhead with a charge diameter of 50 mm. A 60° conical copper liner with a thickness of 1 mm is accelerated by the detonation products of an explosive charge and subsequently transformed into a high-velocity jet. The experimental program included three explosive materials—TNT, RDX, and HMX—as well as variations in standoff distance. A high-strength alloy steel cylinder was used as the target. In parallel, a numerical model of jet formation and target penetration was developed using the commercial finite element software Abaqus/Explicit and a purely Eulerian formulation. Comparison of the experimental observations and numerical predictions demonstrated good agreement in terms of penetration depth and cavity geometry, while also providing insight into the underlying penetration mechanisms and the influence of key design parameters. The validated numerical model provides a reliable basis for further analysis and optimization of shaped-charge warhead performance.*

Keywords*: precursor shaped charge, shaped charge jet, penetration depth, experimental investigation, numerical simulation*

1. INTRODUCTION

More than a century after its discovery, the shaped-charge effect remains one of the most effective mechanisms for armor penetration and continues to serve as the basis for numerous modern warhead designs. Its operating principle relies on focusing explosive energy and converting it into a high-velocity metal jet through the collapse of a metallic liner [1–5]. Defense applications have driven the continuous improvement of shaped-charge performance through extensive experimental, analytical, and numerical investigations.

The shaped-charge mechanism may be divided into the following phases [1,2]: (i) propagation of the detonation wave through the explosive charge, (ii) acceleration of the liner material by the detonation products, (iii) liner collapse and jet formation, (iv) jet evolution and stretching, (v) jet impact on the target and subsequent penetration, and (vi) process termination, either by target perforation or by arrest of penetration in a sufficiently thick target. Table 1 summarizes representative values of the characteristic parameters of shaped-charge warheads and jets, together with the corresponding performance metrics.

In the present study, an experimental investigation of the performance of a small-diameter (50 mm) shaped-charge warhead was conducted. Subsequently, comprehensive numerical simulations of the complete shaped-charge process were performed. The objective of the research was to develop and validate a numerical model capable of

DOI: 10.5937/OTEH26042E

accurately reproducing the experimental observations, thereby providing a reliable basis for further optimization of the warhead design and enhancement of its performance.

Table 1. Typical ranges of characteristic parameters and performance metrics for shaped-charge warheads and jets [1,2].

Liner base diameter	*CD* = (40…700) mm
Detonation velocity	*D* = (7.0…10.0) km/s
Liner thickness	(0.02…0.04) *CD*, for copper
Jet diameter	≈ (0.03…0.15) *CD*, variable
Jet length	≈ (6…15) *CD,* before breakup
Cavity diameter	≈ (0.1…0.3) *CD*, variable
Jet tip velocity	≤ 1.4 *D*
Jet tail velocity	≈ (0.2…0.5) *D*
Optimum standoff	≈ (2…7) *CD*
Penetration depth	(4…10) *CD,* in steel target

2. EXPERIMENTAL INVESTIGATION

The subject of the experimental investigation was a small-diameter shaped-charge warhead shown in Fig. 1. The warhead is primarily intended for use as a precursor charge in a tandem-warhead configuration; however, it may also be employed as a standalone warhead carried by an unmanned aerial vehicle (UAV) intended for top-attack engagement of lightly armored targets.

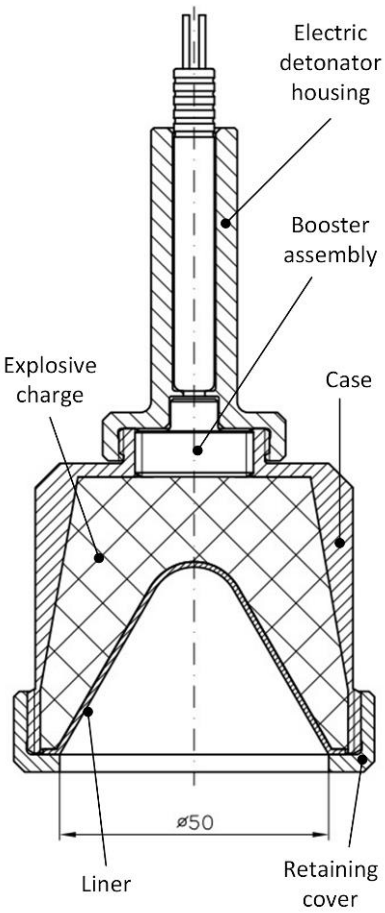

Figure 1. Assembly drawing of the 50 mm shaped-charge warhead configuration employed in static tests, showing its main components.

As a part of a broader experimental campaign, a series of field tests was conducted at the proving ground of Poliex in Berane, Montenegro. In the static tests, the explosive train was initiated using an EDK-8 electric detonator manufactured by Poliex. The detonation impulse was transmitted to a PETN booster charge, ensuring reliable initiation of the main explosive charge. Various explosive formulations were investigated as the main charge material, including phlegmatized RDX, HMX, and TNT. The explosive charges were manufactured by pressing the explosive compositions to the prescribed density.

The conical liner was manufactured at Forging Center LLC Valjevo by cold forging from copper bars supplied by Copper Mill Sevojno, Serbia. The material was DNP-Cu (Class A), a phosphorus-deoxidized copper grade with a copper content of 99.95 wt.% and a phosphorus content below 0.015 wt.%. Following forging and subsequent machining, the liner was placed in a furnace preheated to 300 °C and held at this temperature for 15 minutes. It was then removed from the furnace and allowed to cool in air. The hardness measured immediately after forging, prior to machining and annealing, was 105 HBW 5/250. Due to the small wall thickness of the liner and the limitations of the available hardness testing equipment, its hardness after annealing was not measured.

The warhead case was manufactured from glass-fiber-reinforced polyamide in the baseline configuration, while aluminum and steel were considered as alternative casing materials. The present paper considers only the baseline configuration. The explosive pressing operations, fabrication of individual components, copper liner annealing, and final warhead assembly were all conducted at the Poliex manufacturing facilities. Photographs of the individual components and assembled warheads are presented in Fig. 2.

As a practical substitute for standard rolled homogeneous armor (RHA) steel plates, cylindrical targets made of quenched and tempered Č.4732 steel were employed owing to their availability, cost-effectiveness, and suitability for longitudinal sectioning, which facilitated detailed post-test examination of the penetration cavity. Equivalent designations of this steel in other standards include 42CrMo4 (EN), AISI 4140, and 1.7225 (W.Nr.). The targets had a diameter of 80 mm and lengths of 150 mm and 200 mm.

The standoff distance between the base of the conical liner and the target was controlled using a machined polystyrene spacer designed to ensure accurate alignment and positioning of the warhead relative to the cylindrical target. Adhesive tape was additionally used to secure the assembly during the tests. Photographs of the setup used in the field tests are presented in Fig. 3.

The primary diagnostic parameters considered in the field tests were: (i) penetration depth, (ii) the geometry of the penetration cavity, including the entry and possible exit holes, and (iii) damage to the supporting structure. The experimental results are presented and discussed in Section 4 through comparison with the corresponding numerical predictions.

3. NUMERICAL SIMULATIONS

The numerical investigation of shaped-charge jet penetration was performed using the finite element software Abaqus [6] and its explicit solver. This software has been widely employed for the simulation of transient, high-energy, and high-strain-rate phenomena, including shaped-charge jet formation and penetration into metallic targets [7–11].

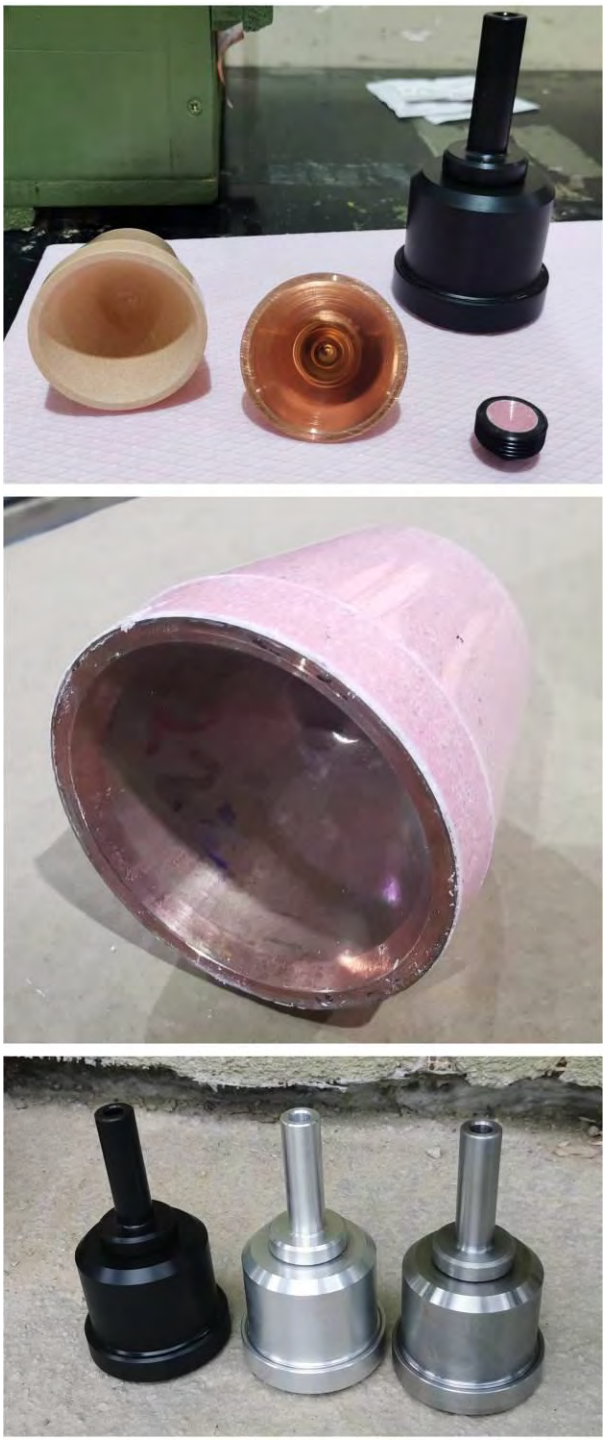

Figure 2. Photographs of the main stages of warhead preparation: (top) individual warhead components, including the RDX explosive charge, liner, booster, and casing; (middle) assembly of the liner and HMX explosive charge; and (bottom) completed warheads with polyamide, aluminum, and steel casings.

Figure 3. Experimental setup: (top) warheads and cylindrical targets configured with various standoff distances; (bottom left) assembled warhead–target configuration before testing and a recovered target showing the penetration cavity; and (bottom right) warhead fitted with an EDK-8 detonator and prepared for testing.

Owing to the severe material deformation associated with the penetration process, a purely Eulerian formulation was employed. A quasi-axisymmetric 15° wedge model was adopted, reproducing the actual geometry of the shaped-charge warhead and target configuration (Fig. 4). Appropriate boundary conditions were applied to enforce symmetry. Following a mesh convergence study, a uniform element size of 0.5 mm was used in the axial direction, while the element size in the radial direction gradually increased from 0.2 mm to 0.8 mm. The total number of Eulerian EC3D8R elements was on the order of 500,000, depending on the model configuration, particularly the target thickness and standoff distance.

Accurate representation of material behavior under highly dynamic loading conditions is of crucial importance for the reliability and predictive capability of the numerical model. The shaped-charge liner and target were modeled using material parameters representative of the copper grade (DNP-Cu, Class A) and Č.4732 steel employed in the experiments, respectively. The dynamic plastic response of both materials is described using the Johnson–Cook constitutive model [12], together with a linear shock-wave equation of state. Material failure is modeled using the Johnson–Cook damage model [13]. The warhead casing was made of glass-fiber-reinforced polyamide (PA-GF), corresponding to the configuration

used in the experimental tests. In the numerical model, the casing material was represented by a simplified isotropic elastic-plastic model with a density of 1350 kg/m³, Young's modulus of 8 GPa, and Poisson's ratio of 0.35. The plastic behavior and ductile damage initiation were described using tabulated parameters estimated based on available literature [14]. Experimental observations and numerical analyses conducted by the authors within broader research program indicated that variations in casing material had a relatively limited influence on the penetration performance of the investigated shaped-charge configurations.

The explosive charge is described using the Jones–Wilkins–Lee (JWL) equation of state [15], coupled with a programmed burn model. The material parameters used in the Abaqus simulations are summarized in Tables 2 and 3.

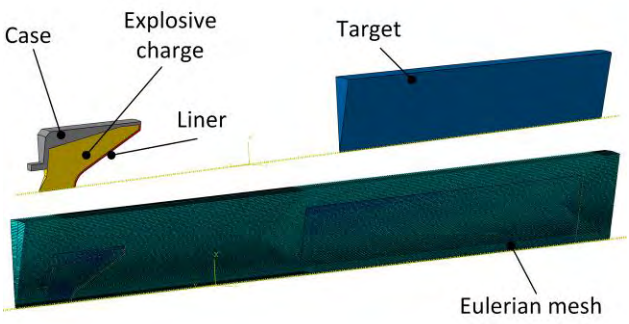

Figure 4. Geometry and Eulerian finite element mesh of the quasi-axisymmetric numerical model.

The total duration of the simulated process, from explosive initiation to the end of jet penetration, is approximately 150–250 µs.

4. RESULTS AND DISCUSSION

Figure 5 presents a representative numerical simulation of an HMX-based shaped charge at a standoff distance of 2.6 charge diameters (CD). The sequence of snapshots illustrates the complete process from jet formation and evolution to target penetration and the attainment of the final penetration depth, providing insight into the temporal development of the shaped-charge jet and its interaction with the target.

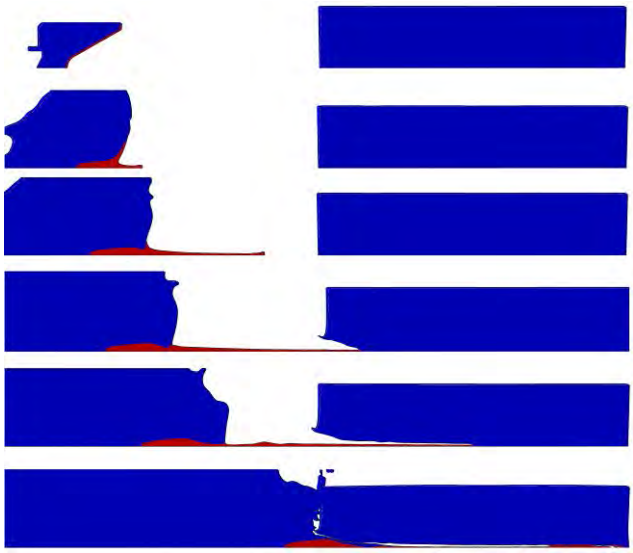

Figure 5. Numerical simulation of shaped-charge jet formation and penetration into a steel target. The snapshots illustrate the temporal evolution of the process at 0, 15, 30, 45, 90, and 240 µs after initiation.

The numerical simulations provide detailed information on the penetration process that cannot be obtained directly from the experiments. For example, the predicted jet tip velocity is approximately 5350 m/s. This relatively low value can be attributed to the large cone angle of the liner, which favors the formation of a heavier but slower jet.

The predictive capability of the numerical model was assessed by comparing the calculated penetration depths for several representative cases with the corresponding experimental measurements, as summarized in Table 4.

Table 4. Comparison of experimentally measured and numerically predicted penetration depths for various explosive charge materials and standoff distances.

Explosive charge	Standoff (CD)	Penetration depth (mm)	
		Simulation	Experiment
HMX	2.6	194	188
RDX	1.2	122	118
TNT	1.2	98	93

Overall, very good agreement between the numerical predictions and the experimental measurements was achieved, with the relative error in penetration depth not exceeding 5%. Interestingly, even the TNT-filled charge provides a significant penetration capability, making it potentially suitable not only for precursor-warhead applications but also as a standalone warhead against lightly armored targets. As expected, the numerical model consistently predicts slightly greater penetration depths, primarily due to the idealized axisymmetric representation of the process, including perfectly symmetric initiation, explosive charge geometry, and liner configuration. These assumptions result in a more coherent and continuous shaped-charge jet than that produced under experimental conditions.

Figure 6 compares the entry holes produced by the HMX-based warhead listed in Table 4, as obtained experimentally and predicted numerically. The comparison demonstrates good agreement between the experimental observations and numerical predictions, confirming the ability of the numerical model to reproduce the principal features of the target response in the vicinity of the entry hole.

After testing, the targets were sectioned longitudinally using wire electrical discharge machining (wire EDM). A comparison between the experimentally obtained penetration cavity profile and its numerical prediction is presented in Fig. 7. The numerically predicted cavity is slightly narrower than that observed experimentally, particularly in the entrance region and over approximately the first third of the penetration depth. This discrepancy can be attributed primarily to the idealized nature of the numerical model, which assumes perfect geometric and loading symmetry and consequently produces a more coherent and better-focused jet. In contrast, the experimental process is inevitably affected by minor geometric and manufacturing imperfections, as well as small asymmetries in initiation and jet formation, which promote jet dispersion and result in a somewhat larger cavity diameter. The agreement improves with increasing penetration depth, indicating that the numerical model captures the overall penetration mechanism and cavity evolution with satisfactory accuracy.

The good agreement between the experimental observations and numerical predictions demonstrates the capability of the numerical model to accurately capture the jet formation and penetration processes, thereby providing a sound basis for further optimization of the shaped-charge warhead design.

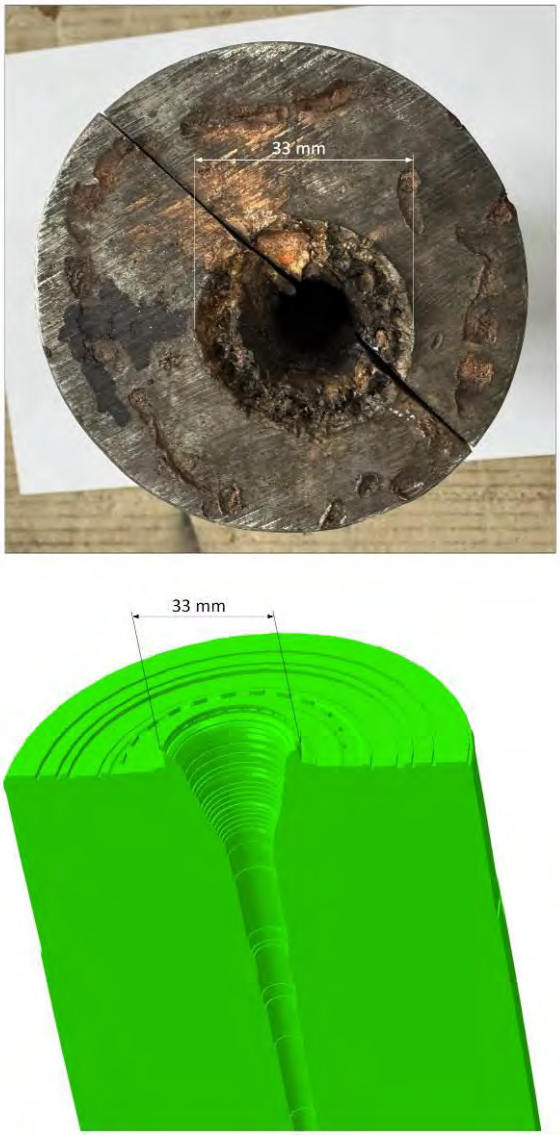

Figure 6. Comparison of experimentally obtained (top) and numerically predicted (bottom) entry holes for an HMX-filled shaped-charge warhead at a standoff distance of 2.6 CD.

5. CONCLUSION

This paper presents an experimental and numerical investigation of a small-diameter shaped-charge warhead with a charge diameter of 50 mm. The field tests examined the effects of explosive charge material and standoff distance using steel cylindrical targets. In parallel, a numerical model of shaped-charge jet formation and target penetration was developed in Abaqus/Explicit using a purely Eulerian formulation.

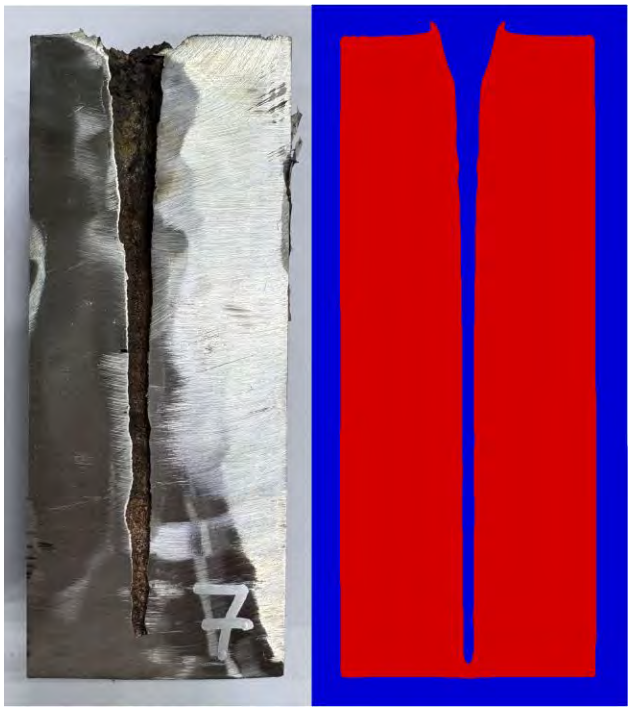

Figure 7. Comparison of experimentally observed (left) and numerically predicted (right) penetration cavity profiles produced in a steel target by an HMX-filled shaped-charge warhead at a standoff distance of 2.6 CD.

Comparison of the experimental observations and numerical predictions demonstrated good agreement in terms of penetration depth, penetration cavity geometry, and entry-hole characteristics. The results indicate that the proposed numerical model is capable of accurately reproducing the essential features of jet formation and penetration, providing a reliable tool for further analysis and optimization of shaped-charge warhead performance.

The present investigation represents the initial stage of an ongoing research effort. Future work will focus on a more comprehensive experimental and numerical assessment of the factors affecting warhead performance, including: (i) the influence of standoff distance on penetration effectiveness, (ii) the effects of liner mass and geometric tolerances, (iii) the influence of explosive charge density, (iv) the effects of case and booster-housing materials, and (v) the influence of initiation conditions on jet formation and overall warhead performance.

The validated numerical model provides a cost-effective framework for the analysis and optimization of shaped-charge warheads, reducing the need for extensive experimental testing during the design process.

Acknowledgements

This research was financially and technically supported by HI Poliex AD, Research and Development Center, Berane, Montenegro. The experimental program was conducted using the company's proving-ground infrastructure, manufacturing facilities, explosive-processing capabilities, technical resources, and expert support. The authors gratefully acknowledge the company's contribution to the preparation of explosive charges, fabrication and assembly of warhead components, safe execution of the experimental tests, and post-test examination of the targets. Special thanks are extended to the technical and engineering staff for their valuable expertise and assistance throughout the experimental campaign.

Abstract: *This paper presents an analysis of energy dissipation during the impact of projectiles fired from an air rifle and an air pistol into granular materials of different grain sizes. The study aims to compare analytically calculated energy values with experimental results using an integrated approach that combines mathematical modeling and high-speed imaging. Projectile velocity immediately before impact was estimated using numerical simulations in MATLAB, accounting for aerodynamic drag. Based on this velocity, the projectile's kinetic energy and its distribution into deformation, heat, vibration, and residual energy were determined. The experimental setup included controlled firing conditions with sand targets of varying grain sizes. The impact process was recorded using digital imaging, and the recorded image sequences were analyzed to estimate particle motion, material displacement, and morphological changes in the granular targets. The results indicate a reasonable consistency between the analytical model and experimental estimates for coarse sand. The observed deviations may be associated with granular heterogeneity, projectile geometry, and uncertainties inherent in the optical measurement method.*

Keywords*: energy dissipation, projectile impact, granular materials, kinetic energy, air rifle, air pistol, numerical modeling, high-speed imaging, experimental analysis*

1. INTRODUCTION

Energy dissipation during the impact of a projectile into granular materials represents a complex physical process involving the interaction between the projectile and the discrete structure of the material [1]. This phenomenon has significant applications in ballistics, the development of protective systems, and the analysis of material behavior under dynamic loading [2].

In the case of low kinetic energy projectiles, such as pellets from air weapons, the effects of energy dissipation depend on a large number of parameters: projectile velocity, its geometry, angle of impact, as well as the granulometric composition of the target [3, 4].

The aim of this paper is to compare an analytical model with experimental results of energy dissipation, with a particular focus on the influence of weapon type and material granulation.

2. THEORETICAL AND EXPERIMENTAL METHODOLOGY

In order to achieve a comprehensive understanding of energy dissipation mechanisms, a combined theoretical and experimental approach was adopted. The

DOI: 10.5937/OTEH26043J

mathematical model provides a basis for predicting projectile behavior, while the experimental methodology enables validation and detailed analysis of the impact phenomena.

2.1. Mathematical Model

The motion of the projectile is modeled as the motion of a material point under the influence of gravity and aerodynamic drag [3, 4]. The kinetic energy of the projectile is defined by the standard expression [3]:

$$E_k = \frac{mv^2}{2} \quad (1)$$

The projectile velocity immediately before impact is determined by numerically solving the differential equations of motion using the Runge–Kutta method [3, 5]. The model includes the following parameters: projectile mass, initial velocity, air resistance coefficient, and air density.

Based on the calculated velocity, the total kinetic energy is determined and further distributed into the following components [3]:

- Energy transferred to the target E_m,
- Plastic deformation energy E_d,
- Thermal energy E_T,
- Sound and shock wave energy E_v
- Residual energy E_R .

The kinetic energy is not entirely transferred to the target, but is divided into several components and is expressed as follows [3]:

$$E_k = E_m + E_d + E_T + E_v + E_R \quad (2)$$

- In the case of granular targets, the energy transferred to the target consists of three main components [3, 5]:
- compression energy — grain separation E_1,
- inertial energy of the grains within the target E_2 ,
- friction energy E_4 .

The compression energy is calculated using the following formula [3]:

$$E_1 = \frac{am}{2b}\ln(1+\frac{b}{a}v_0^2) \quad (3)$$

The inertial component is obtained as the remainder of the total work in the target after subtracting the compression energy and, if applicable, the other energy components [3]. Unlike the compression and inertial components, the friction energy is not explicitly separated in the basic Poncelet formulation, but is introduced in practice as an empirical approximation [3]:

$$E_4 = E_m f_0(1+\alpha\sin^2\theta) \quad (4)$$

with typical values of approximately $f_0 \approx 0.05$, i.e. 5% for normal impact, and α ≈ 1 for oblique impacts. This approximation is based on measurement results and experimental calibrations. It represents an empirical approximation based on measurements [3].

In terminal ballistics, the angle θ denotes the angle at which the projectile impacts the target relative to the normal to its surface.

This distribution serves as the basis for comparison with the calculated and experimentally determined energy values presented in the Results and Analysis section.

2.2. Experimental Methodology

The experimental investigation was conducted using two types of air weapons: the STEYR LG 110 air rifle and the STEYR LP 10 air pistol. Their relevant technical characteristics are presented in Table 1 [6, 7].

Table 1. Technical characteristics of the STEYR LG 110 air rifle and the STEYR LP 10 air pistol [6, 7]

Characteristics	STEYR LG 110 (Rifle)	STEYR LP 10 (Pistol)
Overall length	1170 mm	400 mm
Overall height	200 mm	142 mm
Barrel length	550 mm	227 mm
Caliber	4.5 mm / .177 in	4.5 mm / .177 in
Mass	4750 g	968 g
Width	—	50 mm
Propulsion	Compressed air	Compressed air
Trigger	Mechanical	Mechanical
Trigger pull	50–250 g	50–250 g
Muzzle energy	24 J	17 J
Initial projectile velocity	240 m/s	160 m/s

Furthermore, the experimental conditions were defined through a combination of parameters such as the firing angle, projectile type, and target granulation [5]. The targets were composed of sand with three different granulations, whose characteristics are shown in Table 2 [5].

Table 2. Characteristics of granular materials [5]

Sand Type	Specific density [kg/m3]	Granulation [mm]
Coarse sand	1770	~4-10
Medium-grained sand	1700	~3
Fine sand	1340	~0-0.3

For recording and analyzing the impact process, a Panasonic DMC-FZ200 digital camera was used at a recording rate of 40 frames per second [8].

For the analysis of the granular target response after projectile impact, an existing C++-based image-

processing program using the OpenCV library was modified and adapted to the specific requirements of the present experimental investigation [5].

The image-processing procedure involved tracking selected reference particles in consecutive frames recorded at 40 frames per second, corresponding to a time interval of 0.025 s. Particle velocities were estimated from their displacements between successive frames. Due to particle overlap, occlusion, and motion blur, only clearly identifiable reference particles were included in the tracking procedure.

Image segmentation and contour analysis were applied to characterize morphological changes in the granular target, including particle cloud formation, crater geometry, and subsequent erosion. The granular targets were placed in wooden frames measuring 640 × 640 × 120 mm (width × height × depth), providing known geometric dimensions of the experimental setup. Geometric corrections were considered to account for the inclination of the target and the angular position of the camera.

The resulting measurements were used to estimate particle velocities and the spatial characteristics of displaced granular material. The analysis was subject to limitations associated with image resolution, particle overlap, and the estimation of three-dimensional quantities from two-dimensional images.

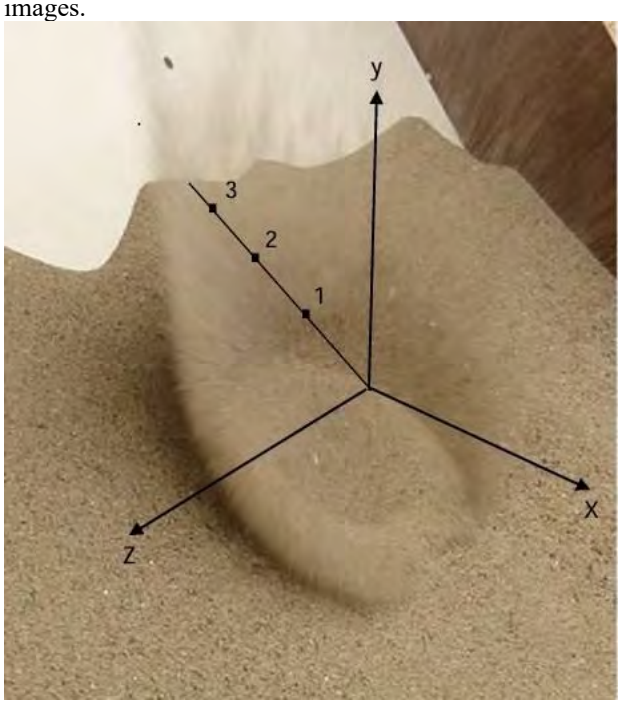

Figure 1. Analysis of photographs of the sand surface

3. RESULTS AND ANALYSIS

Analytical calculations of projectile velocity and energy, as well as their distribution, are presented in Table 3.

Table 3 – Comparison of calculated compression energy and experimentally determined energy

Air weapon type	Sand Type	Calculated compression energy E1 [J]	Experimental energy Eexp [J]
STEYR LG 110	Coarse sand	0.566	0.618
STEYR LP 10	Coarse sand	0.470	0.395

The experimental energy values are estimates based on the volume of displaced material, its density, and the average velocity of selected reference particles. The quantitative comparison was limited to coarse-grained sand due to the greater reliability of optical particle velocity measurements.

Based on the data from Table 3, it can be observed that the projectile fired from the air rifle produces higher calculated compression energy and higher experimentally determined energy compared to the projectile fired from the air pistol, which directly affects the intensity of energy dissipation in the target [5].

Each experimental configuration was repeated three times (n = 3). For coarse sand under normal impact conditions, the standard deviation of the recorded particle cloud volume was 6,844.57 mm³ for the STEYR LG 110 rifle and 1,550.20 mm³ for the STEYR LP 10 pistol. These values characterize the variability of the volumetric response between repeated experiments. The maximum recorded volume was used for the subsequent energy estimation.

In addition to the comparison between analytically calculated compression energy and experimentally estimated energy presented in Table 3, the distribution of the projectile kinetic energy into individual components was also analyzed. The calculated energy values for both air weapons impacting coarse sand at an angle of 0° are presented in Table 4.

Table 4 - Model-based energy components for projectile impact into coarse sand at 0°

Energy component	LG 110 [J]	LP 10 [J]
Compression energy	0.566	0.470
Inertial energy	9.721	4.253
Friction energy	0.541	0.248
Deformation energy	0.343	0.158
Thermal energy	0.162	0.075
Vibration energy	0.114	0.053
Residual energy	0.000	0.000

As shown in Table 4, the inertial component accounts for the largest proportion of the projectile kinetic energy, while smaller contributions are associated with compression, friction, deformation, thermal effects, and vibrations. These components were calculated using adopted coefficients of the mathematical model. Thermal and vibration-related energies were not directly measured, and no temperature measurements were performed during the experiments. Therefore, the presented values represent a model-based energy distribution rather than independently measured energy components.

The analysis of the experimental results shows significant differences in material behavior depending on granulation [5]. The cumulative volumetric particle size distribution of the three sand types, presented in Figure 2, shows clear differences in the internal structure of fine sand, medium-grained sand, and coarse sand [5]. These differences are important for understanding the mechanisms of energy dissipation in granular materials.

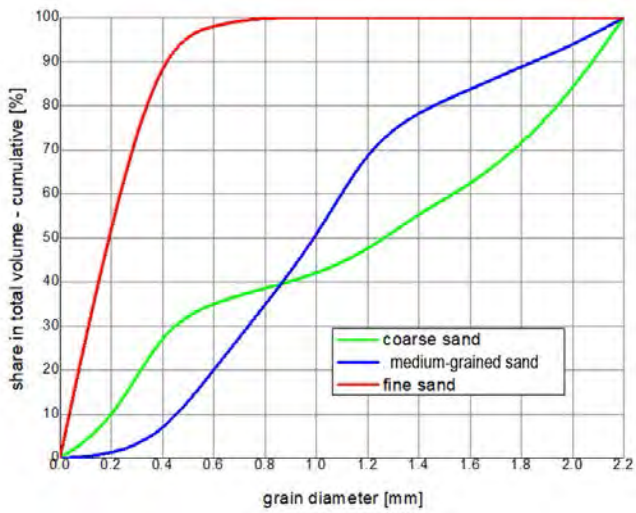

Figure 2. Cumulative volumetric particle size distribution as a function of particle diameter for three sand types

In the case of fine sand, localized energy dissipation is observed, manifested through a small "cloud" volume and limited material displacement. In contrast, coarse sand exhibits more pronounced material displacement and a more gradual dissipation of energy in deeper layers [5]. In this analysis, the combined volume of the particle "cloud" and the locally displaced material in the impact zone is treated as the total impact-related displaced volume. This behavior is illustrated in Figure 3, where the combined cloud and impact volume shows a significantly stronger response of coarse sand compared to fine sand [5].

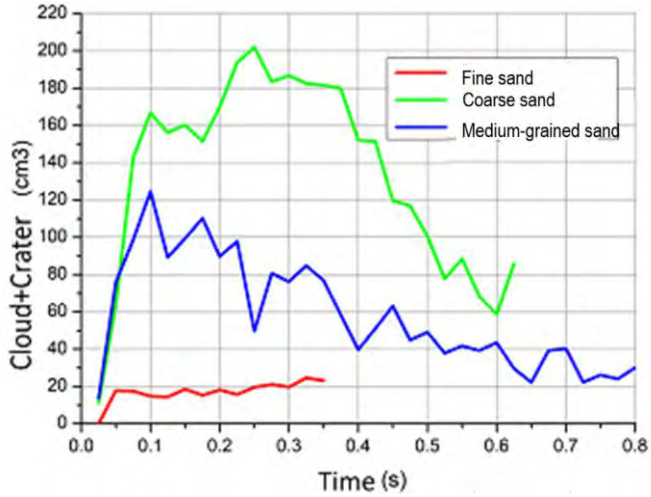

Figure 3. Change in combined cloud and impact-related displaced volume as a function of time for an air rifle shot using a flat-tip diabolo projectile at a firing angle of 0°

The differences between the analytically calculated and experimentally estimated energy values can be partly attributed to the heterogeneous structure of granular materials and the geometry of the projectile. Unlike a homogeneous continuous medium, sand consists of discrete particles with different sizes, shapes, and local packing arrangements. During impact, these characteristics affect interparticle contacts, friction, grain rearrangement, and the spatial distribution of transferred energy. Consequently, the actual granular response may differ from the simplified resistance assumptions adopted in the analytical model.

Projectile tip geometry also influences the interaction between the projectile and the granular target. Flat-tip projectiles produce a more pronounced initial displacement of grains, while conical-tip projectiles exhibit a different spatial and temporal distribution of material displacement and erosion. These differences are consistent with the experimentally observed variations in particle cloud formation and erosion dynamics.

Additional discrepancies may arise from the limitations of optical particle tracking, particularly particle overlap, irregular trajectories, and the use of average particle velocities in estimating the kinetic energy of displaced material. Therefore, the observed differences should be interpreted as the combined effects of granular heterogeneity, projectile geometry, and measurement uncertainty, rather than as the consequence of a single isolated factor.

The obtained results also indicate that the shape of the projectile tip significantly affects the mode of energy transfer [5]. This is consistent with previous analyses of pellet geometry and aerodynamic behavior [9, 10]. The experimental observations indicate that flat-tip projectiles can produce higher and more irregular material displacement and erosion, whereas conical-tip projectiles exhibit a different, more time-distributed granular response [5].

4. CONCLUSION

The results indicate reasonable consistency between the analytical model and the experimentally estimated energy values for coarse sand. The observed differences reflect the complexity of granular material behavior and the limitations of the optical measurement method. Further experimental investigations and statistical analysis are required to establish the model's predictive accuracy across different granular materials.

The obtained results may be applied in the analysis of protective materials and in the optimization of structures exposed to impact loading.

Abstract: *Smokeless powders represent chemically unstable systems whose safety and performance critically depend on the integrity of their non-energetic organic components. Their primary constituent, nitrocellulose, is inherently prone to thermal decomposition, which under unfavorable or long-term storage conditions may lead to autocatalytic degradation and, ultimately, self-ignition of ammunition. In this context, fast and reliable determination of organic stabilizers and additives by gas chromatography (GC) is not only an analytical requirement but a safety imperative in both production and storage environments. In this work, saponification is examined as a key step in sample preparation with the potential to significantly accelerate the analytical workflow. Its performance was directly compared with conventional preparation procedures that do not include saponification, specifically extraction in methanol and extraction in dichloromethane. These approaches were systematically matched under equivalent conditions prior to GC analysis to clearly assess the impact of the saponification step on both efficiency and analytical performance. All investigated procedures provided reliable and reproducible quantification of the non-energetic organic components present in the analyzed samples by GC. However, the saponification-based method enabled a substantial reduction in total sample preparation time, by several hours, while maintaining analytical accuracy and precision. These findings demonstrate that the introduction of saponification as an initial preparation step offers a practical route toward faster GC analysis without compromising data quality. This improvement is particularly relevant for routine quality control, where reduced turnaround time directly enhances process monitoring and operational efficiency.*

Keywords: *smokeless powders, gas chromatography (GC), sample preparation, stabilizers, saponification.*

1. INTRODUCTION

Although the field of composite propulsion materials is developing rapidly, gunpowder and propellants based on nitrocellulose remain the pillar of ammunition technology in small caliber and standard artillery ammunition. Due to the inherent susceptibility of nitrocellulose to chemical degradation [1-4], extensive research has established various instrumental and classical methods to monitor its chemical aging as quality control procedures [5]. Consequently, precise criteria have been defined for evaluating and categorizing the stability of gunpowder and rocket propellants over time. However, before assessing long-term chemical stability, a critical phase in the ammunition life cycle is rigorous quality control during both production and product-acceptance phases. A key aspect of this process is the precise quantification of essential organic components, especially stabilizers and plasticizers. To meet the rigorous demands of quantifying these critical parameters, chromatographic methods emerge as the premier analytical tool, enabling rapid, efficient, and simultaneous identification and quantification of organic compounds within the propellant matrix. [6]

Therefore, the development and implementation of rapid, reliable, and precise analytical methods is essential for manufacturing facilities dedicated to smokeless powder production. While standard chromatographic protocols provide highly accurate results within brief timeframes, sample throughput remains limited by the pre-analytical

Corresponding author: T.Stančić;
E-mail: teodorastancic@gmail.com
DOI: 10.5937/OTEH26044S

preparation phase. Gas chromatography (GC) generally requires between 5 and 10 minutes for analysis. Consequently, the primary obstacle in achieving rapid and reliable analytical systems shifts from instrumental analysis to sample preparation, which demands optimization for exhaustive extraction within the shortest possible time.

International [1] and domestic standards [7-8] aim to establish versatile testing methodologies. These protocols must accommodate an exceptionally wide range of propellant grain geometries, dimensions, and shapes, while seamlessly adapting to the diverse chemical compositions found in modern formulations.

The primary objective of this research is to develop a rapid sample preparation method for production-line gunpowder samples prior to gas chromatographic testing. Given that the exact chemical composition of the control samples was predetermined, three preparation techniques were employed in parallel. The study aims to achieve the fastest possible analytical workflow time without compromising the accuracy and sensitivity. For this reason, the role of saponification in the sample preparation was rigorously evaluated, focusing specifically on its impact on overall analysis speed and extraction efficiency.

2. MATERIALS AND METHODS

The nitrocellulose-based smokeless gunpowder samples used in this research were produced within the last six months at "Milan Blagojević – Namenska" factory.

These samples vary in shape and size and were specifically chosen to demonstrate the diversity of nitrocellulose powders, not only in terms of composition and application but also regarding grain geometry and dimensions. As can be seen in Figure 1, nitrocellulose-based gunpowder can take on various forms depending on the desired burning rate and the specific purpose of the system it serves. Because these physical properties significantly influence ballistic performance, the development of a universal method applicable under identical conditions to all types of gunpowder and rocket fuel is essential. Establishing such a standard aims to unify methodology across the field, ensuring that analytical results remain consistent and comparable regardless of the propellant's specific geometry and compositions.

Figure 1. from left to right: samples of NGB 261, NC-27 and SB 715

Information regarding the selected non-energetic organic compounds (diphenylamine – DPA, ethyl centralite -EC, dibutyl phthalate – DBP, camphor – camp, triethyl acetate -TAC) of the ten selected powders is presented in Table 1. However, since all compositions are currently in operational use, the disclosure of complete formulations or the mass fractions of individual components is restricted.

Table 1. Selected samples of gunpowder

Sample name	Non-energetic organic compounds				
	DPA	EC	DBP	Camp	TAC
NC-46	+			+	
NC-27	+				
NC-49	+				
NC-261	+		+		
SB 620	+	+			
SB 511	+		+		
SB 411	+				
SB 715	+		+		
NGB 051		+			+
NGB 161		+			+

2.1. Gas chromatography

Gas chromatography with a capillary column works by vaporizing a sample and carrying it through a thin, long column using an inert carrier gas. Inside the column, components are separated based on their unique chemical affinity for the stationary phase coating the internal walls. Each gunpowder organic component exits the column at a specific retention time, allowing the detector to identify and quantify them individually.

In this research, for separation, identification and quantification of components of interests, Agilent gas chromatograph model 7890 with flame ionization detector (FID), with autosampler, was used. Capillary column HP-5 has been employed as separating tool. The chromatographic conditions were as follows:

- Injector temperature: 130 °C,
- Initial oven temperature: 130 °C,
- heating rate of 10 °C/min,
- final temperature of 210 °C,
- Detector temperature: 300 °C,
- Carrier gas: Hydrogen (H_2),
- Hydrogen flow rate: 25 mL/min,
- Air flow rate: 400 mL/min.

While high-performance liquid chromatography (HPLC) [9-12] is the recommended method for analyzing older powders, due to the tendency of diphenylamine (DPA) derivatives to convert back into DPA at the elevated temperatures required by GC, creating a false representation of the active stabilizer content, GC remains a highly favorable method for the quality control of new powders because economic and ecologic efficiency. In newly manufactured powders, the DPA has not yet had time to degrade into its derivatives, therefore, the risk of thermal reversion is non-existent, and the results remain accurate. Furthermore, GC offers several technical advantages for these samples: superior column resolution, high precision separation of other components in

gunpowder (especially if sample contain nitroglycerin (NG), dinitrotoluene (DNT) and trinitrotoluene (TNT).

3. EXPERIMENTAL PART

All ten selected powders were prepared using three different methods, with each test performed in duplicate. Since the powders are intended for ammunition up to 20 mm and possess a small original grain size, no preliminary grinding of the samples was required.

3.1. Sample preparation in methanol

A sample of gunpowder 1.000 ±0.001 g was weighed and transferred into a 100 cm^3 volumetric flask. Methanol was added to half of the flask's volume, and the mixture was left for 4-6 hours. Subsequently, the flask was filled to the mark with methanol and agitated on a magnetic stirrer for 6 to 8 hours. The sample requires centrifugation to facilitate nitrocellulose precipitation before proceeding with further analytical steps. A 20 cm^3 volume of the prepared solution was pipetted into a 50 cm^3 volumetric flask, followed by the addition of 5 cm^3 of the internal standard solution (1.5 g dimethyl phthalate dissolved in 250 cm^3 of methanol), and then diluted to the mark with methanol. The sample was then transferred to a vial for autosampler, as it can be seen in Figure 2. To obtain satisfactory results, it is essential to pass the solution through a 0.5 µm PTFE filter prior to usage.

Since an internal standard was introduced into the sample, the concentration of the analyzed substances is calculated using the following equation (1):

$$A = \frac{P_A}{m_u * P_{IS}} * k_A \qquad (1)$$

Where are:

- k_A - mean value of two replicates of proportionality constant for the analyzed component, calculated by instruction from [8]
- m_u - sample mass (g),
- P_A - peak area of the analyzed component (%),
- A - content of the analyzed component in the gunpowder sample (%),
- P_{IS} – peak area of the internal standard (%).

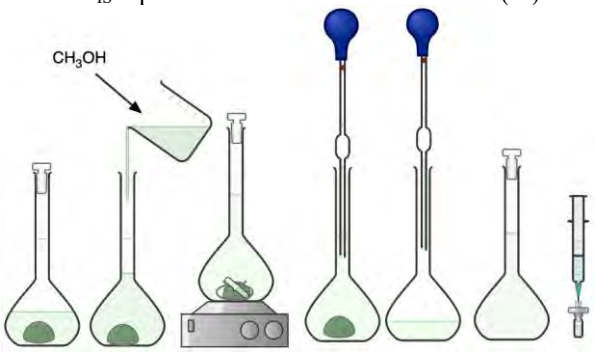

Figure 2. Sample preparation in methanol, from left to right: sample with ½ volume of methanol for 4-6 h, adding methanol to full volume into the flask, stirring sample for 6-8 h, 20 cm^3 volume pipetted and transferred into the new flask, followed by the addition of 5 cm^3 of the internal standard solution, filtrating sample and transferring it to vial

In a 50 cm^3 volumetric flask, weigh the required amount of the component to be determined for calibration and add 25 cm^3 of solvent. Subsequently, add 5 cm^3 of the previously prepared internal standard solution, then dilute to the mark with the solvent. Calibration is performed using standard solutions by testing the organic components under the same chromatographic conditions used for determining organic additives in gunpowder samples.

The calculation of the proportionality constant is performed according to the following equation (2):

$$k_A = \frac{m_A * P_{IS}}{P_A} * 100 \qquad (2)$$

Where are:

- k_A - proportionality constant for the analyzed component;
- m_A - mass of the component weighed for the preparation of calibration solutions (g);
- P_A - peak area (signal) of the analyzed component (%);
- P_{IS} - peak area of the internal standard (%).

3.2. Sample preparation in dichloromethane

A sample of gunpowder 1.000 ±0.001 g was weighed and transferred into a 50 cm^3 volumetric flask. Dichloromethane was added to half of the flask's volume, and the mixture was left for 24 hours, as it can be seen in Figure 3, step by step.

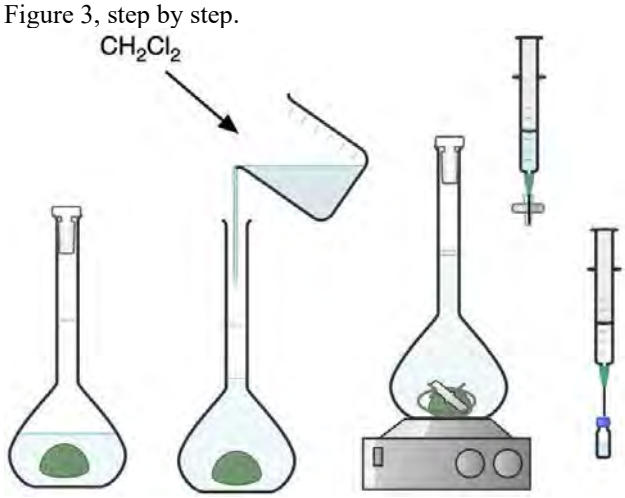

Figure 3. Sample preparation in dichloromethane, from left to right: sample with ½ volume of dichloromethane 24h left in dark place, introducing 5 cm^3 internal standard and adding dichloromethane to full volume into the flask, stirring sample for 4-6 h, filtrating sample and transferring it to vial

Subsequently, the in flask was added 5 cm^3 of the internal standard solution (1.5 g dimethyl phthalate dissolved in 250 cm^3 of dichloromethane) and filled the flask to the mark with dichloromethane. Sample prepared into that manner was agitated on a magnetic stirrer for 4 to 6 hours. The undiluted sample was then transferred to a vial for autosampler. To obtain satisfactory results, it is essential to pass the solution through a 0.5 µm PTFE filter prior to usage. With the internal standard incorporated, the

calculation of target component concentrations is performed using equations (1) and (2) from the section 3.1.

3.3. Sample preparation by saponification

Approximately 5 g of gunpowder was weighed into a flat-bottomed flask, followed by the addition of 80 cm^3 of a 20% (m/m) NaOH solution. The apparatus was assembled for reflux using a reflux condenser. The flask was placed on a heating mantle and refluxed for approximately 2 hours. Without removing the condenser, the flask was cooled in a water bath to room temperature. The condenser was then rinsed with 15 to 25 cm^3 of dichloromethane (Figure 4), and the contents of the flask were transferred to a laboratory separatory funnel, which was firstly added 200 cm^3 of a 5% (m/m) NaCl solution.

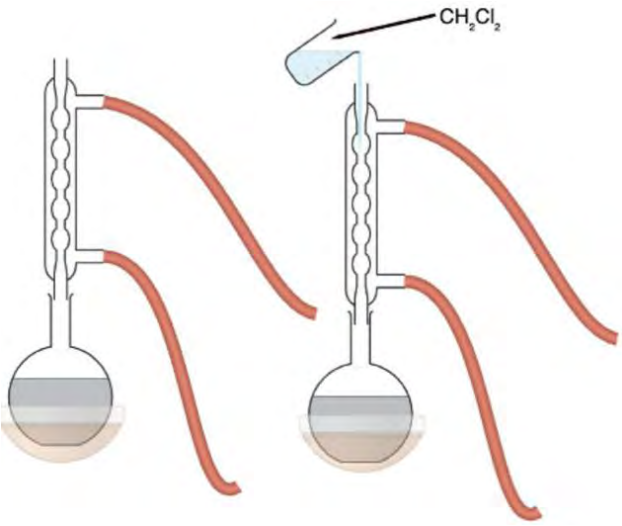

Figure 4. Heating solution of gunpowder and NaOH with reflux for 2h, colling down to the room temperature and rinsed by dichloromethane

The content in separatory funnel was then stoppered and shaken vigorously. The lower layer from the funnel was transferred into a 200 cm^3 volumetric flask. The extraction process from the flask and the separatory funnel was repeated twice more with dichloromethane to ensure quantitative transfer is done. The volumetric flask was then filled to the mark with dichloromethane, as it can be seen in Figure 5.

The sample prepared in this manner was used for the determination of organic components via gas chromatography as follows: 5 cm^3 of the internal standard was added to a 50 cm^3 volumetric flask, which was then filled to the mark with the previously prepared sample. The prepared sample was transferred without dilution into a vial, from which it was injected into the chromatographic column via autosampler or manual injection. At least two replicates were prepared and analyzed for each gunpowder sample.

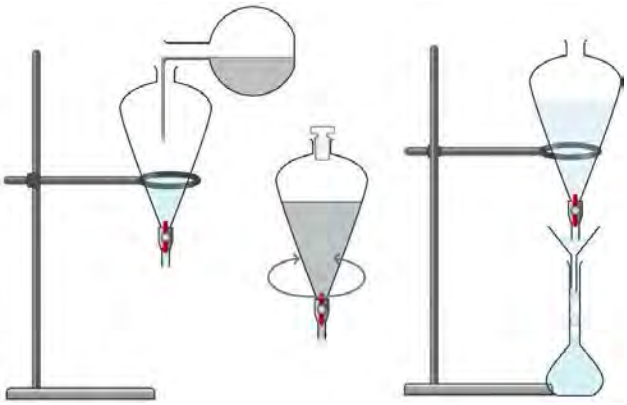

Figure 5. Separation process by using separatory funnel

For the quantification of the target components, it is necessary to prepare calibration solutions for all analyzed components within an appropriate concentration range. Calibration is performed under the same chromatographic conditions as those used for sample testing.

4.RESULTS AND DISCUSION

The stabilizer and other non-energetic organic components content for four different singlebase gunpowder, for all three sample preparation technique, are presented in Table 2. The results were reported as mass percentages, scaled to two decimal places.

Table 2. Results of measuring of other non-energetic organic compound in selected single-based gunpowder

Sample name	Non-energetic organic compounds			
	sample prep.	DPA	DBP	Camp
NC-46	dichloromethane	1.30	/	1.34
	methanol	1.32	/	1.36
	saponification	1.26	/	1.29
NC-27	dichloromethane	1.53	/	/
	methanol	1.50	/	/
	saponification	1.52	/	/
NC-49	dichloromethane	1.33	/	/
	methanol	1.30	/	/
	saponification	1.28	/	/
NC-261	dichloromethane	1.46	3.36	/
	methanol	1.41	3.41	/
	saponification	1.42	/	/

As it can be seen, the relative error between different methods of sample preparation ranges from 1.9 to 2.1%. Furthermore, no consistent trend was observed to indicate that a specific preparation method systematically yields higher values across all sample types. Additionally, a notable deviation was detected in the results for each evaluated component across all three preparation protocols. Nevertheless, all observed values remain within an acceptable margin of error.

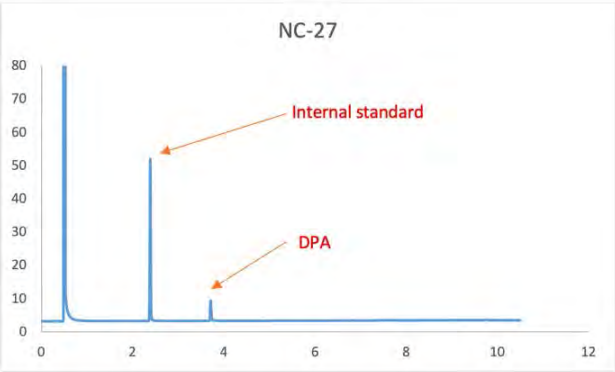

Figure 6. Chromatograms of single-base gunpowder NC-27, extraction in methanol

Regarding spherical (ball) gunpowder, the results for the determination of the content of non-energetic compounds, obtained by analyzing three selected compositions and employing three different sample preparation techniques, are presented in Table 3.

Table 3. Results of measuring of non-energetic organic compound in selected spherical (ball) gunpowder

Sample name	Non-energetic organic compounds			
	sample prep.	DPA	DBP	EC
SB-511	dichloromethane	1.33	5.30	/
	methanol	1.32	5.21	/
	saponification	1.31	/	/
SB-411	dichloromethane	1.37	/	1.32
	methanol	1.36	/	1.31
	saponification	1.39	/	1.30
SB-715	dichloromethane	1.18	6.61	/
	methanol	1.20	6.52	/
	saponification	1.18	/	/

For spherical powders, the determination of non-energetic organic components yields significantly better reproducibility. Specifically, the relative error is approximately 1%, and often lower, for the quantification of stabilizer and plasticizer contents across all three sample preparation techniques evaluated for GC analysis.

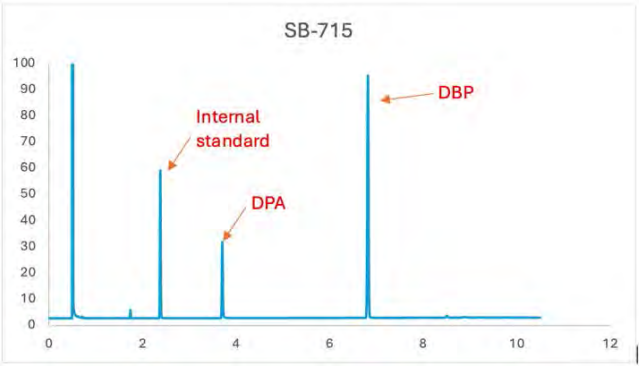

Figure 7. Chromatograms of spherical (ball) gunpowder SB-715, extraction in dichloromethane

Table 4. Results of measuring of non-energetic organic compound in selected double-based gunpowder

Sample name	Non-energetic organic compounds		
	sample prep.	EC	TAC
NGB-051	dichloromethane	1.79	0.40
	methanol	1.76	0.40
	saponification	1.79	/
NGB-161	dichloromethane	1.74	0.29
	methanol	1.79	0.28
	saponification	1.75	/

The results presented in Table 4 indicate nearly ideal agreement between the saponification and dichloromethane preparation protocols for double-base gunpowder. In contrast, the methanol-based preparation yields variations without a consistent trend, the values obtained by methanol preparation are higher for one sample but lower for another. For the stabilizer content, the relative error ranges between 1% and 1.5% when evaluating the results across all three sample preparation technique.

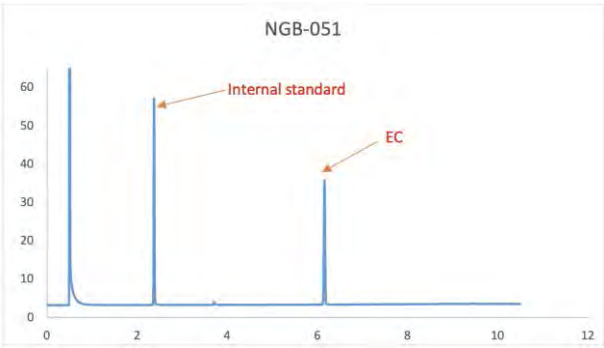

Figure 8. Chromatograms of double-base gunpowder NGB-051, preparation by saponification

5. CONCLUSION

This study focused on evaluating diverse sample preparation methods for gas chromatographic analysis to determine primaly stabilizer and secondary, the other non-energetic compounds in propellants, which serve as essential intermediate and final quality control parameters in manufacturing plants. Based on the findings, every evaluated preparation protocol provides highly reproducible data. The maximum relative error was observed in single-base powders, though it strictly remained below 2.5%, while for all other propellant types, this value was approximately 1% or lower. The primary advantage of the saponification method lies in its rapid sample processing time, less then few hours, compared the other two which demand more between 14 and 30 hours. However, it lacks the capability to determine DBP and triacetin (TAC). Consequently, saponification represents the method of choice when rapid turnaround times are required to obtain immediate feedback on stabilizer concentrations. These stabilizers are critical factors for propellant stability and constitute the primary checkpoint during in-process monitoring, final product

release, and throughout the entire propellant lifecycle. Nevertheless, if the analytical objective requires the comprehensive determination of all non-energetic compounds within the formulation, preparation via methanol or dichloromethane extraction becomes the preferred approach.

Although sample preparation for HPLC is less time-consuming, GC offers a far higher justification, thus, the results of this research carry significant value, as they provide critical insights into the capabilities of various preparation techniques to deliver reliable results through a method that, while perhaps not time-efficient, remains fundamentally sound from both an economic and ecological perspective. The utilization of GC offers distinct advantages, particularly in high-throughput industrial settings such as gunpowder factories, where numerous routine samples are analyzed daily. Economically, GC significantly minimizes operational expenses by employing inert carrier gases instead of the expensive, high-purity solvents required as mobile phases in HPLC. Furthermore, it mitigates the substantial costs associated with high-pressure pump maintenance and column degradation caused by aggressive solvent. From an environmental standpoint, GC operation is fundamentally cleaner and more sustainable, as it virtually eliminates the generation of hazardous liquid chemical waste, thereby bypassing the stringent and costly disposal regulations inherent to HPLC operations. Consequently, for routine quality control in manufacturing plants with heavy daily sample loads, GC represents a highly cost-effective and ecologically viable analytical framework.

Abstract: *Determining the mean ballistic pressure (MBP) of the propellant gases in small-caliber weapon barrels is essential for the analysis and design of weapon systems. This paper presents a method for its estimation based on the energy balance of the propellant charge, utilizing established internal ballistics models.*
A simple analytical method is proposed under the assumptions of an adiabatic process, ideal gas behavior, and the quasi-stationary flow hypothesis. Based on these assumptions, standard internal ballistics relations were applied to determine the parameters required to calculate the mean ballistic pressure at the moment of projectile muzzle exit, establishing its relationship with the internal energy of the propellant charge.
Experimental validation was performed using piezoelectric pressure sensors mounted on a test barrel. The measured values of the propellant gas pressure were compared with the calculated results of the mean ballistic pressure. The agreement between them was analyzed to evaluate the accuracy and reliability of the proposed method. The results show that the method provides a practical and sufficiently accurate tool for estimating the mean ballistic pressure (MBP) of propellant gases in engineering applications.

Keywords: *mean ballistic pressure, propellant gas energy, interior balistics, Resal's equation, Piobert's Formula*

1. INTRODUCTION

For small arms designers who develop muzzle devices, a necessary data point is the value of the mean ballistic pressure (MBP) at the moment the projectile leaves the barrel. An interior ballistic (IB) calculation provides this data. A problem arises when not all required propellant characteristics, as well as the design features of the cartridge and the weapon necessary for a reliable IB calculation, are known.

Therefore, a need exists in practice for a simplified calculation method that does not require detailed IB data to calculate the MBP. For this method, analytical expressions were developed using the known laws of interior ballistics under certain assumptions and corresponding simplifications. These formulas allow the calculation of the MBP value based on the energy balance of the propellant charge at the moment of projectile muzzle exit. Interior ballistics is the science that studies the processes leading to the movement of a projectile inside the weapon barrel under the action of propellant gases formed by the combustion of the propellant charge. The totality of phenomena occurring in the barrel from the moment of propellant charge ignition to the moment the outflow of propellant gases from the barrel ends after projectile exit is called the firing process. High pressure and temperature values of the propellant gases, along with a short duration, characterize the firing process. The firing process is divided into four periods: the preparatory (pyrostatic) period, the first (pyrodynamic) period, the second (thermodynamic) period, and the period of muzzle after-effect period [1].

The period of time from the exit of the projectile until the moment when the projectile leaves the stream of powder gases is called the period of muzzle after-effect period of the propellant gases on the projectile, while the period up to the moment when when the pressure of the powder gases equalizes with the atmospheric pressure is called the period of muzzle after-effect period of the propellant gases.

Corresponding author: S. Orašanin;
E-mail: orsasniper@gmail.com
DOI: 10.5937/OTEH26045O

Developing calculation methods for the projectile's motion parameters is the primary task of interior ballistics. When solving the primary task of interior ballistics, the first three periods are considered, while the period muzzle after-effect period of the propellant gases is not considered [2]. In classical methods of interior ballistics (IB), introducing the concept of the so-called mean ballistic pressure (MBP) into calculations is customary, whereby it is further assumed that both the pressure and temperature of the propellant gases at a given moment in time are equal throughout the entire working volume of the barrel bore.The concept of mean ballistic pressure is defined such that its work is equal to the total work of the propellant gases in the barrel, and that at a specific moment, it is equal at all points of the space behind the projectile. This pressure is called the mean ballistic pressure (MBP), assuming that the propellant burns under this mean pressure [1].The focus of this research is to determine the applicability of simplified analytical models for calculating mean ballistic pressure (MBP) using conventional interior ballistics (IB) formulas for engineering purposes. Their verification will be carried out by comparing the calculated MBP results with the experimental mean values of pressures measured by piezoelectric pressure sensors. The calculated MBP result was obtained using simplified analytical IB models based on the energy balance of the propellant charge for the case of complete combustion of the propellant charge at the moment of projectile muzzle exit.

2. ANALYTICAL MODELS

Two analytical models of classical interior ballistics will be briefly described, based on: Resal's equation (for calculating the mean ballistic pressure) and the formulas of Piobert and Mamontov (for calculating the pressure distribution along the barrel) at the moment of projectile muzzle exit, assuming complete combustion of the propellant charge.

The main assumptions under which these analytical models were derived are that the firing process is:

-adiabatic

-that the pressure, temperature, and density of the propellant gas mixture have identical values across all parts of the volume behind the projectile base at any instant of time t (the quasi-steadiness / quasi-stationary hypothesis).

-the composition of the combustion products does not change during firing, and the specific heat capacity of the gases at constant pressure $c_p=k\cdot R/(k-1)$ and constant volume $c_w=R/(k-1)$ remains the same and has an average value for the entire range of temperature variation; consequently, the adiabatic index $k=c_p/c_w$=const. Also, the gas constant (R) is invariant (constant) throughout the process

-The velocity of the propellant gases in the volume behind the projectile along the barrel varies linearly from zero at the breech to the velocity of the projectile, and the gas flow is one-dimensional.

-The barrel is cylindrical; the expansion of the powder chamber is neglected.

-The barrel remains stationary during firing.

2.1. Resal's Equation – Energy Balance Equation

The calculation of the mean ballistic pressure in the barrel at the moment of muzzle exit is based on the fundamental equation of interior ballistics. The French engineer Henri Resal first derived this equation in 1864. He based it on the first law of thermodynamics regarding the conservation of energy. This law applies to a thermodynamic system that includes both mechanical and thermal energy. The relation was named **Resal's equation** after its author.

Resal's equation applies to:

-Closed thermodynamic systems (energy exchange with the surroundings)

-Open thermodynamic systems (energy and mass exchange with the surroundings) [3].

In internal ballistics, Resal's equation represents the fundamental energy balance equation (the law of conservation of energy). It links the released energy of the propellant combustion and the potential energy of the propellant gases with mechanical work-the main and useful part of which equals the kinetic energy of the projectile-and losses within the firearm barrel.The mathematical formulation of Resal's equation, applied to the case of complete combustion of the propellant charge in the barrel at the moment of projectile muzzle exit before the onset of gas efflux, is:

$$Q= U +\varphi\cdot E_o \quad (1)$$

The total amount of heat (Q) released by the complete combustion of the propellant charge in the firing process

$$Q= \omega \times Q_{sp} \text{ [J]} \quad (2)$$

Unused internal energy of the propellant gases:

$$U =pW/(k-1) \text{ [J]} \quad (3)$$

The basic or useful mechanical work is the energy imparted to the projectile for its motion and is expressed through the kinetic energy of the projectile (muzzle kinetic energy of the projectile, E_0) plus the total secondary work and losses (φ).

$$\varphi \cdot E_o = \varphi \left(\frac{1}{2} q\cdot V_o^2\right) \text{ [J]} \quad (4)$$

The symbols used in the equations are:

ω [kg] - mass of propellant charge

Q_{SP} [J/kg] - specific energy of the propellant

q [kg] - projectile mass

V_0 [m/s] -projectile muzzle velocity

$\varphi=K + \frac{1}{3}\omega/q$ - coefficient of projectile fictitious mass which takes into account the total secondary work of the propellant gases in the barrel (work expended on the rotational motion of the projectile, overcoming friction, movement of gas);

K = 1,1 - coefficient which, according to Slukhotsky, has this value for small arms [1]

W[m^3]- total working (free) volume of the bore behind the projectile at the moment it leaves the muzzle

k- adiabatic index; for small arms propellants, a value of k = 1.25 is used [1]

The value of the mean ballistic pressure in the barrel volume at the initial moment of outflow can be analytically approximated, for the case of complete combustion of the propellant charge in the barrel bore, from expression (3) for the unutilized internal energy

$$p=(k-1)\cdot U/W \quad (5)$$

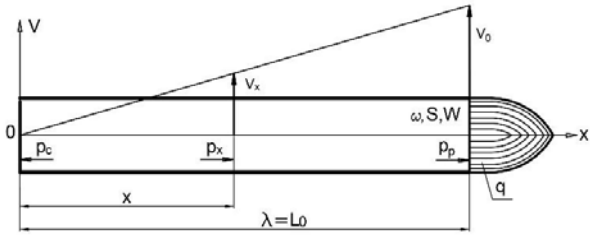

Figure 1. Schematic representation of the barrel at the moment the projectile leaves the muzzle

2.2.Piobert's Formula – Propellant Gas Pressure Distribution Along the Gun Bore Axis

During projectile motion, the propellant gases have different velocities at various cross-sections within the gun bore. These velocities range from zero at the breech end of the bore to the projectile velocity in the gas layer adjacent to the projectile base. Due to the accelerated gas flow through the bore volume, the pressure varies across different cross-sections of the barrel. The pressure distribution in the sections behind the projectile base depends on multiple factors. A functional relationship incorporating all of them would be highly complex and impractical for engineering calculations

Therefore, in conventional interior ballistics, the pressure distribution of propellant gases along the bore axis between the stationary breech face and the moving projectile is calculated using simplified equations, often referred to as Piobert's formulas. These formulas establish a relationship between the mean gas pressure (p), the breech pressure (p_C), and the projectile base pressure (p_p). The relationship between the mean ballistic pressure (p) and the projectile base pressure (p_p) is defined by the following expression:

$$p=p_p\left(1+\frac{1}{3}\frac{\omega}{\varphi_1 q}\right) \quad (6)$$

φ_1=1.05 - The value of the partial coefficient of fictivity for small arms ammunition with a full metal jacket (FMJ) lead-core projectile [1].

Equation (6) is Piobert's formula (French general and scientist Guillaume Piobert), which accounts for the forces resisting the projectile's motion (φ_1), as proposed by the Russian engineer P. N. Shkvornikov [1].
The relationship between the pressure at the breech face (p_c) and the pressure at the base of the projectile (p_p) is determined by the expression:

$$p_c=p_p\cdot\left(1+\frac{1}{2}\frac{\omega}{\varphi_1 q}\right) \quad (7)$$

A contribution to the further upgrade of Piobert's formula was made by the Russian engineer M. A. Mamontov [4]. He correlated the dependence between the pressure at a distance "x" from the breech face and the pressure at the base of the projectile (p_p) (Figure 1). The formula was applied to the case when the combustion of the propellant charge is completed at the moment the projectile leaves the muzzle, and is given by the expression:

$$p_x=\left[1+\frac{1}{2}\frac{\omega}{\varphi_1 q}(1-z^2)\right]p_p \qquad z=x/\lambda \quad (8)$$

3. RESULTS

In order to compare the calculated results with experimental data, bore pressure measurements of the propellant gases must be conducted. An EPVAT*(Electronic Pressure Velocity and Action Time)* 7.62x51mm test barrel was selected as the test case. Firing was conducted using 7.62x51mm M80 FMJ BT 9.4g/145gr reference ammunition, manufactured by Prvi Partizan AD, Užice. The ammunition was loaded with propellant manufactured by Milan Blagojević-Namenska AD, Lučani. Ammunition and propellant data were provided by the manufacturers. Two measurement ports for piezoelectric transducers were configured on the 7.62x51mm EPVAT test barrel in accordance with NATO STANDARD AEP-97 [5] to record pressure-time curves. The measurement port on the test barrel (Figure 2.) with abscissa x_1, as specified by standard, records the maximum barrel pressure (p_m), while the measurement port with abscissa x_2 records the maximum gas port pressure (p_g).Firing was conducted from the test stand using the selected test barrel.

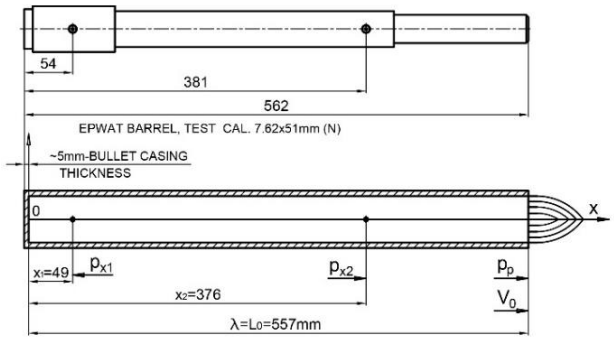

Figure 2. Location of piezoelectric transducers on the EPVAT test barrel (top) and schematic diagram of the barrel with abscissas of the gauge positions in the barrel bore (bottom)

The measurement system is initiated upon firing, precisely at the moment the firing pin strikes the cartridge primer. For each round fired from the selected test barrel, pressure was measured at two gauge ports, and the projectile muzzle velocity was recorded. The projectile exit time from the barrel (t_{ex}) was measured using a stop probe, and the corresponding pressure value at that specific instant was read from the recorded pressure curve. Pressure measurements were performed using a Kistler 6215 piezoelectric transducer. The muzzle velocity

was measured at a distance of 2.5 meters from the muzzle. The measurements and test-firings were conducted in the ballistic tunnel of the Agency for Testing, Stamping and Marking of Weapons, Devices and Ammunition in Kragujevac.

Table 1 lists the data for the selected cartridge (q, ω , V_0), propellant (Q_{sp}, k), data for the selected test barrel-specifically the barrel bore volume (W)-and the value of the total coefficient of projectile fictitious mass (φ)for small arms, as defined by classical interior ballistics (IB). The barrel bore volume (W) comprises the volume of the main bore (bore guide) and the internal volume of the empty cartridge case inserted into the barrel chamber.

The specified data are sufficient to calculate the mean ballistic pressure (MBT) in the barrel at the moment the projectile leaves the muzzle. By substituting the stated data into expressions (1)–(5), the theoretical value of the MBP was calculated in Table 1, amounting to 616 x10^5 [Pa].Table 2. presents the mean values for twenty indipedent firing measurements: the peak pressures for both gauge locations and the measured projectile velocity values extrapolated to the muzzle. The measured projectile velocities and peak pressures at both gauge locations met the criteria regarding both the magnitude of the measured values and the dispersion of the results; therefore, the ammunition lot can be considered a representative sample. The composite diagram of the p(t) pressure curves for both gauge locations is shown in Figure 3.

Table 1. Mean barrel pressure (p) values based on the energy balance for the 7.62x51mm M80 FMJ BT 145 gr PPU cartridge.

Projectile mass q ×10^{-3} [kg]	9.4
Mass of powder charge: ω×10^{-3} [kg]	2.94
Length of test tube L_c [m]	0.56
Bore cross-sectional area S×10^{-4} [m^2]	0.4571
Total working (free) volume of the bore W×10^{-4} [m^3]	28
Muzzle velocity V_0 [m / s]	840
Muzzle kinetic energy of the projectile E_0 =(q·V^2)/2 [J]	3316
Propellant: Spherical, Milan Blagojević-Lučani	SB520
Specific energy of the propellant Q_{sp} [J / g]	3700
Total energy of propellent charge: ω·Qsp [J]	10878
Total coefficient of coefficient of projectile fictitious mass: φ= K + $\frac{1}{3}$ ω/q; K=1.1	φ =1.2
Fictitious muzzle energy of the projectile: φ·E_o [J]	3979
Internal energy of propellant gases in the barrel bore: U= ω·Q_{sp} - φ·E_o [J]	6899
Adiabatic index; for small arms propellants: k	1.25
Calculated mean ballistic pressure in the bore at muzzle exit: p_o=(k-1)·U/W ×10^5 [P a]	**616**

In order to compare the obtained pressure measurement results (Table 2) with the theoretical MBP (Mean Ballistic Pressure) value calculated via the propellant charge energy balance, it is necessary to recalculate the measured values using the Piobert and Mamontov formulas. In formula (8), pressure p_x is a known, measured value, while the pressure at the projectile base (p_p), i.e., at the muzzle, as well as the mean ballistic pressure (p), must be determined from formulas (8) and (6). Therefore, by correcting the measured pressure values, the pressure values at the projectile base and the mean ballistic pressure (p) were determined and are presented in Table 3 for both measurement locations.

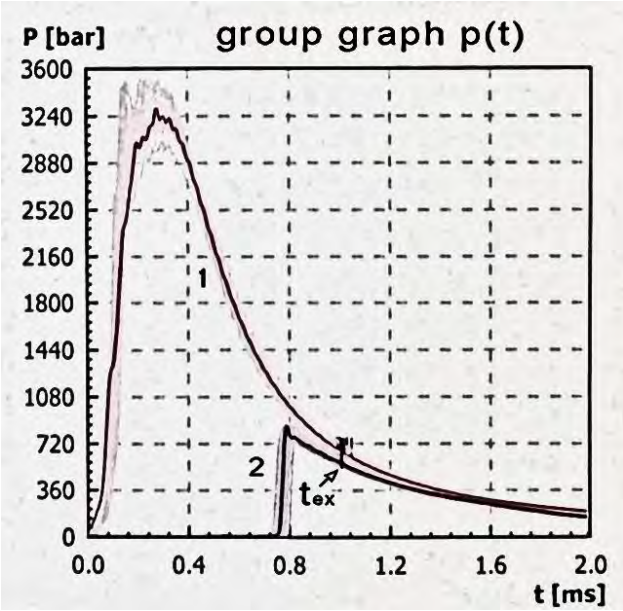

Figure 3. Combined plot of pressure-time curves p(t) for both gauge locations: x_1 (1) and x_2 (2). The projectile muzzle exit time (t_{ex}) was determined by a stop probe and is indicated on the graph by a vertical tick mark. The bold curves represent the mean pressure curves from twenty measurements.

Table 2. Mean measured pressure values at measuring points x_1 and x_2

Measuring point **(Figure 2.)** x [mm]	x_1=49	x_2=376
Mean values of measured max pressures p_m ×10^5[Pa]	p_{m1}=3298.6	p_{m2}=848.6

$p=\left(1+\frac{1}{3}\frac{\omega}{\varphi_1 q}\right)\cdot p_p$ Formula (6)	p_1= 1.09929$\cdot p_{p1}$	p_2= 1.09929$\cdot p_{p2}$
Calculated mean ballistic pressure in the bore at muzzle exit $p \cdot 10^5$[Pa]	**p_1=624.6**	**p_2=572**

4. DISCUSSION

The value of the mean ballistic pressure (MBP) calculated (Table 1) via the propellant charge energy balance (616 × 10^5 [Pa]) practically matches the MBP value obtained by correcting the mean measured value at gauge station x_1 (624.6 × 10^5 [Pa]), being lower by 1.4% (Table 4). When compared to the mean pressure obtained by correcting the mean measured value at gauge station x_2 (572 × 10^5 [Pa]), it is higher by 7.7% (Table 4). The mean ballistic pressure (MBP) calculated using the analytical propellant charge energy-balance method is in very good agreement with the reference value at the first gauge station, (x_1), where the pressure difference is negligible, while at the second gauge station, (x_2), the difference remains within an acceptable range.

The advantage of the analytical method for calculating the mean ballistic pressure (MBP) is its simplicity, as it does not require a detailed knowledge of propellant properties and the design characteristics of the projectile, weapon, and barrel, which are otherwise essential for a reliable internal ballistics (IB) calculation (Table 1).

All the previously mentioned simplifications and assumptions introduced herein aim to streamline the mathematical model and make it suitable for practical engineering calculations

Table 4. Comparative values of theoretical and empirical mean ballistic pressures (MBP) in the gun barrel bore

	Measuring point (**Figure 2.**)	x_1	x_2
4.1.	Pressure curve reading at muzzle exit $p_x \cdot 10^5$[P a]	656.4	564.8
4.2.	Mean ballistic pressure obtained by correcting the read value. $p_x \cdot 10^5$[P a]	**624.6**	**572**
4.3.	Calculated mean ballistic pressure in the bore at muzzle exit $p_0 \cdot 10^5$[P a]	**616**	**616**
4.4.	The relative difference between MBP (4.2) calculated in the bore at muzzle exit (p_0) and (4.3) obtained by correcting the read value (p_x)	-1.4%	+7.7%

In classical interior ballistics methods, it is common practice to neglect phenomena that do not significantly affect calculation accuracy and whose detailed consideration would greatly complicate the computation. Instead, these phenomena are accounted for using simple empirical formulas derived from experimental test results of similar weapon and ammunition models.

5. CONCLUSION

This paper addresses the evaluation of the mean ballistic pressure (MBP) in the bore behind the projectile of a small arms weapon at the instant of muzzle exit, utilizing the energy balance of the propellant charge under the condition of completed propellant combustion. The following conclusions can be formulated:

-Analytical expressions derived within classical ballistics, incorporating specific assumptions and relevant simplifications, enable the computation of the MBP based on the propellant charge energy balance and the pressure variation in the volume between the breech and the moving projectile;

-The derived theoretical MBP value, compared against empirical data measured via piezoelectric transducers, proves acceptable and sufficiently precise for engineering applications;

-The theoretical MBP value can serve as an initial/input value for the engineering design and calculation of muzzle devices (flash suppressors, muzzle brakes, recoil boosters, silencers);

-The primary advantage of the demonstrated analytical analytical method for MBP calculation is its simplicity, as it bypasses the need for in-depth data on propellant properties and the structural parameters of the

weapon, barrel, and ammunition required for reliable internal ballistics modeling.

Abstract: *Most pyrotechnic chains begin with electrical ignition using an electric igniter head. The reliability of electrical igniter heads (EIHs) represents one of the key factors governing the proper functioning of a pyrotechnic chain, since the mere occurrence of successful initiation is not sufficient for a complete assessment of the quality and functional compatibility of the igniter heads. The aim of this study was to develop an experimental method for the quantitative characterization and comparative evaluation of EIHs based on their pressure–time response. The tests were performed in a manometric chamber under controlled conditions, and the qualitative characteristics were determined using the maximum pressure, Pmax, ignition delay time, Tkp, time to maximum pressure, Tmax, and indicators of result variability within a tested series. Seven different types of EIHs were investigated. The obtained results enabled their comparative classification with respect to maximum pressure intensity, temporal characteristics, and repeatability. The study demonstrates that the combined characterization of maximum pressure, temporal response, and statistical variability provides a suitable basis for a more objective assessment of the quality and functional compatibility of electrical igniter heads.*

Keywords: *Electric igniter head, Manometric chamber, Maximum pressure, Delay time, Time to reach maximum pressure.*

1. INTRODUCTION

Electrical pyrotechnic initiators represent the initial elements of numerous pyrotechnic systems, and their primary function is to convert electrical energy into the thermal and chemical energy required to initiate a pyrotechnic chain. Their application encompasses a wide range of systems in which reliable and temporally precise initiation is required. Consequently, electrical initiators are expected to exhibit high reliability, reproducibility, and stable performance throughout their intended service life [1,2].

The mere fact that initiation was successfully accomplished is not always sufficient for a full assessment of the quality and functional compatibility of the initiator. Of particular importance are those characteristics that determine the response time of the initiator and the intensity of energy release, as deviations in these characteristics may affect the operation of subsequent elements in the pyrotechnic chain.

During an adaptation of a fuze for a new warhead model, certain deficiencies were observed with the use of the standardized electric igniter. During a series of tests, the EIH occasionally exhibited an inadequate response. It was assumed that an excessive amount of combustion products and soot could cause mechanical damage to the fuze components, resulting in improper and unreliable operation. Therefore, it was necessary to identify a

Corresponding author: J.Petković Cvetković
E-mail: jpetkovic82@gmail.com

DOI: 10.5937/OTEH26046P

suitable EIH capable of providing a more uniform energy release and a lower amount of soot in the combustion products. Since functional tests performed on the complete adapted fuze and tandem shaped-charge warhead assembly are complex and involve numerous variables, it was necessary to establish a method that would enable the rapid and reliable characterization of electrical igniter heads. [3,4]

The operation of an electrical initiator is based on the heating of an electrical initiating element, i.e., a bridgewire, by the passage of electric current. The released heat is transferred to the primary pyrotechnic charge and, once the temperature required for initiation is reached, an exothermic chemical reaction is initiated. This reaction results in rapid energy release and the formation of gaseous and condensed reaction products. [5]

When an initiator is tested in a closed volume, the gaseous reaction products cause an increase in pressure that can be recorded as a function of time. In this manner, the complex initiation process can be characterized on the basis of a measurable pressure–time response. Jang et al. [6] reported that the time interval between the application of electrical current and the onset of pressure generation can be defined as the ignition delay time, whereas the maximum pressure and the time required to reaching this pressure are associated with the combustion characteristics of the pyrotechnic material. [7]

The pressure–time relationship represents an important source of information regarding initiator behavior. Maximum pressure represents a measure of the intensity of the pressure response, whereas the time required to reach the maximum pressure provides information regarding the dynamics of the process. The ignition delay time, on the other hand, characterizes the interval between the application of the electrical stimulus and the onset of pressure development. According to the results reported by Jang et al., the ignition delay is primarily associated with the condition of the bridgewire and the contact between the bridgewire and the primary pyrotechnic charge, whereas the maximum pressure and the time required to reach it are more closely related to the combustion characteristics of the pyrotechnic material. [8]

The performance of an initiator is influenced not only by its design and the composition of the pyrotechnic charge but also by the conditions to which the initiator is exposed before and during testing. Temperature is one of the important factors that may affect the reaction rate and pressure development. [8]

In addition to the mean values of the characteristic parameters, reproducibility of the results is of great importance for quality assessment. Under practical manufacturing conditions, a certain degree of variability is unavoidable, meaning that individual initiators of the same type may not produce completely identical responses. Therefore, in addition to determining the mean values of the measured parameters, their dispersion should also be evaluated. Standard deviation is one of the basic measures of variability, while the coefficient of variation can be used to compare the relative dispersion of results between different groups.

Considering the above, reliable verification of the qualitative characteristics of electric igniter heads requires a method that simultaneously addresses time response, reaction intensity, pressure-development dynamics, and reproducibility of the results. Accordingly, the principal parameters considered for characterization are ignition delay time (t_{kp}), maximum pressure (P_{max}), maximum pressure arrival time (t_{max}), and the standard deviation of the results within the tested series.

The aim of this study is to define a method for verifying the qualitative characteristics of electric igniter heads based on their pressure-time response recorded in a pressure measurement chamber. Five different types of electric igniter heads will be investigated under controlled testing conditions. The obtained results will be used to analyze the selected characteristic parameters, compare their values, and evaluate the dispersion of results within each series. In this way, the study seeks to establish a method that enables an objective assessment of the quality and reproducibility of electric igniter heads and provides an appropriate basis for their verification.

2. MATERIALS AND METHODS

2.1. Materials

The experimental investigation was conducted using different types of electrical igniter heads (EIHs) in order to determine and compare their combustion characteristics. Five different types of electric igniter heads were investigated under controlled testing conditions and at a loading density of 0.01 g/cm³. In the initial phase of the investigation, standard electrical igniter labeled as MB-2N, MB-2NP1, and DISV types were analyzed. In the second phase, two series of modified EIH, MB-2N M and DISV M, were tested.

The investigated EIH types were selected because of differences in their design and manufacturing characteristics, which may result in differences in the intensity and dynamics of pressure development. The MB-2N and MB-2NP1 igniter heads are manufactured individually using a predominantly manual process, whereas DISV igniter heads are produced in comb-like assemblies, allowing entire series to be simultaneously immersed in a slurry of the initiating pyrotechnic composition. Additionally, these igniter heads feature different initial pyrotechnic mixture compositions. The MB-2N and MB-2NP1 igniter heads are based on potassium perchlorate and Lead (II) thiocyanate, and DISV based on Zirconium and Lead (II) oxide.

2.2. Testing Method

The electrical circuit resistance was measured for all samples from the five investigated EIH series with OM200 M, Trio Electronics Ltd, and EIHs with closely comparable resistance values were selected within each series in order to minimize the influence of electrical resistance on the ignition rate and, consequently, on the ignition delay time.

The characteristics of the EIHs were determined using a

closed manometric bomb, based on the measurement of pressure changes within a confined volume following activation of the electrical igniter head. The products generated during the pyrotechnic reaction produce an increase in pressure inside the chamber, and this pressure change is recorded as a function of time.

The application of the manometric method enables the behaviour of an EIH to be characterized by means of its pressure-time curve. This approach allows simultaneous analysis of the intensity of the generated pressure, the time response of the igniter, and the rate of pressure development. A similar approach has been applied in previous studies of electric pyrotechnic initiators, in which the Closed Bomb test was used to characterize initiator performance on the basis of the recorded pressure-time response. [9]

The pressure transducers used in the present study were designed for the measurement of static and dynamic pressures in liquids and gases. They are available in various measuring ranges, from 1 to 3000 bar. Transducers with measuring ranges between 0 and 3000 bar operate according to the strain-gauge principle. The strain gauge is located on the side of the measuring tube opposite the measurement medium and is enclosed within a hermetically sealed reference chamber, thereby protecting it from external environmental influences.

All five EIH series were tested in a modified manometric bomb [10] Figure 1., with a free volume of 2 cm^3, corresponding to a loading density of approximately 0.01g/cm^3. The setup was equipped with a calibrated PZ|IC pressure transducer with a measuring range of up to 200 bar.

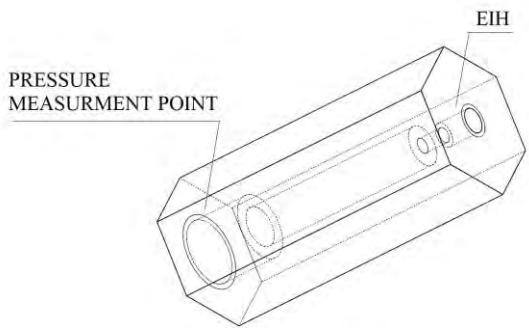

Figure 1. Modified manometric bomb used for testing electrical igniter heads.

The transducer housing was made of stainless steel and hermetically sealed the measuring system, thereby protecting it from harmful external influences and ensuring that the reliability and accuracy of the transducer were not impaired even under demanding operating conditions.

During the first phase of the EIH investigation, three types of igniter heads were assembled into the holders of the modified manometric bomb. The first series consisted of standardized MB-2N EIHs, for which deficiencies had previously been observed during operation in an adapted warhead fuze. The second series consisted of non-standardized DISV EIHs. Owing to their low production cost and high reliability, these EIHs are used in initiation chains during internal investigations of various pyrotechnic elements. The third series consisted of MB-2NP1 EIHs, which are also standardized EIHs. They are manufactured using the same technology as MB-2N EIHs, but differ in the composition of the initiating pyrotechnic mixture.

The investigated EIHs were subsequently modified. First, the MB-2N EIH was modified, designated MB-2N M, by reducing the amount of initiating pyrotechnic composition applied to the bridgewire. Specifically, the igniter head was immersed in the initiating composition once instead of twice.

The DISV EIH was modified, designated DISV M, only in terms of its design, without changing the composition of the initiating pyrotechnic mixture. A protective sleeve was designed and placed around the igniter head in order to provide a directed effect required for its application in warhead fuzes.

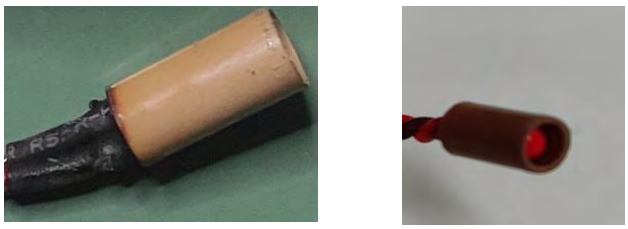

Figure 2. Modified, DISV-M and MB-2N M, electrical igniter heads.

2.3. Determination of Characteristic Parameters

The pressure-time response obtained during testing of the electrical igniter heads was characterized by four time parameters: T_{start}, T_{max}, T_{km}, and T_{kp}. T_{start} denotes the onset of the recorded pressure response, whereas T_{max} corresponds to the time at which the maximum pressure, P_{max}, is reached. The pressure-development time, T_{km}, was calculated as:

$$T_{km}=T_{max} - T_{start}$$

Unlike T_{start} and T_{max}, which represent absolute time coordinates, T_{km} represents the duration of the pressure-development phase from the onset of the pressure response to the attainment of P_{max}.

T_{kp} represents the ignition delay time, defined as the time interval between application of the electrical activation pulse and the onset of the recorded pressure response. If (T_0) denotes the reference time corresponding to the application of the electrical pulse, T_{kp} is calculated as:

$$T_{kp}=T_{start} - T_0$$

where T_0 denotes the reference time corresponding to the application of the electrical pulse.

For the investigated EIH types, an extensive set of statistical methods is not required. The basic statistical analysis includes determination of the mean value, standard deviation, and coefficient of variation.
Mean value:

$$\bar{x} = \frac{1}{N}\sum_{i=1}^{N} x_i$$

Standard deviation:

$$s = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}(x_i - \bar{x})^2}$$

Coefficient of variation:

$$CV = \frac{s}{\bar{x}} \times 100\%$$

3. RESULTS AND DISCUSION

For all samples belonging to the five investigated EIH series, the electrical circuit resistance was measured, and EIHs within a narrow resistance range were selected in order to minimize its influence on the ignition rate and, consequently, on the ignition delay time. Table 1 presents the applicable resistance requirements according to the relevant internal standards, together with the measured resistance ranges of the tested samples.

Table 1. Required and measured resistance range

EIH type	Required resistance range [Ω]	Measured resistance range [Ω]
MB-2N	2,5-4,5	2,92-3,31
MB-2NP1	0,6-1,2	0,93-1,06
DISV	1,5-2,5*	1,75 – 1,94
MB-2N M	2,5-4,5	2,92-3,31
DISV M	1,5-2,5*	1,67 – 1,91

*For DISV EIHs, the resistance value is not defined by a formal standard; the indicated range represents the range used for sample selection during the present investigation.

Tables 2–4 present the measured values of maximum combustion pressure, ignition delay time, and pressure-development time. For the first three EIH groups, MB-2N, MB-2NP1, and DISV. The pressure variation as a function of time is also presented graphically in Figures 3 for the MB-2N EIHs.

Table 2. Maximum combustion pressure, ignition delay time, and pressure-development time for the MB-2N EIHs

	T_{kp}[s]	T_{km}[s]	P_{max}[bar]
MB2N_1	0,0054	0,0099	10,8780
MB2N_2	0,0053	0,0095	10,9207
MB2N_3	0,0108	0,0099	9,5658
MB2N_4	0,0069	0,0104	11,7066
MB2N_5	0,0081	0,0103	14,8482
MB2N_6	0,0060	0,0102	12,9888
MB2N_7	0,0066	0,0100	10,0929
Mean value	0,0070	0,0100	11,5716
St.deviation	0,0019	0,0003	3,3129

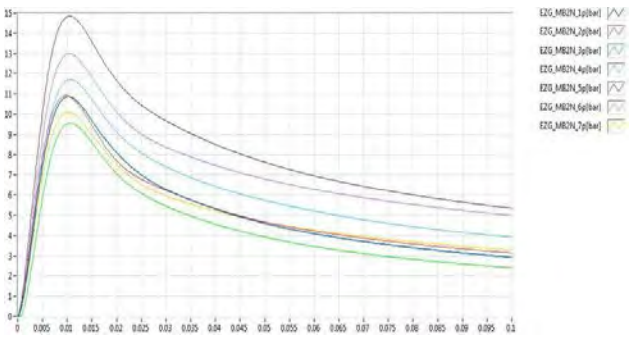

Figure 3. The pressure variation as a function of time for the MB-2N EIHs

The measured maximum pressure values for the MB-2N EIHs ranged from 9,56 to 14,85 bar, with a mean value of 11,57 bar and a standard deviation of 3,31. The range of the results indicates relatively pronounced variability in the maximum pressure among individual samples. A coefficient of variation of approximately 28.6% further demonstrates that the differences between the samples are not negligible relative to the mean response level obtained. This variability is likely attributable to the manufacturing process, specifically to variations in the amount of pyrotechnic composition applied to the initiator element, which most likely points to the underlying causes of failures and problems encountered during its application in the fuze of the warhead.

From the perspective of quality control, this result demonstrates that the behavior of the tested samples cannot be characterized solely by the mean value; the stability of the response from sample to sample must also be considered. In contrast to the observed variation in Pmax, the pressure-development times were highly consistent, ranging from 0,95ms to 1,04 ms with a standard deviation of 0,0003. This is the result of a narrow resistance range of selected group.

Table 3. Maximum combustion pressure, ignition delay time, and pressure-development time for the MB-2NP1 EIHs

EIH type	T_{kp} [s]	T_{km} [s]	P_{max}[bar]
MB2NP1_1	0,0016	0,0016	9,055
MB2NP1_2	0,0005	0,0015	11,675
MB2NP1_3	0,0007	0,0045	7,711
MB2NP1_4	0,0014	0,0013	8,952
MB2NP1_5	0,0026	0,0052	7,212
Mean value	0,0014	0,00282	8,920
St.deviation	0,00018	0,00187	1,728

The maximum pressure values obtained for the MB-2NP1 EIHs ranged from 7.21 to 11.68 bar, with a mean value of 8.92 bar and a standard deviation of 1.73. The corresponding coefficient of variation was approximately 19.4%, indicating that the differences among individual samples were not negligible relative to the mean response level.

Table 4. Maximum combustion pressure, ignition delay time, and pressure-development time for the DISV EIHs

EIH type	T_{kp} [s]	T_{km} [s]	P_{max}[bar]
DISV_1	0,0062	0,0230	4,4128
DISV_2	0,0114	0,0180	4,6951
DISV_3	0,0061	0,0280	3,3053
DISV_4	0,0054	0,0216	5,4752
DISV_5	0,0095	0,0241	2,3857
Mean value	0,0077	0,0230	4,0548
St.deviation	0,0026	0,0036	1,4759

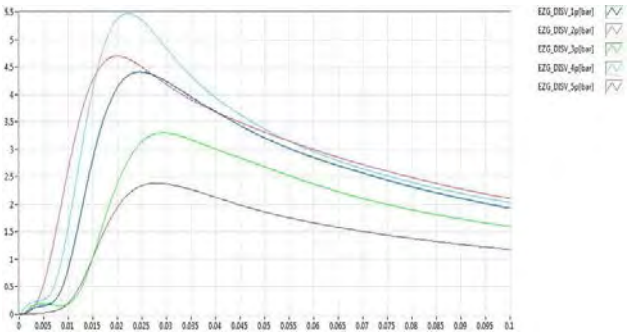

Figure 4. The pressure variation as a function of time for the DISV EIHs

The measured maximum combustion pressure values for the DISV EIHs ranged from 3,305 to 5,475 bar, with a mean value of 4,05 bar and a standard deviation of 1,47. In contrast to the observed variation in Pmax, the pressure-development times were highly consistent, ranging from 1,8 ms to 2,8 ms with a standard deviation of 0,0036. This is the result of a narrow resistance range of selected group.

Following these investigations, tests involving DISV EIHs installed in adapted tandem shaped-charge warhead fuzes were performed. Several EIHs were damaged during assembly into the fuze and subsequently failed during functional testing. In order to eliminate this problem while simultaneously enabling the directed action required for application in the warhead fuze, a protective sleeve was designed and manufactured around the igniter head, resulting in the modified DISV M configuration.

Table 5 presents the measured parameters for the modified MB-2N M electrical igniter heads. Modification of the MB-2N design resulted in a reduction of the mean maximum pressure and the amount of soot produced, as expected, since the igniter head was immersed in the initiating pyrotechnic mixture once instead of twice.
However, the dispersion of the individual maximum pressure values remained relatively high, with a standard deviation of 1.70 and a coefficient of variation of approximately 20.42 %.

Table 5. Maximum combustion pressure, ignition delay time, and pressure-development time for the MB-2N M EIHs

EIH type	T_{kp} [s]	T_{km} [s]	P_{max}[bar]
MB2N M_1	0,0075	0,0039	10,95
MB2N M_2	0,0086	0,0024	9,17
MB2N M_3	0,0082	0,0017	7,56
MB2N M_4	0,0054	0,0026	7,91
MB2N M_5	0,006	0,0016	9,78
MB2N M_6	0,0108	0,0085	6,45
MB2N M_7	0,0083	0,0136	6,49
Mean value	0,0078	0,0049	8,33
St.deviation	0,001786	0,001786	1,70

Table 6. Maximum combustion pressure, ignition delay time, and pressure-development time for the DISV M EIHs

EIH type	T_{kp} [s]	T_{km} [s]	P_{max}[bar]
DISV-M_1	0,0104	0,0285	3,9482
DISV-M_2	0,0124	0,0378	2,3896
DISV-M_3	0,0127	0,0288	4,7043
DISV-M_4	0,0098	0,0351	3,5008
DISV-M_5	0,0125	0,0368	2,7811
Mean value	0,0116	0,0334	3,4648
St.deviation	0,0014	0,0045	0,8487

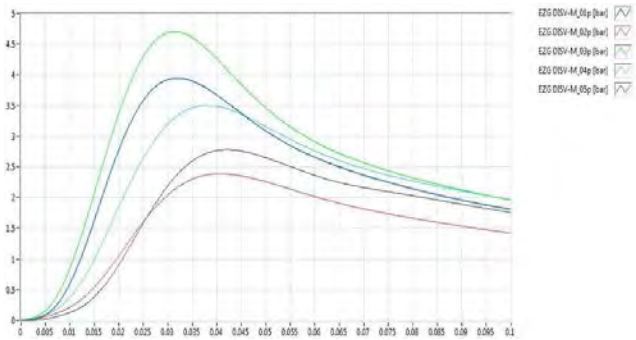

Figure 5. The pressure variation as a function of time for the DISV EIHs

The measured values for the DISV M EIH group were relatively uniform, ranging from 2,39 to 4,70 bar, with a mean value of 3,46, although the mean value was somewhat lower than that obtained for the original DISV configuration. This modification resulted in an EIH with a low soot content, low standard deviation 0,95, and simplified laboratory handling, making it suitable for application in the warhead fuze.

Since the modification and assembly of the DISV M EIH in the actual fuze configuration required an increase in the available free volume, EIHs with a higher energy output will be required in further investigations. Accordingly, future research should focus on modifying the composition of the initiating pyrotechnic mixture in order to achieve a higher energy output than that of the DISV EIH while producing fewer solid combustion residues than the modified MB-2N M configuration.

4. CONCLUSION

The study developed and experimentally verified a method for the multiparametric characterization of electrical igniter heads (EIHs), based on the analysis of pressure variation as a function of time under controlled manometric testing conditions. Testing of five EIH types, using the parameters P_{max}, t_{kp}, t_{max}, and result variability, confirmed the existence of measurable differences in response intensity, temporal dynamics, and repeatability. Thus, the combined analysis of pressure, temporal, and statistical parameters provides a more reliable basis for the assessment of EIH characteristics than the analysis of individual parameters alone. Integration testing within a real functional assembly confirmed that individual tests should be regarded as a necessary, but not sufficient, level of verification. The proposed method has the potential to provide more objective quality control, facilitate the comparison of design variants, and enable the early detection of deviations. Future research should focus on larger sample series, statistical validation of the proposed criteria, investigation of the effects of aging and environmental conditions, and the development of predictive models linking component-level parameters with system-level performance and reliability.

Abstract: This study examines the influence of inorganic fullerene-like tungsten disulfide nanoparticles (IF-WS_2) on the rheological behavior of Viton A solutions and their application in the phlegmatization of octogen (HMX). IF-WS_2 nanoparticles were selected due to their unique quasi-spherical morphology, lubricating properties, thermal and mechanical resistance. Their incorporation into fluoropolymer binders like Viton A is expected to reduce interparticle friction and enhance energy dissipation under mechanical stimuli, thereby decreasing sensitivity to impact and friction. At the same time, IF-WS_2 nanoparticles influence the processing parameters such as viscosity and particle coating efficiency. Two polymer-bonded explosive (PBX) formulations were prepared via aqueous suspension coating: a reference system HMX/Viton A, known as a standardized explosive PBXN-5, and a modified system containing 1 wt.% IF-W_2 dispersed in the polymer solution. The binder was introduced as a solution in ethyl acetate, while nanoparticles were ultrasonically dispersed. Rheological behavior of the solutions were examined by viscosity measurements over time, performed using an MCR 302 rheometer at constant shear rate and temperature. The presence of IF-WS_2 significantly accelerated increase in viscosity, indicating enhanced solvent evaporation and possible nanoparticle–polymer interactions. After drying, PBX granules were characterized by bulk density, sieve analysis of the particle size distribution, microscopic analysis, DSC, and sensitivity to impact and friction. The results suggest that IF-WS_2 nanoparticles influence both processing behavior and final material properties, offering potential for improved control of PBX performance and safety.

Keywords: *HMX, Viton A, PBX, IF-WS_2 nanoparticles, rheology, sensitivity.*

1. INTRODUCTION

Polymer-bonded explosives (PBX) represent an important class of energetic materials designed to combine high explosive performance with improved mechanical properties and reduced sensitivity to accidental initiation. Their structure consists of energetic crystalline particles embedded in a polymeric binder matrix, which provides mechanical integrity, improves handling safety, and protects explosive crystals from external mechanical stimuli. They may be produced by different technologies and using various types of polymers: like granular formulations with thermoplastic binder, intended for pressing, then like cast-cured polymers with elastomeric binder, or like hand-mealable putty-like explosives with highly plasticized partly cured elastomeric binders [1-4]. In case of granular compositions they represent explosive materials in which explosive powder is bound together in a matrix using 5-10wt.% of a synthetic polymer. These PBXs were first developed in 1952 at Los Alamos National Laboratory, as RDX embedded in polystyrene with plasticizer [1, 5]. Later on, during the following decades, formulations were developed using other nitramines, like HMX, PETN, CL-20, or other high explosives, with a wide variety of polymer phlegmatizers, like polycarbonate, PMMA, Teflon, fluoropolymers like Viton, thermoplastic elastomers like Estane, and some energetic polymers [2, 4].

DOI: 10.5937/OTEH26047B

Among the high explosives used in PBXs, hexogen (RDX) and octogen (HMX) remain most widely employed secondary explosives due to their high detonation velocity, high detonation pressure, and excellent energy output. However, the sensitivity to impact and friction necessitates the application of efficient phlegmatization techniques to improve safety without significantly compromising energetic performance.

Fluoropolymer binders are frequently utilized in PBXs because of their excellent chemical compatibility with nitramines, thermal stability, hydrophobicity, and ability to reduce mechanical sensitivity [4-6]. Viton A, a copolymer based on vinylidene fluoride and hexafluoropropylene, is among the most commonly used fluoropolymer binders in military PBX formulations. One of the best-known examples is PBXN-5, which consists predominantly of HMX particles coated with a small amount of Viton A binder (95/5 wt.%). The performance and safety characteristics of such materials strongly depend on the quality of particle coating, binder distribution, particle size distribution, and the microstructure developed during the coating process [7-9].

In recent years, significant attention has been devoted to the incorporation of nanomaterials into energetic formulations. Various nanoparticles have been investigated as additives capable of modifying mechanical, thermal, and sensitivity characteristics of explosives and propellants. Due to their high specific surface area and unique physicochemical properties, nanoparticles can alter crystal-binder interactions, influence heat transfer mechanisms, modify rheological behavior during processing, and improve resistance to accidental mechanical initiation [10]. The use of nanostructured additives therefore offers new possibilities for tailoring the performance and safety of advanced energetic materials.

Among the available nanomaterials, inorganic fullerene-like tungsten disulfide (IF-WS_2) nanoparticles have attracted considerable scientific and technological interest. Unlike conventional layered WS_2 particles, IF-WS_2 nanoparticles possess a closed-cage, quasi-spherical morphology consisting of multiple concentric WS_2 layers. This unique structure provides exceptional tribological properties, including low friction coefficients, high wear resistance, and efficient energy dissipation under mechanical loading. These nanoparticles exhibit excellent thermal stability, high mechanical strength, and good compatibility with polymer matrices [11-18]. Previous studies have demonstrated their effectiveness as reinforcing and lubricating additives in various polymer composites, where improvements in mechanical and tribological performance have been observed [17-22]. The tribological characteristics of IF-WS_2 nanoparticles suggest that they may also contribute to reducing the sensitivity of energetic materials. Mechanical initiation of PBXs is commonly associated with localized energy concentration and hotspot formation occurring at crystal contacts, defects, or frictional interfaces. By reducing interparticle friction and promoting more uniform stress distribution, IF-WS_2 nanoparticles may mitigate the mechanisms responsible for hotspot generation. In addition, their presence may influence the rheological behavior of polymer binder solutions during PBX preparation, affecting coating efficiency, solvent evaporation, particle agglomeration, and the final microstructure of the explosive composition.

Despite the extensive investigation of IF-WS_2 nanoparticles in tribological and polymer-composite applications, their potential use in polymer-bonded explosives has not been explored or not reported. In particular, little information is available regarding their influence on the rheological properties of fluoropolymer binder systems and their role during the aqueous suspension coating process, which is commonly employed for RDX or HMX phlegmatization. Therefore, the objective of this study was to investigate the effect of IF-WS_2 nanoparticles on the preparation and properties of PBXN-5 explosive. Particular attention was devoted to the rheological behavior of Viton A solutions containing dispersed nanoparticles, as well as to the resulting particle morphology, granulometric characteristics, thermal behavior, and sensitivity to impact and friction.

2. EXPERIMENTAL

2.1. Materials and PBX preparation

The materials used for the preparation of PBX formulations in this study were the following:
- octogen (HMX), supplied by Prva Iskra – Namenska, Barič, Serbia;
- Viton A fluoropolymer binder (DuPont);
- inorganic fullerene-like tungsten disulfide nanoparticles (IF-WS_2) produced by ApNano, NanoLub – Israel;
- ethyl acetate as the solvent for the polymer binder, MERCK; and
- distilled water.

Two HMX-based PBX formulations were prepared. The reference composition corresponded to a conventional PBXN-5 formulation consisting of HMX coated with Viton A binder in ratio 95/5 wt.%. The modified formulation contained the same HMX/Viton A system with the addition of 1 wt.% IF-WS_2 nanoparticles (regarding the amount of Viton A) dispersed within the polymer solution prior to coating. The PBX samples were prepared using the aqueous suspension coating method based on polymer precipitation from solution. HMX crystals were first dispersed in water in a jacketed glass reactor equipped with mechanical stirring and temperature control. Viton A was dissolved in ethyl acetate to obtain a homogeneous polymer solution. For the nanomodified formulation, IF-WS_2 nanoparticles were dispersed in the Viton A solution by ultrasonic treatment before addition to the explosive suspension in order to ensure uniform nanoparticle distribution. The polymer solution was then gradually introduced into the stirred HMX/water suspension. During continuous stirring and controlled heating, ethyl acetate evaporated, causing precipitation of the polymer onto the surface of HMX crystals, producing PBX granules. In the nanomodified system, IF-WS_2 nanoparticles became incorporated within the precipitated

polymer coating.

After the complete solvent evaporation, the coated granules were separated, thoroughly washed with water to remove residual processing impurities, and dried in a laboratory oven at moderate temperature to avoid softening of the polymer binder and agglomeration of the granules. Part of the preparation procedure is schematically shown in Figure 1.

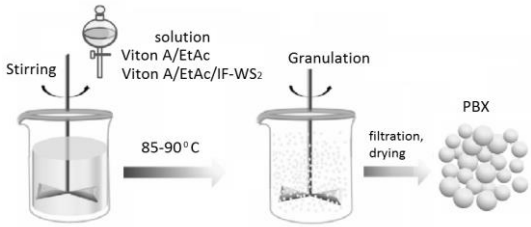

Figure 1. Ilustration of preparation of PBX samples

2.2. Methods

Prior to addition of the HMX suspension in water, small amount of the polymer phlegmatizer solutions in ethyl acetate, with and without the nanoparticles of tungsten disulfide, was taken aside and submitted to examination of viscosity on a rheometer, to monitor the change in apparent viscosity with time caused by the evaporation of ethyl acetate and to evaluate the influence of WS_2 particles on this change. The measurements were carried out using an Anton Paar MCR 302 rotational rheometer equipped with a 35 mm parallel-plate measuring system and P-PTD 220 and H-PTD 220 temperature-control elements. The gap between the plates was set to 1 mm, and the measurement temperature was maintained at 25 °C. Each sample was tested at a constant shear rate of 0.1 s^{-1} for 30 min. The apparent viscosity was continuously recorded as a function of time.

The prepared PBX granules were characterized using a combination of physical, chemical, thermal, and sensitivity analyses. Bulk density was determined by measuring the mass of a known volume of freely poured granules. The morphology and surface characteristics of the coated granules were examined by optical microscopy in order to assess particle shape, coating quality, and the presence of coarse agglomerates. This control of the phlegmatization success was done using LEICA M205A stereo microscope. Particle size distribution was evaluated by dynamic image analysis using DIA 500 Anton Paar device, in liquid mode, with water as a dispersion medium.

Thermal behavior was investigated by differential scanning calorimetry (DSC), using device Nexta DSC200, to determine characteristic phase transitions and decomposition temperatures of the prepared compositions and to assess the influence of IF-WS_2 nanoparticles on the thermal stability of the explosive material. Measurement was done in a temperature interval -80 to 325°C.

The safety characteristics of the PBX formulations were evaluated through standard sensitivity tests. Impact sensitivity was determined using a drop-hammer apparatus Julius Peters by measuring the response of the samples to controlled mechanical impact, using standard steel collars and cylinders made by OZM Research. Friction sensitivity was assessed using a friction tester Julius Peters under standardized loading conditions, using standard porcelain plates and pins produced by OZM Research.

3. RESULTS AND DISCUSION

3.1. Rheological behavior of the polymer solutions

The examined samples of neat and nanomodified Viton A/EA system showed a similar three-stage change in apparent viscosity with time, shown in Figure 2.

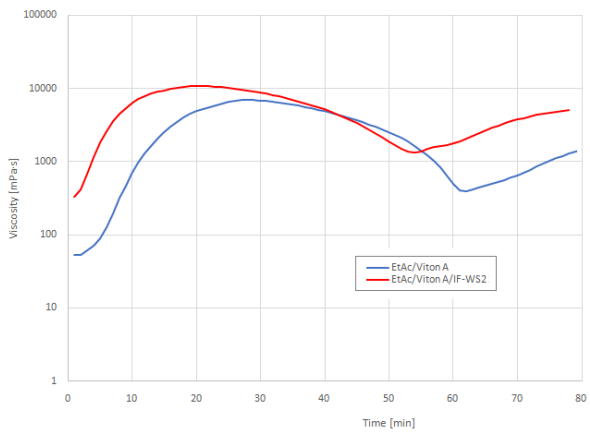

Figure 2. Apparent viscosity as a function of time for Viton A/ethyl acetate solutions with and without WS_2.

The apparent viscosity increased during the first 7-9 min of the measurement until a maximum value was reached. This initial increase was expected due to the progressive evaporation of ethyl acetate, which increased the concentration of Viton A and, in the nanomodified sample, the concentration of solid particles. After reaching the maximum, the apparent viscosity decreased until approximately 18-21 min. A second increase was then observed and continued until the end of the measurement. As it can be seen, a higher peak apparent viscosity was detected for the Viton A/EA/WS_2 sample, which reached 10.77 Pa·s after 7.0 min. Viton A/EA reference sample reached 7.09 Pa·s after 9.3 min. The apparent viscosity decreased to 1.32 Pa·s at 18.0 min for the WS_2-containing sample, and 0.393 Pa·s at 20.7 min for the sample without the nanoparticles. At the end of the measurement, the apparent viscosity increased again to 7.24 Pa·s for the Viton A/EA/IF-WS_2 dispersion, and 2.40 Pa·s for the Viton A/EA system. In the parallel-plate geometry, the sample was exposed to the surrounding atmosphere mainly along the outer edge of the plates. Therefore, solvent evaporation was probably more pronounced in this region, resulting in the formation of a solvent-depleted, polymer-rich layer. Under continuous shear, this layer may have been progressively disrupted or partially detached. Edge effects, including possible wall slip or partial loss of contact between the sample and the measuring plates, may have reduced the measured torque

and caused the observed decrease in apparent viscosity. The subsequent increase was most likely related to the continued evaporation of ethyl acetate and the resulting increase in the concentration of Viton A and solid particles in the remaining sample.

3.2. Morphology of the PBX granules

The appearance of the granules of the reference PBXN-5 and the nanomodified formulation are given in Figure 3. As may be observed, both formulations appear to have expected morphology of the granules, typical for this type of PBX [7-9].

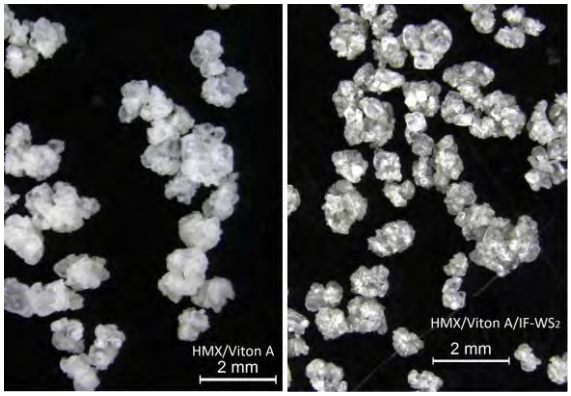

Figure 3. Micrographs of the PBX granules

3.3. FTIR analysis results

FTIR spectra registered for the analyzed PBXs are given in Figure 4.

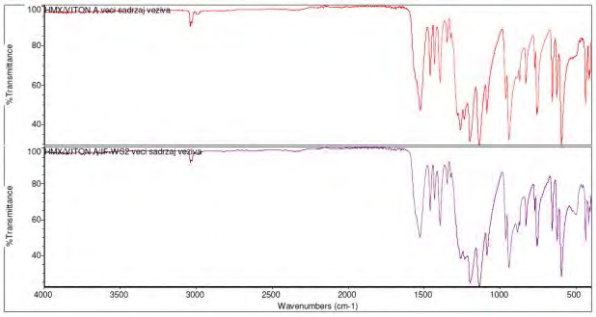

Figure 4. FTIR spectra of the prepared PBXs

It may be observed that there is no significant difference between the registered spectra, so the addition of WS_2 nanoparticles does not have a notable chemical interaction. FTIR spectra of the reference and nano-modified PBXN-5 samples exhibited the same characteristic absorption bands. No new absorption peaks or significant band shifts were observed after incorporation of IF-WS_2 nanoparticles, indicating that the modification did not induce chemical changes in the PBX matrix. Minor variations in band intensities suggest predominantly physical interactions between the nanoparticles and the composite constituents, and to differences in component distribution at the specific point of ATR contact.

3.4. Granulometric size distribution and loose bulk density of the PBX granules

The results of the measurement of the particle size are given in Figure 5. It may be noted that the obtained granules had practicaly same size distribution.

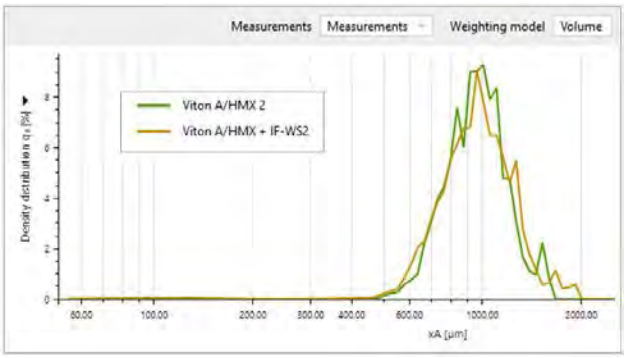

Figure 5. Size distribution of the PBX granules

For the reference PBXN-5 sample, loose bulk density was measured to be 654.1 g/dm^3, and for the WS_2-nanomodified PBXN-5 it was 667.1 g/dm^3. The obtained values are similar to those obtained earlier for PBXN-5 [7-9]. This small difference in the loose bulk density might have explanation in improved packing and reduced void volume caused by the presence of IF-WS_2 nanoparticles in the phlegmatizer [23-26].

3.4. DSC results

DSC thermograms of the HMX/Viton and HMX/Viton/IF-WS_2 formulations exhibited similar thermal behavior over the entire investigated temperature range. The DSC thermograph of the analyzed PBX sample HMX/Viton A is given in Figure 6.

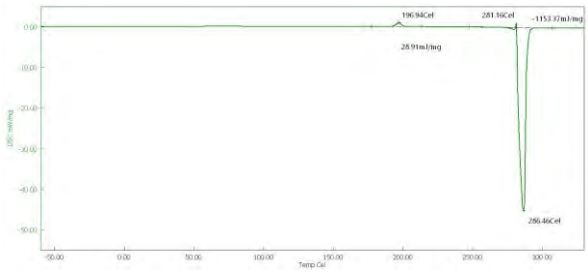

Figure 6. DSC thermograph for PBXN-5

An endothermic event observed at approximately 197-198°C corresponds to the well-known β to δ polymorphic transition of HMX. The transition temperature showed only a minor increase from 196.94 °C for HMX/Viton to 198.22 °C for HMX/Viton/IF-WS_2. At higher temperatures, both formulations displayed a pronounced exothermic decomposition peak centered at approximately 286.5 °C, indicating that the incorporation of IF-WS_2 nanoparticles does not significantly affect the thermal stability of HMX. A small increase in the decomposition peak temperature was observed for the nanomodified formulation (286.54 °C compared to 286.46 °C for the reference sample), although the magnitude of this shift is within the typical uncertainty of DSC measurements. Similarly, the melting endotherm of

HMX, partially overlapped by the onset of decomposition, appeared at slightly higher temperatures in the presence of IF-WS_2 (281.50 °C compared to 281.16 °C). Overall, all characteristic thermal events exhibited a consistent but very small shift toward higher temperatures after the addition of IF-WS_2, suggesting a weak stabilizing effect associated with nanoparticle-matrix interactions. However, additional measurements would be required to confirm the statistical significance of this trend. The slightly higher decomposition enthalpy observed for the formulation with IF-WS_2 may indicate a more complete decomposition process resulting from improved thermal coupling and enhanced interfacial contact within the composite microstructure. A higher decomposition enthalpy was recorded for the IF-WS_2-modified formulation (1263 J g^{-1}) compared to the reference composition (1153 J g^{-1}). However, considering that only a single DSC measurement was performed for each sample and that the analyzed sample masses were approximately 1 mg, this difference should be interpreted cautiously until confirmed by replicate measurements.

A more pronounced effect of IF-WS_2 was observed in the glass transition region of the Viton binder. The part of DSC thermographs of the compared samples where we may observe enlarged part with detectable Tg is given in Figure 7.

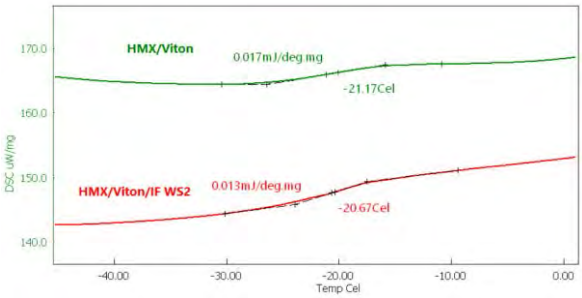

Figure 7. Enlarged DSC thermographs with Tg of Viton A detected in PBXN-5 and PBXN-5/IF-WS_2

in the glass transition region revealed a Tg value of -21.17 °C for the HMX/Viton formulation and -20.67 °C for the HMX/Viton/IF-WS_2 composite. The incorporation of IF-WS_2 nanoparticles therefore resulted in a slight increase of the glass transition temperature by approximately 0.5 °C. Although the shift in Tg is relatively small, a noticeable reduction in the heat capacity increment at the transition was observed. The ΔCp value decreased from 0.017 $mJ \cdot deg^{-1} \cdot mg^{-1}$ for the reference formulation to 0.013 $mJ \cdot deg^{-1} \cdot mg^{-1}$ after the addition of IF-WS_2, corresponding to a reduction of approximately 24%. The negligible change in Tg suggests that IF-WS_2 does not significantly alter the molecular structure of the Viton binder nor induce extensive changes in chain flexibility. However, the reduced ΔCp indicates the presence of restricted polymer segments at the polymer–nanoparticle interface. Such behavior is commonly attributed to physical adsorption of polymer chains on the nanoparticle surface, resulting in the formation of an interfacial region with reduced segmental mobility. The nanoparticles slightly constrain the motion of Viton chains without substantially affecting the overall glass transition temperature. The reduced ΔCp indicates that a fraction of the Viton chains becomes immobilized at the IF-WS_2 surface, suggesting stronger filler-binder interactions and a more constrained interfacial polymer layer.

3.5. Sensitivity to impact and friction

The results of sensitivity tests performed on the prepared granular PBXs are given in Table 1.

Table 1. Sensitivity of the prepared granular PBXs

Sample	Impact sensitivity	Friction sensitivity
PBXN-5	3.14 J	324 N
PBXN-5/IF-WS_2	2.94 J	240 N
PBXN-5/graphite	2.76 J	268 N

Contrary to the expected desensitizing effect of solid lubricant nanoparticles, IF-WS_2 slightly increased the mechanical sensitivity of PBXN-5. This behavior may be attributed to the introduction of additional interfacial regions, local stress concentration sites within the PBX microstructure and to the presence of hard nanoscale particles. This might have helped formation of hot-spot under mechanical stimuli [6, 23]. This means that in order to achieve the desired effects, different approach of incorporation of the nanostructures should be applied, so the further research will consider possibility of applying a thin layer of the solid lubricating particles ontop of the PBX granules.

CONCLUSIONS

Nanomodified PBXN-5 was prepared and characterized. The incorporation of 1 wt.% IF-WS_2 nanoparticles into the Viton A binder influenced the processing behavior and properties of PBXN-5 explosive. Rheological measurements showed a significant increase in apparent viscosity of the Viton A/ethyl acetate solution with added nanoparticles during solvent evaporation, indicating interactions between the nanoparticles and the polymer solution that may affect coating efficiency and granule formation. FTIR analyses confirmed that the addition of IF-WS_2 did not induce chemical changes in the PBX matrix. DSC demonstrated that the presence of the nanoparticles slightly altered PBX`s thermal stability, with a slight increase in Tg and reduction in ΔCp. The nanomodified formulation exhibited morphology comparable to the reference PBXN-5. However, a slight increase in mechanical sensitivity was observed, which will direct further research towards different technology of incorporation of IF-WS_2 nanoparticles in formulation of PBXs.

APPLICATION OF A CASCADE OF NEURAL NETWORKS FOR MODELING AND PREDICTING DETONATION CHARACTERISTICS OF HIGH-ENERGY MATERIALS

V.S. ABRUKOV, D.A. ANUFRIEVA, S.S. KUZMIN, D.A. SAPEROV

I.N. Ulyanov Chuvash State University, Cheboksary, Russia, abrukov@yandex.ru

Abstract: *Machine learning methods, particularly neural networks, offer the ability to identify complex nonlinear relationships between detonation characteristics, structure, and composition of HEMs. This work employs a novel approach—a cascade of neural networks—to improve model quality and enable comprehensive analysis of HEM characteristics.*

Keywords: *Machine learning, neural networks,high-energy materials, detonation characteristics.*

1. INTRODUCTION

Modern challenges in the study of high-energy materials (HEMs) require effective methods for predicting performance characteristics.
Traditional approaches based on experimental studies and theoretical calculations are often resource-intensive.

Machine learning methods, particularly neural networks (NNs), offer the ability to identify complex nonlinear relationships between detonation characteristics, structure, and composition of HEMs [1-3].

This work employs a novel approach—a cascade of neural networks—to improve model quality and enable comprehensive analysis of HEM characteristics.

2. MATERIALS AND METHODS

The study was conducted on a dataset comprising 32 individual and composite explosives. For each HEM, 7 physicochemical parameters were considered: density, oxygen balance, nitrogen content, total nitrogen and oxygen content, standard enthalpy of formation, melting point, and decomposition point. The Table of experimental results used is depicted in the end of paper.

A cascade neural network method (sequential approximation) was used to predict four target variables: detonation velocity, detonation pressure, impact sensitivity, and friction sensitivity. The method proceeds as follows:

The first neural network (NN1) is trained directly on experimental data: 7 HEM descriptors are input, and one detonation characteristic is output. The values obtained from NN1 are used as output targets for training the second neural network (NN2). The third cascade level (NN3) is trained on the output data of NN2, resulting in a maximally smooth dependence. Each subsequent network uses the previous network's output as target values, equivalent to sequential filtering of high-frequency noise. The final model produces a smooth mapping with RMSE below 10^{-5}.

For objective validation, the dataset was divided into training (80%) and test (20%) sets. Training was stopped when the minimum validation error was reached. Five-fold cross-validation confirmed stability (mean R^2 for detonation velocity: 0.994±0.003).

3. RESULTS

The constructed models demonstrate high quality (Table 1).

Table 1. Model quality metrics

Parameter	R^2	MSE	MAE	MAPE %
Detonation velocity	0.996	0.070	0.025	0.76
Detonation pressure	0.993	0.662	0.002	0.27
Impact sensitivity	0.862	5.611	1.743	22.37
Friction sensitivity	0.877	42.35	8.624	6.92

Comparison with alternative methods [4-6] shows typical R^2 values of ~0.95-0.99, while our cascade approach achieves $R^2 \approx 0.996$ and 0.993 for detonation velocity and pressure, confirming its high quality.

Analysis of physical regularities: The models reveal fundamental explosion physics: monotonic increase of detonation velocity and pressure with density (following classical detonation equations [7, 8]), dependence of detonation velocity on enthalpy of formation, and dependence of impact sensitivity on nitrogen content and decomposition temperature.

DOI: 10.5937/OTEH26048A

Some of the results are depicted in Figures 1-5.

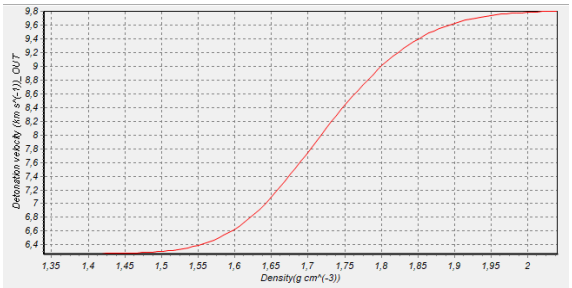

Figure 1. Dependence of detonation velocity on the density of the explosive

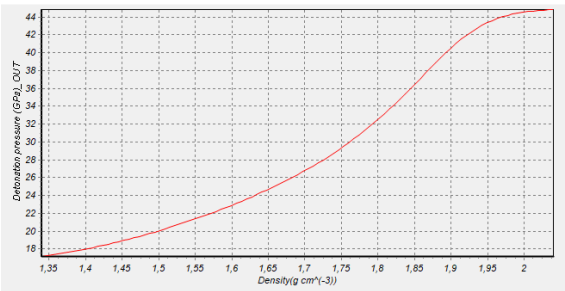

Figure 2. Dependence of detonation pressure on the density of the explosive

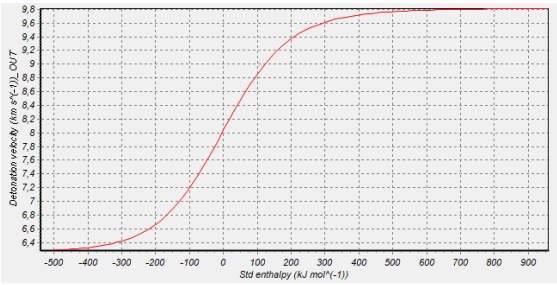

Figure 3. Dependence of detonation velocity on standard enthalpy of formation

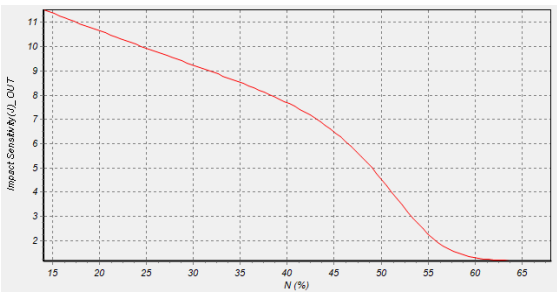

Figure 4. Impact sensitivity as a function of nitrogen content

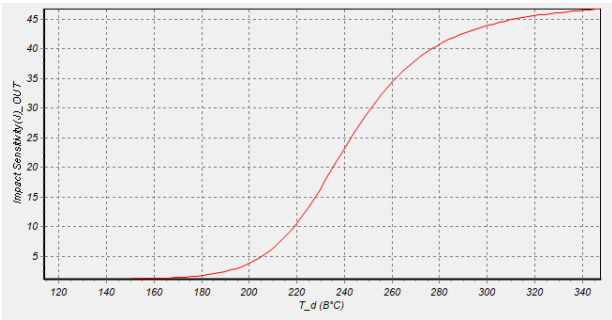

Figure 5. Impact sensitivity as a function of decomposition temperature

Only the most common dependencies are shown. Analysis shows maximum influence on detonation velocity/pressure from density and oxygen balance, while sensitivity depends most on total nitrogen and oxygen content and decomposition temperature, agreeing with physicochemical concepts.

4. DISCUSSION

While only the most common dependencies are visualized in Figures 1–5, a deeper analysis of the constructed cascade neural network models reveals a strong alignment with classical detonation physics and thermochemistry.

Regarding detonation performance, the models confirm the paramount influence of density (ρ) and oxygen balance (Ω_CO) on detonation velocity (D) and pressure (P).

As illustrated in Figures 1 and 2, there is a pronounced monotonic positive correlation between density and both D and P. This is physically governed by the Chapman-Jouguet theory, where higher density implies tighter molecular packing, leading to a greater concentration of reactive sites and higher reaction zone pressures. For instance, the model accurately maps the transition from low-density DNAN (ρ = 1.34 g/cm³, D = 6.26 km/s) to high-density CL-20 (ρ = 2.04 g/cm³, D = 9.85 km/s).

Furthermore, Figure 3 demonstrates the critical dependence of detonation velocity on the standard enthalpy of formation (ΔH_f). Compounds with highly positive (endothermic) enthalpies of formation, such as CL-20 (397 kJ/mol) or BNCP (350 kJ/mol), store substantial chemical energy that is released upon decomposition, significantly boosting detonation velocity compared to exothermic counterparts like TNT or PETN, assuming comparable densities. Oxygen balance also plays a vital role; values closer to zero optimize the formation of stable gaseous products (CO_2 and H_2O), maximizing the heat of explosion and, consequently, D and P.

Conversely, the safety and sensitivity characteristics—impact sensitivity (IS) and friction sensitivity (FS)—are governed by different structural and thermodynamic factors.

The models indicate that sensitivity depends most heavily on the total nitrogen and oxygen content (N+O) and the decomposition temperature (T_d).

Figure 4 highlights a distinct inverse relationship between nitrogen content and impact safety: high-nitrogen

compounds (e.g., $C_4N_{10}O$ with 68.6% N) possess numerous relatively weak N–N and N–O bonds and high positive heats of formation, resulting in extreme sensitivity (IS = 0.9 J). In contrast, lower nitrogen content generally correlates with higher structural stability.

Additionally, Figure 5 confirms a strong direct correlation between thermal stability and mechanical insensitivity. Materials with high decomposition temperatures, such as TATB (T_d = 350 °C) and TNT (T_d = 300 °C), possess high activation energies for thermal decomposition, which translates to a higher threshold for mechanical initiation (high IS values of 50 J and 39.2 J, respectively).

Ultimately, the cascade neural network successfully extracted these complex, non-linear physicochemical regularities from the dataset. The fact that the model independently converged on dependencies that perfectly agree with established theoretical concepts validates its reliability for the comprehensive analysis and predictive design of high-energy materials.

Future work involves database expansion and creating a "High-Energy Materials Genome" [9-13].

***Abstract**: Within this paper, a comparative analysis of the results obtained by numerical simulation and experimental testing of the penetration of an explosively formed projectile (EFP) was performed. The mentioned type of projectile is characterized by a complex process of penetrator formation. Understanding the dynamics of penetrator formation and its interaction with the target material is of key importance for analyzing the performance and comparing the construction parameters of these systems. The numerical model was developed with the aim of simulating the detonation process, projectile formation and studying its penetration. Experimental tests were conducted under strictly controlled conditions to determine the basic penetration parameters and validate the numerical model. The analysis includes a comparison of key parameters, including the geometry of the explosively formed projectile, the speed of movement and the depth of penetration in the target material. The obtained results indicate a significant agreement between the numerical and experimental data, thus confirming the adequacy of the applied numerical approach. Observed deviations were analyzed in the context of the simplification of the numerical model and limitations of the experimental methodology. The research results contribute to a better understanding of the mechanism of explosively formed projectile penetration and confirm the importance of numerical simulations as a reliable tool for evaluating their performance.*

***Keywords:** explosively formed projectile, numerical simulation, experimental testing, penetration, model validation.*

1. INTRODUCTION

An explosively formed projectile (EFP) is a specific type of warhead in which a metal casing is transformed into a compact, high-velocity projectile under the action of a detonation wave [1,2]. Unlike a conventional cumulative shaped charge, in which the metallic liner is typically conical and its collapse produces a high-velocity cumulative jet, an EFP (Explosively Formed Projectile) uses a shallow concave metallic liner, typically with a spherical or similar profile [1,2]. Under the influence of the detonation products, the EFP liner undergoes plastic deformation and forms a compact penetrator. Unlike a cumulative jet, which achieves its highest effectiveness within a specific and relatively limited range of stand-off distances and gradually loses coherence during flight, an EFP penetrator can maintain its integrity over significantly greater distances and achieve substantial penetration at longer stand-off distances from the target.

Its penetration characteristics depend not only on the velocity and mass of the projectile, but also on the penetrator geometry, mass distribution, stability in flight, and mechanical properties of the target material [3, 4]. The development of EFP research over the past few decades has been accompanied by advances in experimental techniques and numerical methods. Early research showed that projectiles with similar velocities can achieve different penetration depths depending on the projectile shape and characteristics of the target material, confirming that their performance cannot be reliably assessed based on a single ballistic parameter [3]. The development of three-dimensional numerical models has enabled the analysis of the complete process, from the formation and flight of the projectile to its interaction with the target. Comparison of numerical and experimental results has shown that reliable validation requires simultaneous analysis of the projectile geometry, its velocity, and the achieved penetration depth [4, 5].

Particular attention in modern research is paid to the influence of structural and material parameters on the process of formation and penetration of EFPs. The results show that the choice of liner material, its geometry and thickness distribution significantly affect the final shape, stability and penetration characteristics of the projectile [6, 7]. In addition, by changing the configuration of the liner, using a two-layer liner and detonation wave deflectors, it is possible to control the formation process and increase the length-to-diameter ratio of the penetrator [8]. Research on

DOI: 10.5937/OTEH26049I

sintered liners has further indicated the importance of microstructure and manufacturing methods for preserving the integrity of the projectile during formation [9].

Modern approaches increasingly combine numerical simulations and experimental tests to more reliably assess the behavior of the projectile and the target. Experimental and numerical studies of penetration into different target materials have shown that measuring the penetration depth alone is not sufficient for a complete model assessment, but it is also necessary to analyze the geometry of the projectile and the characteristics of the resulting damage [10]. Validated numerical models are also used for design optimization, including the geometry of the cladding, projectile stabilization, and material selection, which significantly reduces the number of required experimental tests [11].

Based on the analyzed literature, it can be concluded that there is a need for further validation of numerical models through the simultaneous comparison of several characteristic parameters and different target configurations.

The aim of this paper is a comparative analysis of the results obtained by numerical simulation and experimental testing of the penetration of an explosively formed projectile. A numerical model was developed to simulate the detonation process, projectile formation and its interaction with the target material, while experimental tests were conducted under controlled conditions to determine the basic penetration parameters. By comparing the geometry of the formed projectile, its velocity and penetration depth, an analysis of the agreement between the numerical and experimental results was performed.

2. EXPERIMENTAL

In the following, preliminary warhead model has been designed and for it, the ANSYS Autodyn is used to simulate its EFP formation process. Used materials for each part of the EFP warhead and steel target are listed in Table 1.

Table 1. Materials used in numerical simulation

Component		Material	model	equation of state
Warhead-EFP	explosive	Octogen (HMX)	-	JWL
	liner (disc)	Cu-OFHC (Oxygen-Free High-Conductivity Copper)	Johnso-Cook	-
	case	EN AW-6061T6	Steinberg Guinan	-
	deviator	Polyethylene (PE)	-	-
Steel target		Armor steel (hardness up to 340HB)	Johnson-Cook	-

In accordance with the results obtained by numerical simulation, warheads were manufactured. All the components of the polygon tests (warhead, steel target) were in agreement with the numerical model. Used materials in accordance with the respective standards are listed in Table 2.

Table 2. Materials of components for the experimental set up

Component		Material
Warhead – EFP	explosive	phlegmatized octogen (HMX)
	liner (disc)	phosphorus-deoxidized copper (CW024A)
	case	EN AW-6061 T6
	deviator	Polyethylene (PE)
Steel target		Armor steel (hardness up to 340HB)

2.1 Numerical simulation

The numerical simulation applied in this research was developed with the aim of analyzing the formation process of an explosively formed projectile and its interaction with the target material (armour steel target). The simulation includes the detonation process of the explosive charge, the deformation of the liner (disk), the formation of the projectile, its movement through the air space and penetration into the steel target. The obtained results represent the basis for comparison with experimental tests and assessment of the ability of the numerical model to faithfully reproduce the physical processes that determine the performance of the EFP system [3, 4].

Due to pronounced deformations, high deformation rates and short duration of the process, the numerical model is based on the combined Euler–Lagrange approach. In this approach, the explosive charge and airspace are modeled in the Eulerian domain, while the liner (disc), warhead shell, and steel target are modeled in the Lagrangian domain. Such a formulation enables efficient modeling of the movement of detonation products while at the same time a precise description of the deformation of solid bodies and their mutual interaction, which is why it represents a standard approach in simulations of explosive processes [5, 10].

2.1.1 The geometry of EFP warhead model

The geometry of the numerical model of the warhead is defined in accordance with the geometric characteristics of the real experimental sample in order to ensure identical conditions for numerical simulation and experimental tests. Figure 1 shows a schematic representation of the geometry of the EFP warhead.

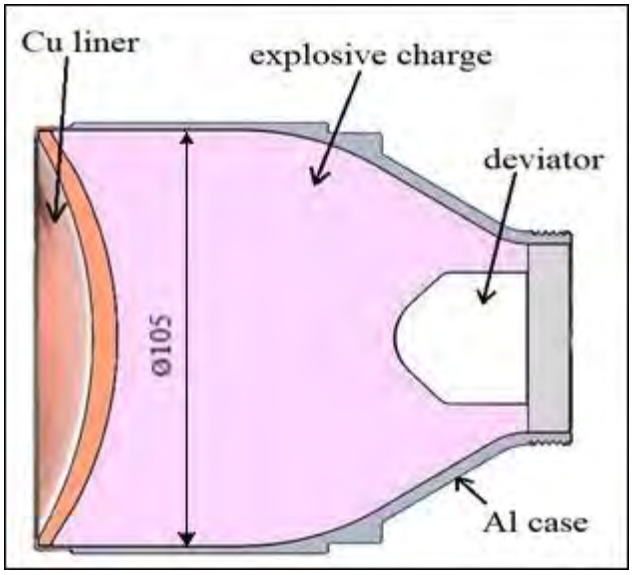

Figure 1. Geometric shape of the EFP warhead

2.1.2 Numerical models for description of EFP warhead elements and penetration process

To describe the material behavior of EFP warhead components, constitutive models and equations of state were used, which enable the simulation of processes characteristic of explosive loads, including large plastic deformations, high deformation rates and the spread of detonation products [3, 6].

The behavior of metal components is modeled using the Johnson–Cook constitutive model, which describes the dependence of yield stress on plastic strain, strain rate, and temperature. The Johnson-Cook constitutive relation is expressed as:

$$\sigma = (\mathrm{A} + B\varepsilon^n)(1 + C\ln\dot{\varepsilon})\left(1 - \left|\frac{T-T_r}{T_m-T_r}\right|^m\right) \quad (1)$$

Where σ is the equivalent flow stress; A, B, C, n and m are material constants; ε is the equivalent plastic strain; $\dot{\varepsilon}$ is the equivalent plastic strain rate; T is the current temperature; T_m is the melting temperature; T_r is the reference temperature [3, 6].

Due to its ability to realistically describe the behavior of metallic materials under dynamic loading, this model is one of the most commonly used in the analysis of explosive processes and high-speed impacts [3, 4, 6, 7].

To describe the behavior of the explosive charge, the Jones–Wilkins–Lee (JWL) equation of state was applied. The JWL equation relates the pressure of the detonation products to their relative volume and specific internal energy and can be expressed as:

$$P = A\left|1 - \frac{\omega}{R_1 V}\right| e^{-R_1 V} + B\left|1 - \frac{\omega}{R_2 V}\right| e^{-R_2 V} + \frac{\omega E_0}{V} \quad (2)$$

Where P is the pressure of the detonation products; V is the relative volume; A, B, R_1, R_2 и ω are material constants; E_0 is the specific internal energy in explosiv [3, 6].

Due to its reliability in modeling detonation processes, the JWL equation represents a standard in numerical analyzes of explosive charges [6, 7].

The parameters of the used models were taken from the available literature and appropriate databases, with the values selected for the materials used in this research.

2.2 Experimental setup - Static penetration test

Experimental tests (static penetration tests in real conditions) were conducted with the aim of determining the penetration characteristics of an explosively formed projectile and validating the results obtained by numerical simulation. The experimental setting was defined so that the warhead was placed at a standoff distance of 1,5 m in relation to the armored target.

A schematic representation of the experimental setup for penetration tests is shown in Figure 2, and the materials of the target and warhead components are listed in Table 2.

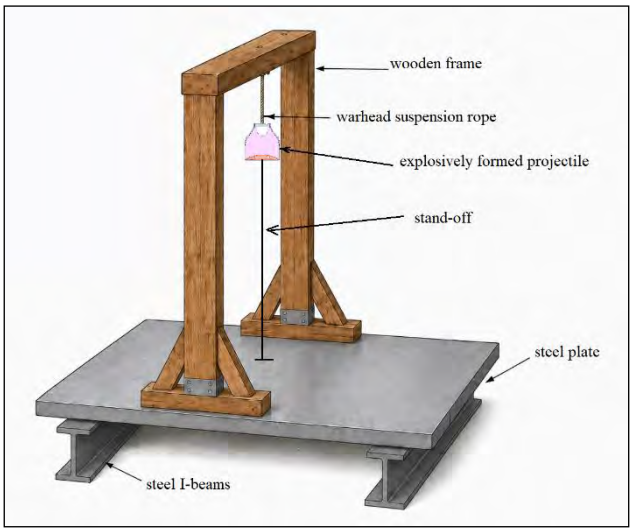

Figure 2. Setup for static penetration test

For the purposes of numerical simulation, the chosen explosive is octogen (HMX), while for the needs of real explosive charging, this explosive was used with the addition of phlegmatizer in a small mass fraction (an inert component that enables safe pressing of HMX). The presence of the inert component was neglected for the purposes of the numerical simulation.

Experimental tests included static penetration tests with two different target configurations. In configuration I, penetration through a 50 mm thick steel plate was analyzed, while in configuration II, penetration through a 100 mm thick steel plate was tested. The change in plate thickness was performed in order to see the full penetration effect, i.e. to estimate the depth of penetration. In this way, it was possible to analyze the behavior of an explosively formed projectile upon impact with a homogeneous obstacle. The obtained experimental results represent the basis for assessing the accuracy of the numerical model and analyzing the degree of agreement between the numerical and experimental approaches.

Table 3. Parameters for static penetration test

Parameter	
Stand-off	1,5 m
Configuration I	Armor steel, thickness 50 mm
Configuration II	Armor steel, thickness 100 mm
Result	Penetration depth - 85 mm

3. RESULTS AND DISCUSION

3.1. Process of explosivly formated projectile

The numerical model was developred asa a 2D axisymmetric model, with one quarter of the model considered due to the axis symmetry of the problem. A Lagragian formulation was applied to both the liner and the target. The liner was discretized with 201 elements, while the target mesh consisted of 400 elements. Numerical simulation was then used to analyze the process of forming an explosively formed projectile after the initiation of the explosive charge. During detonation, intense plastic deformation of the copper disk occurs, forming a compact projectile capable of maintaining stability during flight and achieving significant penetration when hitting a target.

Folowing the initiation of the explosive charge, the pressure of the detonation produts causes deformation and acceleration of the liner, leading to EFP formation. The stage of projectile formation at different time instants are shown in Figure 3. Figure 4 shows a ilustration of the formed penetrator.

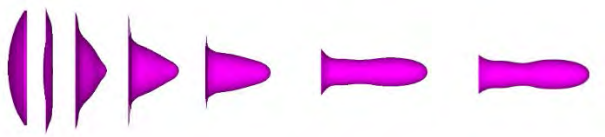

Figure 3. Penetrator formed over numerical simulation

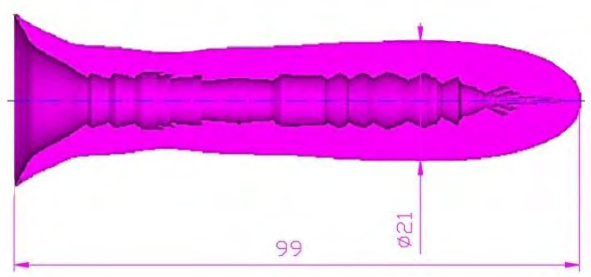

Figure 4. Penetrator formed over numerical simulation

Based on the results of the numerical simulation, the basic geometric and ballistic characteristics of the formed projectile were determined, including its shape, characteristic dimensions, mass and speed immediately before hitting the target. These characteristics represent the basis for the analysis of the penetration process and comparison with the test results in real conditions.

Table 4. Caharacteristics of EFP from numerical simulation

Parameter	Value
Projectile length	99 mm
Projectile diameter	21 mm
Projectile mass	295 g
Projectile speed	2050 m/s
Penetration depth	90 mm

3.2. Penetration of the EFP

Penetration characteristics of the explosively formed projectile were analyzed by numerical simulation and experimental through static penetration tests.

The results of the numerical simulation showed that an explosively forming projectile of a given geometry achieves penetration through a steel target (homogeneous armor plate) of approximately 90 mm, which was also confirmed in the real conditions of the penetration test (of about 85 mm).

By comparing the results of numerical simulation and experimental tests, a very good agreement can be observed regarding the achieved penetration depth. The obtained agreement between the numerical and experimental results confirms that the applied numerical model can reliably predict the penetrating characteristics of the explosively formed projectile under the analyzed test conditions. Minor deviations that may occur between numerical and experimental results can be attributed to the idealization of the numerical model, the limitations of the applied material models and experimental uncertainties, which is in accordance with the observations of other authors who were involved in the validation of numerical models of explosively formed projectiles [4, 5, 10].

4. CONCLUSIONS

In this paper, a comparative analysis of the results obtained by numerical simulation and experimental testing of an explosively formed projectile was performed. The analysis included the formation of the projectile, the determination of its basic geometric and ballistic characteristics, as well as the comparison of the achieved penetration depth in numerical simulation 90 mm through real static penetration tests.

The results of the numerical simulation showed that the applied model successfully describes the formation process of an explosively formed projectile and enables reliable determination of its basic characteristics. A comparative analysis with the results during real static penetration tests showed a high degree of agreement, whereby a penetration depth of about 85 mm was achieved. With a 100 mm thick steel plate, the projectile did not achieve complete penetration, while with a configuration with a single 50 mm thick steel plate, it completely penetrated the plate and continued to penetrate the soil base, with the total depth of penetration remaining practically unchanged.

The scientific contribution of this work is reflected in the validation of the numerical model through real static penetration tests. The confirmed agreement between numerical simulation and static penetration tests indicates that numerical simulations can be successfully used for the analysis and optimization of the construction of explosively formed projectiles, thereby reducing the need for a large number of complex and expensive polygon tests in the initial stages of their development.

The results presented in this paper represent the basis for further research aimed at the optimization of the disk geometry, the choice of materials and the improvement of numerical models, with the aim of increasing the efficiency and reliability of explosively formed projectiles in different application conditions.

Abstract: *Determination of the parameters of the power law of combustion (the Saint-Robert and Vieille law, the Murali-Saint-Robert law) is the basis for the design and optimization of the composition of high-energy materials. In most works, the parameters are determined using logarithmic transformation and linear regression, which provides only averaged values. This paper proposes a new method that allows one to determine the dependence of burning rate on pressure as a function of a high degree of smoothness, and then, based on this, the dependence of the power law parameters on pressure and composition of high-energy materials. The method is based on the application of neural networks and the method of neural network sequential approximations. The method allows solving both direct and inverse problems.*

Keywords: *high-energy materials, combustion law parameters, neural network sequential approximation method.*

1. INTRODUCTION

The dependence of the burning rate of high-energy materials on pressure is described by the power law of combustion: $u = b \cdot P^n$, where u is the linear burning rate, P is pressure, b is the combustion coefficient, and n is the pressure exponent.

Traditional methods of linear regression in logarithmic coordinates yield only averaged values of b and n due to random measurement errors [1-4]

This paper proposes a method to determine the dependence u(P) as a function of a high degree of smoothness, and then the dependences n(P) and b(P).

2. RELATION BETWEEN THE COMBUSTION LAW PARAMETERS AND THE DERIVATIVE OF BURNING RATE WITH RESPECT TO PRESSURE

Let us write the combustion law of combustion for an arbitrary point i:

$$u_i = b_i \cdot P_i^{n_i} \quad (1)$$

Differentiating (1) with respect to pressure and assuming b and n are constant in an infinitesimal neighborhood of point i:

$$\left.\frac{du}{dP}\right|_{P_i} = \frac{d}{dP} \cdot \left(b_i \cdot P_i^{n_i}\right) \quad (2)$$

Since b in an infinitesimal neighborhood of point i does not depend on P, it can be taken outside the derivative sign:

$$\left.\frac{du}{dP}\right|_{P_i} = b_i \cdot \frac{d}{dP} \cdot P_i^{n_i} \quad (3)$$

or

$$\left.\frac{du}{dP}\right|_{P_i} = b_i \cdot n_i \cdot P_i^{n_i - 1} \quad (4)$$

Now we divide both sides of equation (4) by u_i, where $u_i = b_i \cdot P_i^{n_i}$

After simplification we obtain:

$$\frac{1}{u_i} \cdot \left.\frac{du}{dP}\right|_{P_i} = \frac{n_i}{P_i} \quad (5.3)$$

$$n_i = \left.\frac{du}{dP}\right|_{P_i} \cdot \frac{P_i}{u_i} \quad (6)$$

$$b_i = \frac{u_i}{P_i^{n_i}} \quad (7)$$

3. METHOD OF NEURAL NETWORK (NN) SEQUENTIAL APPROXIMATIONS

The method consists of three steps:

1. The first neural network is trained on the original noisy experimental data of burning rate versus pressure.
2. The second neural network is trained on the output of the first network and refines the initial approximation.
3. The third neural network (NN3) is trained on the output of the second network, further smoothing the function.

The Deductor platform was used to create the models. A feedforward neural network was employed: an input layer (6 neurons: pressure, percentage of ammonium perchlorate, particle size of ammonium perchlorate, percentage of PEBA binder, percentage of aluminum, percentage of lithium fluoride), one hidden layer (3–5 neurons), and an output layer (1 neuron – burning rate).

Corresponding author: I.N. Ulyanov;
E-mail: kafedra.pfn@mail.ru
DOI: 10.5937/OTEH26050A

The activation function was the hyperbolic tangent with a steepness of 0.2.

The data were randomly split: 80% for training, 20% for testing. The loss function was the mean squared error. Training was stopped when the error reached a minimum. No overfitting was observed.

4. MODELING METHODOLOGY AND RESULTS

The models were created based on experimental data for seven compositions (author: Vladica Bozic), Table 1. The compositions differed in the content of ammonium perchlorate, its particle size, PEBA binder, aluminum, and lithium fluoride. The pressure range was from 1.45 to 17.39 MPa. The burning rate was measured using the "small motor" method [5,6].

Table 1. HEM compositions used for model development.

Composition	Pressure range, MPa
AP particle size = 120 µm, AP = 78%, PEBA = 12%, Al = 10%, LiF = 0%	2.02–15.92
AP particle size = 120 µm, AP = 77%, PEBA = 12%, Al = 10%, LiF = 1%	1.45–11.17
AP = 85%, AP particle size = 90 µm, PEBA = 15%, Al = 0.5%, LiF = 0%	1.75–10.26
AP = 85%, AP particle size = 200 µm, PEBA = 15%, Al = 0.5%, LiF = 0%	2.81–17.39
AP particle size = 200 µm, AP = 84.8%, PEBA = 15%, Al = 0.5%, LiF = 0.2%	2.29–6.80
AP particle size = 200 µm, AP = 84.5%, PEBA = 15%, Al = 0%, LiF = 0.5%	2.14–9.35
AP particle size = 200 µm, AP = 84%, PEBA = 15%, Al = 0.5%, LiF = 1%	2.27–6.54

The available experimental data were organized in a special table format. A part of the organized data table is shown in Table 2.

Table 2. Example of organized data (fragment).

The structure of the NN3 model is shown in Figure 1

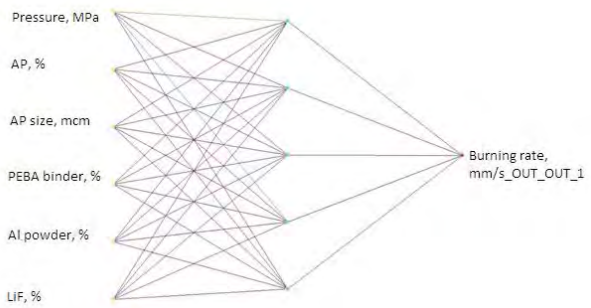

Figure 1. The structure of the NN3 model

Curves of n(P) and b(P) were constructed for all seven compositions and are depicted in Figure 2.
Figure 2 presents curves of the dependences of the power-law combustion parameters *n* and *b* on the row number in Table 2, which corresponds to seven different compositions of HEM. The ordinate axis shows the values of *n* (upper curves) and *b* (lower curves); the abscissa axis shows the row number, sequentially covering all compositions and all pressures within each composition. The blue curves show the values calculated directly from the initial experimental data u(P), while the red curves show the values obtained using the method of neural network sequential approximations (NNSA) after smoothing.

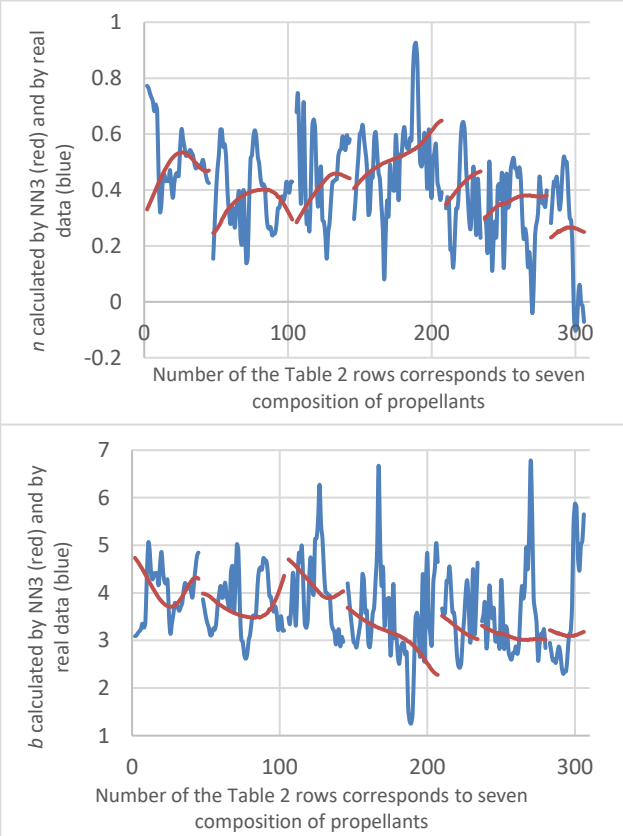

Figure 2. Curves of n(P) and b(P)

Notes:

1. Character of the blue curves (initial data).

The blue curves, obtained by direct differentiation of the noisy experimental dependences u(P), exhibit a pronounced chaotic character:

- For the exponent n, the values fluctuate over a wide range — approximately from −0.2 to 1.0 which is physically unjustified.
- For the coefficient b, the scatter ranges from 1×10−6 to 7×10−6, and the curve contains numerous sharp peaks and dips.

Such behavior is due to the fact that numerical differentiation amplifies random measurement errors, which are always present in experimental data. As a result, the blue curves are unsuitable for analysis of combustion regularities and cannot be used for solving practical problems.

2. Character of the red curves (NNSA method).

The red curves, obtained after sequential application of three neural networks, are smooth functions of a high degree of smoothness. They are free from random outliers and reflect the fundamental regularities of the combustion process.

For the exponent n:

- The values of n lie in a physically reasonable range of 0.2–0.6, which corresponds to typical values for composite solid propellants.
- A smooth variation of along the abscissa axis is observed: at the beginning (composition 1, low pressures) n≈0.35; then n increases to 0.5–0.55 in the middle of compositions 1–2; further, on passing to compositions 3–4 (with lower aluminum content and larger AP particle size), n decreases somewhat to 0.4; for the final compositions (5–7), n stabilizes in the region of 0.4–0.5.
- The transitions between compositions (at the boundaries of rows 46, 104, 144, 208, 235, 281) are smooth, without jumps, which indicates good generalizing ability of the neural network model.

For the coefficient b:

- The values of b are in the range of ~3×10−6–5×10−6.

The red curve b shows a general tendency to decrease from the beginning to the end: in the first compositions b≈4.5×10−6, and by the last compositions it decreases to 3×10−6.

As for n, the transitions between compositions are smooth, which allows analysis of the influence of composition on the coefficient b.

3. Main regularities following from Figure 2

Physical validity**.** The red curves fully agree with classical concepts of HEM combustion: 0<n<1, and b varies within a narrow range. The blue curves do not demonstrate such regularities.

Influence of composition**.** The changes in n and b correlate with composition variations:

- The introduction of the depressant LiF (compositions 2, 5, 7) leads to a certain decrease in n compared with compositions without LiF (compositions 1, 3, 4).
- An increase in aluminum content (compositions 1, 2 — 10% Al) gives higher values of n compared with compositions with low Al content (compositions 3, 4 — 0.5% Al).
- A change in the dispersity of ammonium perchlorate (90, 120, 200 μm) also affects n and b, which is reflected in smooth shifts of the red curves.

4. Identification of combustion regimes.

The smooth dependences n(P) within each composition allow identification of pressure regions where the combustion mechanism changes. For example, a change in the slope of the n curve may indicate a change in the dominant phase (gas or condensed).

Figure 2 clearly demonstrates the effectiveness of the NNSA method. The blue curves, constructed from "raw" experimental data, are unsuitable for analysis due to chaotic scatter. The red curves, obtained after neural network smoothing, represent smooth, physically consistent dependences of n and b on pressure and composition.

They allow:

- correct determination of the power-law combustion parameters;
- analysis of the influence of composition on these parameters;
- solution of inverse problems for targeted adjustment of HEM formulations.

Thus, Figure 2 confirms that the proposed method of neural network sequential approximations is a reliable tool for processing noisy experimental data and extracting hidden physical regularities from them.

Dependences of n and b on the percentage of aluminum and lithium fluoride at different pressures were obtained also. The results allow solving inverse problems: for example, determining how much lithium fluoride is needed to obtain a desired value of n at a given pressure. It will be presented later.

5. CONCLUSIONS AND PROSPECTS

The developed methodology fundamentally improves the processing of experimental data on the dependence of burning rate on pressure and the determination of the parameters of the power law of combustion and their dependence on pressure.

The analysis of n(P) and b(P) helps to identify different combustion regimes. The method of neural network que approximations provides an effective approach for eliminating random errors in experimental measurements.

The method can be applied to any experimental data contaminated with random errors, especially when the first derivative is important for process analysis.

A brief summary of the methodology presented in this paper was previously presented in [7-9].

The general principles of this methodology are presented in [10-14].

INFLUENCE OF GROOVE GEOMETRY ON THE INTERNAL BALLISTICS OF A MONOLITHIC .308 CALIBER BULLET

IGOR BABIĆ
Prvi Partizan, Užice, igor.babic@prvipartizan.com

MIHAILO ERČEVIĆ
Prvi Partizan, Užice, mihailo.ercevic@prvipartizan.com

Abstract: *With the growing awareness of environmental protection and the harmful effects of lead, regulatory changes have been introduced, accompanied by a clear trend toward the gradual elimination of conventional "Soft Point" and "FMJ" bullets and their replacement with monolithic ("solid") bullets made of copper alloys. These bullets are characterized by a reduced negative impact on human health and the environment, as well as by certain properties favorable for sporting applications. A drawback of the monolithic design is the absence of a softer (lead) core, which results in increased resistance during the engraving of the bullet into the barrel rifling. To mitigate this issue, grooves are formed on the bullet surface, whose function is to accommodate and redistribute displaced material during the engraving process into the rifling grooves. This paper analyzes the influence of the geometry of these grooves on the internal ballistics of a .308 caliber "Wadcutter Match" bullet, with the aim of establishing a basis for further development and optimization of monolithic bullet design.*

Keywords*: bullet, solid , rifling, grooves, internal balistics.*

1. INTRODUCTION

Monolithic projectiles have become increasingly attractive alternatives to conventional lead-core bullets due to their environmental compatibility, high structural integrity, and superior terminal performance. However, their larger bearing surface and increased engraving resistance often produce higher chamber pressures than conventional projectiles, making the optimization of projectile geometry an important aspect of internal ballistic design.

This study experimentally investigates the influence of material displacement groove geometry on the internal ballistic performance of monolithic bullets. Three groove geometries with different engraved material volumes were manufactured while maintaining identical projectile mass, calibre, and external dimensions. The projectiles were tested using two propellant types under controlled laboratory conditions, and chamber pressure and muzzle velocity were recorded.

The experimental results demonstrate that groove geometry significantly affects peak chamber pressure while producing only minor changes in muzzle velocity. The projectile with the smallest engraved material volume exhibited the lowest chamber pressure and the highest Internal Ballistics Efficiency Index, indicating the most favourable balance between ballistic performance and mechanical loading of the firearm. Additional experiments investigating the influence of groove number shows that the pressure/velocity relation curve peaks at a optimal point and any additional decrease in engraving resistance does not improve end results.

The results suggest that engraved material volume represents a practical geometric design parameter for optimizing monolithic projectiles. The proposed Internal Ballistics Efficiency Index provides an additional engineering criterion for comparing projectile designs and may support the future development of pressure-optimized monolithic ammunition.

2. MATERIAL DISPLACEMENT GROOVE GEOMETRY

In the first stage of the experimental investigation, three groove geometries were selected to evaluate the influence of groove profile on the internal ballistic performance of monolithic projectiles. All projectile variants were manufactured with identical external dimensions, mass, material, and manufacturing tolerances. The only variable was the geometry of the grooves.
The investigated groove configurations were:

Type A – Raised Bands: The bearing bands have a diameter equal to the nominal projectile diameter, while the recessed regions between the bands have a reduced diameter (Figure 1).
Type B – Depressed Grooves: Conventional grooves are machined directly into the projectile body, resulting in a continuous bearing surface interrupted by circumferential grooves (Figure 2).
Type C – Wavy Profile: The bearing surface follows a continuous wave-shaped profile, providing a gradual transition between the bearing bands and recessed regions (Figure 3).

DOI: 10.5937/OTEH26160B

The objective of this comparison was to determine how the groove profile influences projectile engraving resistance, chamber pressure, and muzzle velocity while maintaining all other projectile parameters constant.
Following the identification of the most favourable groove geometry, a second series of experiments was conducted to investigate the influence of the **number of** grooves on internal ballistic performance.

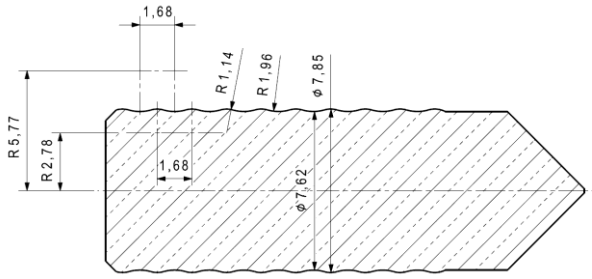

Figure 3. Groove design. C.

3. EXPERIMENT SETUP

The experimental investigation was conducted at the Prvi Partizan Užice company inside a controlled indoor ballistic testing facility. All firing tests were performed under identical laboratory conditions in order to minimize the influence of external factors on the measured ballistic parameters.

The test ammunition consisted of .308 cartridges loaded with CNC lathe turned monolithic brass projectiles. All projectiles were manufactured from CuZn39Pb2 alloy, maintained identical external dimensions, and were manufactured using identical machining procedures. The investigated variables were limited exclusively to the geometry and number of grooves, allowing the influence of these parameters on internal ballistic performance to be isolated.

The cartridges were assembled using identical cartridge cases, primers, and carefully controlled propellant charges. Two propellant types, **SB511** and **SB520**, were selected to investigate whether the observed influence of projectile geometry remained consistent under different combustion characteristics.

All projectiles were fired from the same test barrel mounted in a rigid fixture. Using a single barrel eliminated variations caused by manufacturing tolerances, barrel wear, chamber dimensions, and rifling characteristics, ensuring that differences in measured chamber pressure and muzzle velocity resulted solely from changes in projectile geometry.

Peak chamber pressure was measured using a piezoelectric pressure transducer installed in accordance with the C.I.P standard pressure measurement procedure for small-calibre ammunition.

Projectile muzzle velocity was measured using a chronograph.

To evaluate experimental repeatability, 5 shots were fired for each projectile configuration and propellant combination. Mean values, standard deviations, and coefficients of variation were subsequently calculated for both chamber pressure and muzzle velocity. The use of repeated measurements enabled the assessment of measurement uncertainty while reducing the influence of random experimental variation.

The experimental procedure was performed in two successive stages. The first stage investigated the influence of three different groove geometries while maintaining identical projectile mass. Following identification of the most favourable groove configuration, the second stage examined the influence of the number of grooves and projectile mass reduction through the introduction of an internal cavity. This sequential approach enabled the individual effects of groove geometry, groove number, and projectile mass on internal ballistic performance to be evaluated independently.

Powder was manufactured by Milan Blagojević Namenska factory in Lučani, all powder is used from the same lot to exclude manufacturing differences.
Overall bullet length is $60{,}5^{-0{,}5}$ mm for all tests.

4. EXPERIMENTAL RESULTS

The internal ballistic performance of the investigated monolithic projectiles was evaluated by measuring the maximum chamber pressure and muzzle velocity for each projectile configuration.

The experimental investigation was performed in two stages. In the first stage, three groove geometries (Types A, B, and C) having identical mass and external dimensions were compared in order to isolate the influence of groove profile on internal ballistic performance. Following the identification of the most favourable groove geometry, the second stage investigated the influence of the number of grooves and projectile mass reduction.

For each projectile configuration, multiple firing tests were conducted to ensure measurement repeatability. The recorded chamber pressures and muzzle velocities were subsequently processed to obtain average values and standard deviations, which were used for the comparative analysis presented in the following sections.

The experimental results are first discussed in terms of the influence of groove geometry on chamber pressure and muzzle velocity. Subsequently, the effects of groove number and projectile mass are analysed using the additional experiments performed with the two propellant types. Finally, the Internal Ballistics Efficiency Index (IBEI) is introduced as a supplementary engineering parameter for evaluating the relationship between muzzle velocity and peak chamber pressure.

4.1 Influence of Groove Geometry

For the first experiment iteration a load of SB511 powder and charge of 2,75g was used to record obtained pressure and adjust the powder charges according to maximum pressure.

Table 3. Results of first experiment iteration.

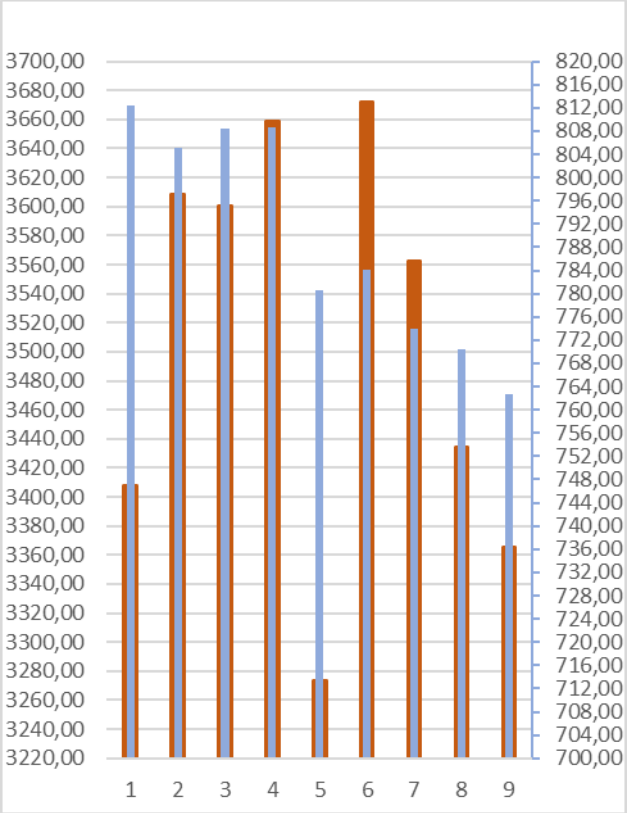
Rb.	G.Geometry	OAL [mm]	Velocity [m/s]	Pressure [bar]
1.	A	60,48	814	3770
2.	B	60,46	804	4040
3.	C	60,47	818	4199

For the second experiment iteration the powder charge was adjusted for expected max pressure of ~3600 bar as a safe upper limit, for each groove geometry and both SB511 and SB520 powders.

Table 4. Results of second experiment iteration

Rb	G. Geometry	Powder	Powder charge [gram]	Velocity [m/s]	Pressure [bar]
1.	A	SB520	3	812,32	3408,00
2.	B	SB520	3	805,04	3608,86
3.	C	SB520	3	808,31	3600,37
4.	A	SB511	2,75	808,72	3658,69
5.	A	SB511	2,65	780,56	3273,32
6.	B	SB511	2,65	784,10	3671,97
7.	B	SB511	2,60	773,98	3562,72
8.	C	SB511	2,60	770,51	3434,11
9.	C	SB511	2,55	762,64	3365,31

The results of the second experiment iteration is a correlation between maximum pressure and obtained velocity for each powder charge and grove geometry type combination used.



Graph 1. Relationship between velocity and pressure.
Orange bar, left side – Pressure [bar]
Blue bar, right side – Velocity.[m/s]

From the experiment results and accompanying graph it can be concluded that the groove geometry model "A" provides the highest velocity compared to max pressure meaning that a bullet with "A" groove geometry can be propelled at higher powder loads to achieve higher velocity while still being under the maximum safe chamber pressure.

For the SB520 powder from the graph can be concluded that under the same load od 3g of powder for all three groove geometries used, "A" type achieves the highest velocity for a significant difference in pressure compared to "B" and "C" types. The measured velocity is about the same for all three, but the pressure is the most impacted by groove geometry.

The experiment also shows us that for powder SB511 and "A" g. geometry a difference in 0,1 gram of powder can drastically change the pressure-velocity relation.

Grove geometry type "B" shows us a unfavorable correlation between pressure and velocity compared to "A" and "C", achieving the highest pressures with moderate velocity. Comparing 5-6 with same load "B" achieves negligible higher velocity (4m/s) than "A" but for a 400 bar higher pressure.

Groove geometry type "C" achieves marginally better results than "B", comparing 7-8 that have the same load, "C" achieves negligible lower velocity (3m/s) with ~130 bar lower pressure.

4.2Analysis of first part

From an internal ballistic point of view the geometry which achieves the highest velocity and lowest pressure is the most favorable. Increasing bullets starting velocity achieves flatter trajectory and greater range, while keeping safe operating pressures does not compromise firearm integrity and safety. Here we can conclude that within the investigated geometries, Type A exhibited the most favorable pressure–velocity relationship.

While all three designs have the same material, overall length, weight, diameter and tolerances, the only difference being the geometry of the grooves.

The grooves here have two major functions:

1. Gas sealing
2. Engraving the bullet into barrel rifling and spinning the bullet.

Increasing the sealing of gases has the benefit of better efficiency where more energy of burning powder goes directly into propelling the bullet forward increasing its velocity, but preventing gas leak past the projectile could cause a increase in peak pressure.

Increasing how much material engages the rifling and is directly engraved into it causes the increase in the frictional resistance of the projectile which decreases its velocity while increasing the peak pressure.

For analysis the nominal barrel diameters are used according to C.I.P. Barrel tolerance and wear are not considered although in real world they affect the depth of rifling grooves and directly affect the engraving resistance.

The volume of "engraved" material for all three groove geometry types is :
A - 11,322 mm^3
B - 26,623mm^3 velocit
C- 21,908mm^3

We can see that type "A" has half the volume of the projectile engraving into rifling compared to other two types. Comparing them for minimal engraved volume we have:

1. A - the lowest,
2. C - second
3. B - the highest

Comparing this to the results we have a clear trend of "A" being the best, and "C" being only marginally better than "B". These observations suggest a positive relationship between engraved material and the projectiles resistance to maximum pressure and velocity.

The results suggest that engraved volume may be treated as an independent design variable for predicting the internal ballistic behavior of monolithic projectiles. Reducing the volume of material displaced during rifling engraving decreases peak chamber pressure while increasing muzzle velocity, making engraved volume a promising optimization parameter for future projectile development.

4.3 Influence of the Number of Grooves

Following the identification of the most favorable groove geometry, a second series of experiments was conducted to investigate the influence of the number of grooves on the internal ballistic performance of monolithic projectiles.

The "A" type groove geometry with raised bands was chosen as the optimal of analyzed variants.
A model with decreased mass and same number of grooves was also included in testing to establish a relation for future experiments.

There were 5 new projectiles for this experiment:

1. A - 6 bands on the bullet, 8g mass (as used before)
2. A.1 - 3 bands evenly spread on the bullet, ~8g mass.
3. A.2 - 3 bands, two at the back and one on the front of the bullet, ~8g mass.
4. A.3 - 4 bands evenly spread on the bullet, ~8g mass.
5. A.4 - 5 bands evenly spread on the bullet, ~8g mass.
6. A.5 - 6 bands evenly spread on the bullet, with lightening hole, ~7,2g mass.

The average values of maximum chamber pressure and muzzle velocity obtained for each projectile configuration are presented in Tables 5 and 6.

Table 5. Second experiment 1. Iteration, powder SB520.

5.	A.4	5	3	812,41	3402,67
6.	A.5	6+hole	3	818,32	3093,33

Table 6. Second experiment 2. Iteration, powder SB511.

Rb	G. Geometry	Number of bands	Powder charge [gram]	Velocity [m/s]	Pressure [bar]
1.	A	6	2,65	775,41	3177,00
2.	A.1	3 even	2,65	771,98	2972,33
3.	A.2	3	2,65	765,51	2911,00
4.	A.3	4	2,65	735,67	2427,67
5.	A.4	5	2,65	773,64	3022,33
6.	A.5	6+hole	2,65	779,42	2693,00

During the initial stage of projectile motion, part of the projectile material is plastically displaced into the rifling lands. The mechanical work required for this deformation increases the resistance opposing projectile motion and contributes directly to the generation of peak chamber pressure. Consequently, projectile designs requiring a smaller volume of material to be displaced during engraving exhibit lower chamber pressures while maintaining comparable muzzle velocities.

The experimental results demonstrate that decreasing the number of grooves (and the engraved material volume at the same time) does not produce a proportional reduction in chamber pressure. Although the engraving resistance is decreased measured pressure differences between the investigated groove configurations remain relatively modest. This observation indicates that there is a limit at a certain point where decreasing the engraving resistance stops affecting pressure/velocity relation at an favourable way.

This trend was consistently observed for both propellants. Although the absolute chamber pressures and muzzle velocities differed due to the different combustion characteristics of SB511 and SB520 powders, the relative influence of projectile geometry remained similar. The consistency of these observations under two independent propellant conditions supports the conclusion that the results are primarily due to bullet geometry rather than propellant-specific.

The projectile incorporating an internal cavity exhibited an additional reduction in chamber pressure while simultaneously producing the highest muzzle velocity among the investigated configurations. This behaviour can be attributed primarily to the reduction in projectile mass, which decreases the force required to accelerate the projectile during the initial phase of internal ballistics. The reduced inertial resistance allows the projectile to begin moving earlier, thereby increasing the available expansion volume for the combustion gases and limiting the maximum chamber pressure.

Overall, the second experimental series confirms that decreasing engraved material volume past a certain „lower limit“ does not necessarily improve internal ballistic performance. Rather, the results indicate that optimization should focus on reducing engraving resistance through careful control of engraved material volume and projectile mass while maintaining sufficient bearing surface to ensure reliable guidance and sealing within the barrel.

5.INTERNAL BALLISTIC EFFICIENCY INDEX

To evaluate the ballistic performance of the tested projectile designs from an engineering perspective, an additional parameter, referred to as the Internal balilistics efficiency index (IBEI), was introduced. While muzzle velocity and maximum chamber pressure are commonly analyzed separately, neither parameter alone fully describes the effectiveness of a projectile design. A projectile that achieves a high muzzle velocity at the expense of substantially increased chamber pressure cannot be considered equally efficient as one producing similar velocity at lower pressure.

The IBEI is therefore defined as:

$$IBEI = V/P \quad (1)$$

where:

- (V) is the average muzzle velocity (m/s),
- (P) is the average maximum chamber pressure (bar).

The IBEI represents the amount of muzzle velocity generated per unit of chamber pressure. Higher values indicate that a projectile converts the available propellant energy into muzzle velocity more efficiently while imposing a lower mechanical load on the firearm.

Table 7. IBEI for first experiment.

No.	Geometry	Powder	Charge (g)	Velocity (m/s)	Pressure (bar)	IBEI ($m \cdot s^{-1}$/bar)
1	A	SB520	3.00	812.32	3408.00	0.2384
2	B	SB520	3.00	805.04	3608.86	0.2231
3	C	SB520	3.00	808.31	3600.37	0.2245
4	A	SB511	2.75	808.72	3658.69	0.2210
5	A	SB511	2.65	780.56	3273.32	0.2385
6	B	SB511	2.65	784.10	3671.97	0.2135
7	B	SB511	2.60	773.98	3562.72	0.2172
8	C	SB511	2.60	770.51	3434.11	0.2244
9	C	SB511	2.55	762.64	3365.31	0.2266

The calculated IBEI values show us that groove geometry type A has the most favorable pressure and velocity relation of tested designs and loads, acros booth powders.

Using the experimental results obtained with the SB520 propellant, the calculated IBEI values are presented in Table 8.

Table 8. Internal ballistics efficiency index for SB520.

Projectile configuration	Mean velocity [m/s]	Mean pressure [bar]	IBEI [$m \cdot s^{-1}$/bar]
3 grooves (even)	807.75	3271.3	0.2466
3 grooves (2 rear)	809.69	3339.7	0.2425
4 grooves	806.90	3326.3	0.2426
5 grooves	812.41	3402.7	0.2387
6 grooves	809.05	3433.7	0.2356
6 grooves + cavity	818.32	3093.3	0.2646

The results demonstrate measurable differences in

pressure efficiency among the investigated projectile geometries. Although the muzzle velocities differ by less than approximately 2%, the corresponding chamber pressures vary considerably, resulting in noticeable differences in the Pressure Efficiency Index.

The projectile incorporating six grooves and an internal cavity achieved the highest PEI value (0.2646 $m \cdot s^{-1}$/bar), indicating the most favorable balance between muzzle velocity and chamber pressure. Compared with the conventional six-groove configuration, this represents an improvement of approximately 12%, primarily due to the reduction in projectile mass and the corresponding decrease in chamber pressure while simultaneously achieving a higher muzzle velocity.

Among the projectiles of identical mass, the differences in IBEI are smaller but remain significant. Configurations with reduced engraving resistance generally exhibit higher pressure efficiency, suggesting that projectile geometry influences internal ballistic performance primarily through its effect on engraving resistance rather than through changes in muzzle velocity alone.

The calculated IBEI values for the SB511 propellant are presented in Table 9.

Table 9. Internal ballistics efficiency index for SB511.

Projectile configuration	Mean velocity (m/s)	Mean pressure (bar)	PEI ($\times 10^{-3}$ $m \cdot s^{-1}$/bar)
3 grooves (even)	771.98	2972.3	0.2597
3 grooves (2 rear)	765.51	2911.0	0.2630
4 grooves	735.67	2427.7	0.3030
5 grooves	773.64	3022.3	0.2560
6 grooves	775.41	3177.0	0.2441
6 grooves + cavity	779.42	2693.0	0.2894

The calculated IBEI values exhibit larger variation than those obtained with the SB520 propellant. Although the muzzle velocities differ by approximately 5%, the corresponding chamber pressures differ by more than 700 bar, resulting in substantial differences in pressure efficiency.

Among the tested configurations, the four-groove projectile produced the highest IBEI value (0.3030$m \cdot s^{-1}$/bar). This result is primarily a consequence of its considerably lower chamber pressure while maintaining a relatively high muzzle velocity. Interestingly, this same configuration exhibited the lowest absolute velocity of all projectiles tested with SB511. Consequently, the high IBEI value should not be interpreted as evidence of superior overall ballistic performance but rather as an indication of exceptionally low chamber loading relative to the achieved velocity.

The six-groove projectile with an internal cavity also demonstrated a comparatively high IBEI (0.2894 $m \cdot s^{-1}$/bar), confirming that reducing projectile mass can improve pressure efficiency by lowering the resistance to acceleration and reducing peak chamber pressure.

The remaining projectile configurations produced IBEI values ranging from 244.1 to 263.0 $\times 10^{-3}$ $m \cdot s^{-1}$/bar, indicating relatively similar pressure efficiencies despite differences in groove arrangement. The conventional six-groove projectile exhibited the lowest IBEI, primarily because it generated the highest chamber pressure while providing only a marginal increase in muzzle velocity compared with the remaining configurations.

Overall, the SB511 results indicate that pressure efficiency is influenced by both projectile geometry and projectile mass. However, unlike the SB520 propellant, the relationship is less uniform due to the unexpectedly low chamber pressure recorded for the four-groove configuration. This observation suggests that additional mechanisms, such as engraving sequence, bearing surface interaction, or gas sealing characteristics, may contribute to the internal ballistic behavior of this particular design.

These findings indicate that the IBEI provides a useful supplementary parameter for comparing monolithic projectile designs. Unlike velocity or chamber pressure considered independently, the IBEI simultaneously accounts for both ballistic performance and mechanical loading on the firearm. Consequently, it enables a more comprehensive assessment of projectile efficiency and may serve as a practical design criterion during the optimization of future monolithic projectiles. Further investigation with a larger experimental sample is recommended to determine whether this result represents a reproducible physical phenomenon or an isolated experimental effect.

6.CONCLUSION

The results demonstrated that modifications to the groove geometry significantly influence peak chamber pressure while also producing changes in muzzle velocity. Among the three groove profiles investigated in the first experimental series, **Type A** consistently exhibited the lowest chamber pressure while maintaining the highest muzzle velocity, indicating the most favourable balance between firearm loading and ballistic performance within the investigated configurations.

Analysis of the groove geometries showed that the observed differences in chamber pressure are primarily associated with the engraved material volume rather than with the groove profile itself. Projectile configurations requiring a smaller volume of material to be plastically displaced during rifling engagement generated lower chamber pressures, indicating that engraving resistance is one of the dominant mechanical factors governing the initial stage of internal ballistics.

The second experimental series demonstrated that simply increasing the number of pressure-relief grooves does not necessarily result in proportional reductions in chamber pressure. Instead, the experimental results indicate that the effectiveness of pressure-relief grooves depends on their influence on engraved material volume and the resulting resistance to projectile engraving. Furthermore, the projectile incorporating an internal cavity exhibited lower chamber pressure and increased muzzle velocity,

confirming that projectile mass also contributes to internal ballistic performance by reducing inertial resistance during projectile acceleration.

An important finding of this study is that projectile geometry produced substantially larger relative changes in chamber pressure than in muzzle velocity. This observation demonstrates that chamber pressure can be reduced through geometric optimization without significantly compromising ballistic performance, providing valuable guidance for the future design of monolithic projectiles.

Overall, the experimental results suggest that engraved material volume represents a practical engineering parameter for the optimization of pressure-relief groove geometry. Rather than considering groove number or groove shape independently, future projectile design should focus on minimizing the volume of material displaced during rifling engraving while maintaining sufficient bearing surface to ensure reliable guidance, structural integrity, and gas sealing.

Future research should investigate a wider range of projectile geometries, calibres, materials, and propellant types, as well as develop predictive numerical and statistical models capable of estimating chamber pressure from measurable geometric parameters.

Abstract: *TKX-50 is a new and very promising secondary explosive with low sensitivity (IS = 20 J, FS = 120 N) and good calculated energetic performance parameters at its theoretical maximum density (1.877 g cm^{-3} @ 298 K) such as D = 9642 m s^{-1} and pCJ = 37 GPa. Thermobaric explosives (TBX) are a combination of high explosive (RDX, HMX, TKX-50) and pyrotechnic combustion of the (usually) metallic fuel (Al, Mg, B, Be, BeH_2, H_3N-BH_3 etc.), and in some formulations, oxidizer. In this research new TBX formulations were surveyed based on: (i) conventional (RDX) and new (TKX-50) high explosives, (ii) conventional (AP) and new (TNEF) oxidizers, and (iii) conventional (Al, Mg) and new (B, Be, BeH2, H3N-BH3 etc.) metallic and non-metallic fuels.*

Keywords: *beryllium, high explosives, oxidizers, thermobarics*

1. INTRODUCTION

Thermobaric explosives (TBXs) derive their effectiveness not only from the initial detonation of the high explosive but also from the subsequent combustion of metallic fuels. Unlike conventional explosives, TBXs produce an extended pressure pulse and prolonged thermal output through post-detonation reactions, making them particularly effective in confined and semi-confined environments. The efficiency of these systems depends strongly on the ability of the metallic fuel to participate in both the oxygen-deficient (anaerobic) reactions immediately following detonation and the later oxygen-supported (aerobic) combustion that occurs as atmospheric air mixes with the expanding fireball [1-3].

Aluminum has traditionally been the preferred metallic fuel for thermobaric formulations because of its high energy density and relatively low cost. However, the practical utilization of aluminum is limited by the presence of a stable oxide layer and by the high melting and boiling temperatures of aluminum and alumina. These characteristics slow ignition and oxidation, reducing the fraction of aluminum that reacts during the relatively short lifetime of the expanding detonation products. Consequently, improving the reactivity of metallic fuels remains an important objective in the development of more efficient thermobaric explosives [4-6].

The present work summarizes two investigations which examined possible alternative strategies for improving TBX performance. The first study direction compares beryllium directly with the conventionally employed aluminum and magnesium as the sole metallic fuel in model thermobaric compositions. The second study direction investigates whether small additions of highly reactive metals - specifically beryllium or cerium - can act as activators that enhance the performance of aluminum without replacing it completely [6-10]. Together, these studies provide new insight into the role of metallic fuel chemistry during both the anaerobic and aerobic stages of thermobaric explosions.

This work also presents effects of introducing new oxidizer TNEF as a replacement for AP in thermobaric formulation.

2. METAL FUELS AND HIGH EXPLOSIVES

In order to consider in more detail the impact of the metal used, formulations were prepared which all employed a common energetic matrix consisting of RDX passivated with wax and ammonium perchlorate, and only the metallic component was varied. In the first approach, the metallic fuel consisted exclusively of aluminum, magnesium, or beryllium. In the second study approach, aluminum served as the principal fuel and was partially replaced by small amounts of either beryllium or cerium. Using the same formulation strategy ensured that differences in measured performance could be attributed primarily to the properties of the metallic additives rather

Corresponding author: T. M. Klapötke;
E-mail: tmk@cup.uni-muenchen.de
DOI: 10.5937/OTEH26051K

than changes in the energetic matrix.

TKX-50 has recently been studied as a potential replacement for HMX in thermobaric formulations and showed extraordinary performance, introducing higher detonation properties in the observed mixtures [11-14].

3. OXIDIZERS

Tris(2,2,2-trinitroethyl) orthoformate (TNEF) (Fig. 2) is one of the most interesting examples of a purely CHNO-based oxidizer developed in recent years [13-17]. It could be shown that TNEF combines several properties that are rarely achieved simultaneously in organic oxidizers, namely a favorable oxygen balance, comparatively high density and a halogen-free composition that avoids chlorine-containing combustion products. In this respect, TNEF addresses key limitations associated with conventional oxidizers such as ammonium perchlorate. The significance of TNEF is further supported by its demonstrated applicability in practical formulations. Incorporation into nitrocellulose-, HTPB-, PDMS- and GAP-based systems has shown that TNEF is compatible with technologically relevant binders and can deliver promising thermal and combustion-related performance. Recent stability studies also indicate that TNEF possesses a more robust thermo-chemical profile than might be expected from its highly nitrated molecular structure. At the same time, the current state of research on TNEF is still at an early development stage. Comprehensive ballistic data, large-scale production routes, long-term aging studies, and full motor-level validation have so far not been realized. TNEF should therefore not be considered a replacement-ready oxidizer at present. Overall, TNEF is best regarded as a highly promising pre-technical oxidizer candidate. Its importance lies not only in its individual performance metrics, but also in demonstrating that purely organic CHNO compounds are realistic targets for use in propulsion applications. Further experimental and computational studies will determine whether this potential can be translated into application. Figure 1 shows chemical structure of TNEF molecule.

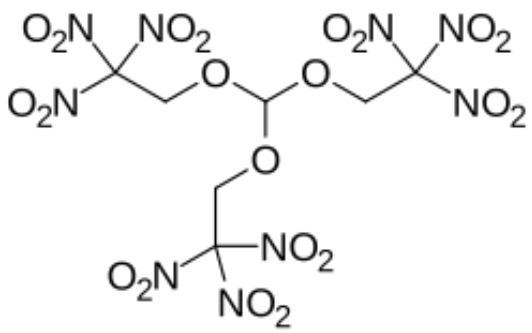

Figure 1. Structure of TNEF

The observed thermobaric composition with new oxidizer TNEF was made as cast-cured mixture with silicone binder, HMX/Al/TNEF/PDMS, and compared to a reference composition HMX/Al/AP/PDMS. They were labeled as TBX-1 (with AP) and TBX-2 (with TNEF).

4. CHARACTERIZATION OF THE THERMOBARIC FORMULATIONS

In order to characterize experimentally the explosive performance of selected thermobaric formulations, several techniques were used. For example, heat of detonation measurements were performed using bomb calorimetry under inert conditions to quantify the energy released during detonation. Quasi-static overpressure was measured inside a nitrogen-filled explosion chamber, allowing evaluation of energy release during the anaerobic combustion stage without interference from atmospheric oxygen. Finally, 500 g pressed charges were detonated in a semi-confined bunker where detonation velocity, peak blast pressure, and blast impulse were determined, thereby assessing the combined effects of anaerobic and aerobic combustion under realistic conditions. The experimental measurements were complemented by thermochemical calculations using the EXPLO5 code with the BKWs equation of state to compare measured behavior with equilibrium predictions.

5. RESULTS AND DISCUSSION

Calculated and measured heats of detonation for TBX formulations containing 60% RDX, 20% AP and 20% fuel (metal) are compared in Figure 2. LiF was included as an inert reference material. Here we may observe the effects of individual metal fuels incorporated in the reference thermobaric composition.

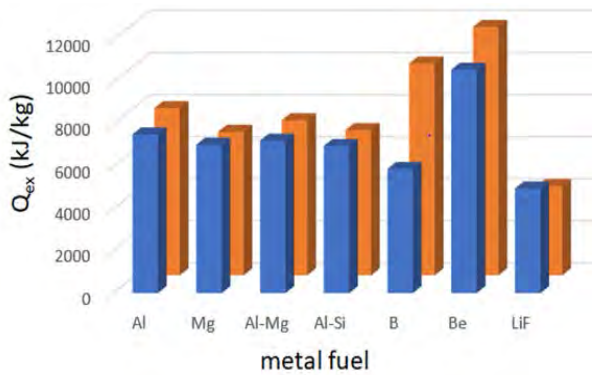

Figure 2. Calculated (orange) and measured (blue) heats of detonation for TBX formulations.

Direct comparison of the results obtained using aluminum, magnesium, and beryllium demonstrated that beryllium possesses a substantially greater ability to contribute energy during both stages of the thermobaric process. The beryllium-containing formulation produced the highest experimentally measured heat of detonation, exceeding the corresponding aluminum and magnesium formulations by more than forty and fifty percent, respectively.

Although equilibrium calculations predicted even greater energy release, the measured values indicate that reaction kinetics and incomplete oxidation limit full utilization of

beryllium under experimental conditions. Nevertheless, the energy contribution of beryllium remained significantly greater than that of conventional metallic fuels (Fig. 2).

Measurements in the nitrogen-filled chamber further demonstrated the exceptional activity of beryllium during anaerobic combustion. The composition containing beryllium generated the highest quasi-static overpressure and the largest TNT equivalent among the formulations investigated. These results show that beryllium reacts efficiently with the gaseous products formed immediately after detonation, even before atmospheric oxygen becomes available. Subsequent bunker experiments confirmed that this enhanced reactivity also translates into superior blast-wave characteristics under practical conditions, including increased peak overpressure and blast impulse. Overall, the data consistently indicate that beryllium is considerably more effective than either aluminum or magnesium in promoting energy release throughout the thermobaric event.

Building upon these findings, the second investigation explored whether smaller quantities of highly reactive metals could improve the thermobaric performance of aluminum-based formulations. Partial replacement of aluminum by only 4 wt% beryllium or cerium produced measurable improvements in explosive performance despite the comparatively small concentration added. Both modified formulations generated approximately ten percent higher quasi-static overpressures than the aluminum reference composition, while corresponding TNT equivalents derived from chamber measurements and blast-wave impulses also increased noticeably. These observations indicate that both additives (Be or Ce) accelerate or promote aluminum participation during the early stages of combustion, thereby improving overall energy utilization.

The behavior of beryllium and cerium, however, differs in important respects. Beryllium possesses an exceptionally high heat of combustion and therefore contributes both chemical activation and substantial additional energy release. Cerium, in contrast, has a considerably lower calorific value but exhibits high chemical reactivity toward oxidizing species generated during detonation. Consequently, cerium appears to function primarily as an ignition promoter that facilitates earlier aluminum oxidation rather than serving as a major energy source itself. Despite these different mechanisms, both additives successfully enhance the effectiveness of aluminum-containing thermobaric formulations.

Thermochemical calculations further support the experimental observations while also highlighting the importance of reaction kinetics. Equilibrium calculations generally predict greater energy release than is measured experimentally, indicating that complete oxidation of metallic particles is not achieved during the rapid expansion of detonation products. This discrepancy is particularly significant for beryllium because of its high oxygen demand and the limited time available for complete combustion. Nevertheless, the experimental results demonstrate that even partial reaction of beryllium provides substantial performance benefits owing to its high intrinsic energy content and rapid participation in post-detonation chemistry.

Regarding the thermobaric output of the formulations with new oxidizer, TNEF, the observed outputs are given graphically in Figures 3 and 4. It may be noted that TNEF provides equal to somewhat higher thermobaric output compared to AP. Being an eco-friendly, chlorine-free oxidizer, TNEF is a promising replacement for AP and other chlorinated oxidizers.

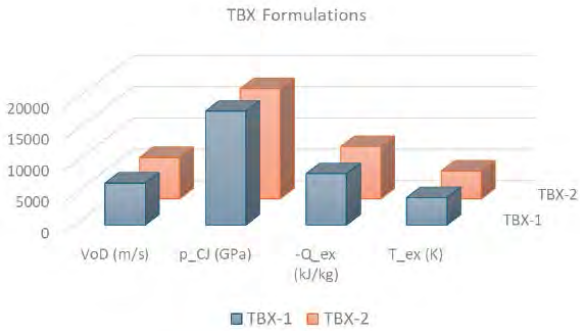

Figure 3. Graphical representation of the performance parameters of the TBX formulations TBX-1 (containing AP) and TBX-2 (containing TNEF instead of AP).

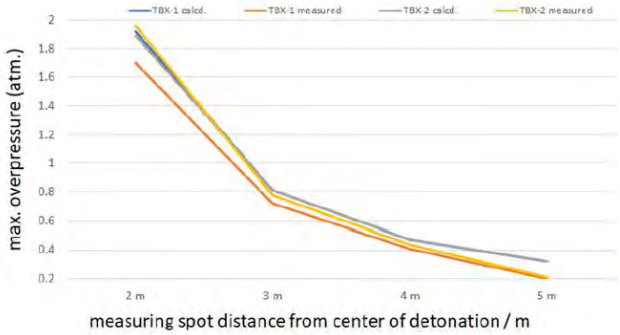

Figure 4. The maximum overpressures at different distances for TBX-1 (with AP) and TBX-2 (with TNEF) as a function of the distance

Replacing RDX in model thermobaric formulations by the highly promising secondary explosive TKX-50 was of particular interest since TKX-50 is a nitrogen-rich secondary explosive with the empirical formula $C_2H_8N_{10}O_4$ and therefore raised the question as to whether using a nitrogen-rich secondary explosive would reduce the quantity of oxidizer required in the TBX formulation, with the metal fuel potentially forming a metal nitride e.g. AlN (aluminum nitride) in the post-detonation products [11-12]. However, it was found that the heat of detonation of a 90/10 TKX-50/Al formulation was 90 J/g lower than the value for 100% TKX-50. It was found that in the post-detonation stage, Al reacts with the detonation products of TKX-50 contributing in this process 375 J/g. In an air-filled detonation chamber adding Al to TKX-50 results in a higher observed maximum temperature of the explosion products by 700 K, while this difference is reduced to 370 K in an argon-filled chamber. It was also found that the addition of Al under air-filled chamber conditions resulted in a much longer duration of time during which a temperature of at least 1600 K is observed. Interestingly

however, X-ray powder diffraction identified solid residue from the detonations performed under an Ar atmosphere as being predominantly $Al_{2.811}N_{0.435}O_{3.565}$ and not pure aluminum nitride, and under air-filled chamber conditions, essentially no aluminum oxynitride phase was observed. It should also be mentioned that TKX-50/ph/Al (70/3/27) shows a maximum overpressure value which is 30% higher than that of TKX-50ph (TKX-50/paraffin 97/3) in air atmosphere chamber conditions, which suggests that Al reacts with both oxygen from the air as well as the detonation products of nitrogen-rich TKX-50.

Based on these experimental observations, it was concluded that in this case, despite the higher concentration of nitrogen in the post-detonation products of nitrogen-rich TKX-50 in comparison with less nitrogen-rich secondary explosives, the burning of Al in nitrogen does not provide vast quantities of energy and aluminum oxides appear to be preferentially formed, even when the concentration of nitrogen in post-detonation products is considerably higher than that of oxygen.

6. CONCLUSION

Two promising approaches for improving thermobaric explosives have been described. Complete replacement of conventional metallic fuels by beryllium or, potentially, a beryllium-aluminum alloy, produces the greatest overall enhancement in detonation energy, quasi-static overpressure, and blast-wave performance. Alternatively, small additions of either beryllium or cerium to conventional aluminum formulations provide significant improvements while requiring only limited modification of existing compositions. The results show that careful selection and optimization of metallic fuel chemistry can substantially improve the efficiency of energy release during both the anaerobic and aerobic stages of thermobaric explosions. These findings provide valuable guidance for the future design of advanced thermobaric formulations in which both the energetic properties and the reaction kinetics of metallic additives are considered simultaneously. TKX-50 as a nitrogen-rich secondary explosive also significantly enhances thermobaric output of aluminized formulation in controlled conditions.

New oxidizer TNEF has shown potential as a chlorine-free replacement for AP on TBX formulations, providing even higher thermobaric output compared to reference AP-based TBX.

***Abstract**: This paper presents a physics-based simulation of a modular compliant robotic system that couples a cable-driven parallel mechanism with a scissor lift extension stage. The mechanism employs three DC servo motors (rated at 490.3325 Ncm with a 25 mm pulley radius) and three antagonistic spring elements (stiffness k_s = 7878 N/m), arranged on a hexagonal base of radius R = 35 mm to achieve controlled tilt and vertical displacement of the end-effector platform. The simulation runs at 1 kHz within PyBullet and exposes a real-time graphical interface supporting both interactive and automated demonstration modes. Bézier curve interpolation generates smooth actuator trajectories between discrete waypoints. The simulation is coupled to a physical prototype via an STM32 Nucleo F401RE microcontroller through a UART serial link. Motor commands are encoded as PWM pulse widths in the range 500-2500 µs. The four-stage scissor lift provides vertical extension without disturbing the kinematic configuration of the parallel module. Simulation results demonstrate stable platform tracking across the full trajectory range under gravity loading, with no constraint violations observed during open-loop operation.*

***Keywords:** modular robotics, parallel mechanism, scissor lift, physics simulation, kinematic modelling, compliant actuation.*

1. INTRODUCTION

Parallel mechanisms offer a well-established combination of structural stiffness, high load-to-weight ratio, and predictable kinematic behaviour that serial-chain architectures cannot match at comparable actuator masses [1]–[3]. The most prominent is a Stewart-Gough platform, incorporating six independently extensible legs connecting a fixed base to a mobile platform, providing six degrees of freedom (DOF) pose control [4].

Many field applications, such as inspection, agriculture, wearable assist devices, and similar, require mechanisms that can accommodate unstructured contact, absorb disturbances, and be physically compact for transport, yet extendable to a useful working range on demand [5], [6]. Actuators compliance addresses the first two requirements. Whether implemented through series elasticity [7], antagonistic spring pairs [8], [9], or passive cable compliance, elastic elements are used to absorb impact energy, regularize force transmission, and decouple the controller from high-frequency mechanical resonances. Cables transmit only tension, removing the need for rigid link pairs, and the resulting low inertia enables fast reconfigurations of the workspace, giving cable-driven parallel robots (CDPRs) additional advantages over their rigid-link counterparts [5], [10]. The main constraint is that the cables must remain taut. This makes workspace definition and trajectory planning non-trivial tasks. However, for mechanisms operating about a nominal configuration, linear approximations of the inverse kinematics are tractable and have been validated experimentally [3], [11]. Scissor-type lifting mechanisms provide orthogonal capability and compact storage with almost linear vertical extension, described by a closed-form height-to-angle relationship [12], [13]. Integrating a scissor stage above a rotating platform module decouples the elevation positioning from the fine orientation, which simplifies both the kinematic model and the control hierarchy.

Modular architectures exploit these properties by stacking identical modules, each contributing additional DOFs without requiring a complete redesign of the controller [14], [15]. The platform described in this paper aims to achieve that type of design: a base module with three drive motors and three antagonistic springs provides tilt and limited heave, while a four-stage scissor lift provides the required vertical reach. Physics-based simulation at 1 kHz in PyBullet [16] closes the development loop before hardware deployment, with a—command-forwarding interface to an STM32 Nucleo [17] enabling open-loop system validation.

2. SYSTEM DESCRIPTION

The Mimi platform consists of two stackable modules and each module has two segments. Base segment that is doing

Corresponding author: N. Tanasković;
E-mail: nemanja.tanaskovic@biosense.rs
DOI: 10.5937/OTEH26052T

rotating motion and scissor mechanism segment that is doing translational motion along local z-axis. One such module is shown on Figure 1. Each base segment has three DC servo motors and three antagonistic spring elements that are mounted on a hexagonal base of radius $R = 35$ mm, with the actuators interleaved at 60° angular intervals. The motors drive the platform through cables, while the springs provide passive restoring forces that maintain cable tension and contribute stiffness. On top of each rotating segment, a four-stage scissor lift provides pure vertical extension along the module's local z-axis without altering the relative orientation between the scissor base and the platform above it. Two linear guide rails stabilize the scissor mechanism by reducing its lateral tilt. The scissor is driven by a separate spool and cable arrangement, decoupled from the tilt actuation. Stacking two modules with their respective scissor stages provides a system with independent tilt control at each level, enabling spatial configurations that a single-module design cannot achieve.

3. KINEMATIC MODEL

3.1. Geometric Definition

The global fixed frame $F_o = \{O;\ \hat{e}_x, \hat{e}_y, \hat{e}_z\}$, whose origin coincides with the centre of the base plate shown in the Fig. 2. is used as a reference. Actuators are arranged in two interleaved sets at radius R. Main actuators, motors indexed $k \in \{1,2,3\}$ at angular positions:

$$\theta_{m,k} = \frac{2\pi(k-1)}{3}, \quad (1)$$

Error! No sequence specified.

with planar coordinates $p_{m,k} = R\{cos\theta_{m,k}, sin\theta_{m,k}, k\}^T$. Antagonistic springs are placed at $\theta_{c,k} = \theta_{m,k} + \frac{\pi}{3}$, with coordinates $p_{c,k}$ defined analogously.

The 60° offset ensures that each spring contact point lies at the bisector of two adjacent motor positions, thereby ensuring symetricall placement of motors and springs.

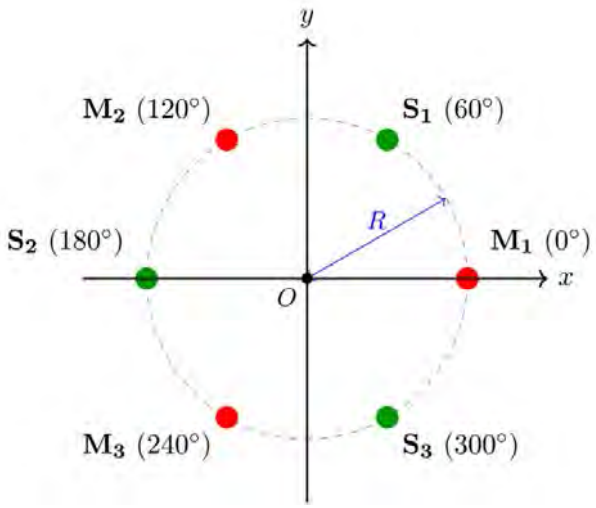

Figure 2. Motor (red) and spring (green) position on the base plate, with shown radius R

3.2. Actuation Kinematics

Let $\varphi(t) = \{\varphi_1, \varphi_2, \varphi_3\}^T$ be the motor input vector, with $\varphi_k > 0$ denoting cable shortening at motor k. The system operates at a nominal height z_0. The z-heights imposed at the main actuator contact points are:

$$Z_{m,k}(t) = z_0 - r_k \cdot \varphi_k(t), \quad (2)$$

while the antagonistic control actuators satisfy the constant-diameter constraint:

$$Z_{c,k}(t) = z_0 + r_k \cdot \varphi_{opp,k}(t), \quad (3)$$

where the opposing permutation is $\varphi_{opp,k} = \{\varphi_3, \varphi_1, \varphi_2\}^T$. Concretely, the spring at 60° opposes motor 3 at 240°; the spring at 180° opposes motor 1 at 0°; the spring at 300° opposes motor 2 at 120°. This pairing preserves platform planarity to a first order and is analogous to the constant-sum constraints exploited in antagonistic joint designs [8], [9].

3.3. Trajectory Generation: Constrained Bézier Interpolation

The system computes a travelling vector $V(\tau)$ that sweeps continuously around the hexagonal arrangement. The sweep parameter $\tau \in [0,1]$ is obtained by normalising the global azimuth angle within each 120° sector:

$$\tau = \frac{\theta_{global}\,(mod 120°)}{120°}. \quad (4)$$

Smooth interpolation between the discrete motor heights uses quadratic Bézier curves [18], [19]. The imposed constraint defines that the curve must pass exactly through the control actuator height $Z_{c,k}$ at the sector midpoint $\tau = 0.5$. For a standard quadratic Bézier with control points $P_{start}, P_{virt}, P_{end}$:

$$B(0.5) = 0.25P_{Start} + 0.5P_{virt} + 0.25P_{end} = P_{target}. \quad (5)$$

Solving for the virtual control point:

$$P_{virt} = 2Z_{c,k} - 0.5(P_{start} + P_{end}). \quad (6)$$

Substituting (6) back into (5), now evaluated at an arbitrary τ rather than at τ = 0.5, and collecting the terms in τ, the three scalar weight functions W_i are:

$$W_1(\tau) = 1 - 3\tau + 2\tau^2, \quad (7)$$

$$W_2(\tau) = 4\tau - 4\tau^2, \quad (8)$$

$$W_3(\tau) = 2\tau^2 - \tau, \quad (9)$$

The proposed weights satisfy $W_1(\tau) + W_2(\tau) + W_3(\tau) = 1$ for all τ. The partition of unity property, which ensures that the interpolated height is a convex combination of the actuator heights when $W_i \geq 0$ which is a property that bounds the travelling vector within the convex hull of the actuator values.

3.4. Per-Sector Height Equations

Substituting (2), (3), and (7)–(9) into the Bézier formula for each sector gives a new set of equations:

Sector 1 starts at motor 1, midpoint at spring 1, whose opposing motor is 3, and ends at motor 2:

$$V_{z,1}(\tau) = W_1(z_0 - r_k\varphi_1) + W_2(z_0 - r_k\varphi_3) + W_3(z_0 - r_k\varphi_2). \quad (10)$$

Sector 2 starts at motor 2, midpoint at spring 2, whose opposing motor is 1, and ends at motor 3:

$$V_{z,2}(\tau) = W_1(z_0 - r_k\varphi_2) + W_2(z_0 - r_k\varphi_1) + W_3(z_0 - r_k\varphi_3). \quad (11)$$

Sector 3 starts at motor 3, midpoint at spring 3, whose opposing motor is 2, and ends at motor 1:

$$V_{z,3}(\tau) = W_1(z_0 - r_k\varphi_3) + W_2(z_0 - r_k\varphi_2) + W_3(z_0 - r_k\varphi_1). \quad (12)$$

In all three sectors, z_0 factors out and the deviations from nominal collapse to a common matrix form. Let the sector index $s \in \{1, 2, 3\}$, then:

$$V_{z,s}(\tau) = z_0 + r_k\left[W_2(\tau)\varphi_{opp,s} - W_1(\tau)\varphi_s - W_3(\tau)\varphi_{s+1}\right], \quad (13)$$

which is the closed-form expression for the travelling vector height in any sector, parameterised entirely by the three motor inputs, φ, and the Bézier vectors, illustrated in Fig 3. When all motor inputs are equal, $V_{z,s}(\tau) = z_0$ for all τ, confirming that symmetric actuation produces pure heave without tilt.

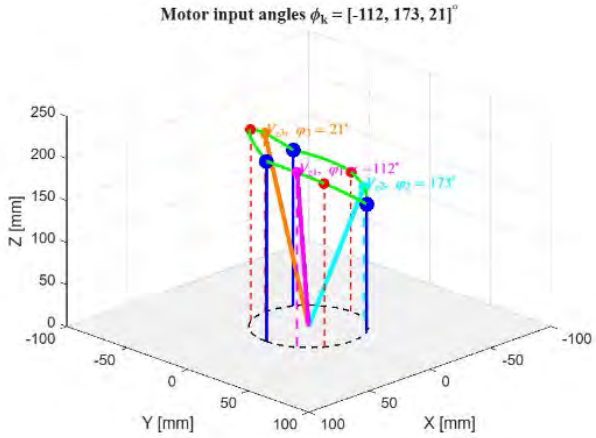

Figure 3 Bézier travelling vector (green) for φ = [−112, 173, 21]°. Motor contact heights (blue) and antagonistic spring heights (red) define the interpolation endpoints and midpoints in each of the three sectors

3.5. Scissor Lift Kinematics

The scissor lift, shown in Fig 4, consists of n = 4 identical stages, each built from crossed links of length $l = 0.08$ m. A spool of radius $r_{sc} = 0.0125$ m winds a control cable, and $l_0 = 0.05$ m is initial horizontal span of the scissor links at rest. The total lift height as a function of spool angle φ_{sc} is [12], [13]:

$$H(\varphi_{sc}) = n\sqrt{\left(\frac{l}{2}\right)^2 - \left(\frac{l_0 - r_{sc}\varphi_{sc}}{2}\right)^2} \quad (14)$$

The transmission Jacobian, sensitivity of lift height to spool angle, is:

$$\frac{dH}{d\varphi_{sc}} = -\frac{nr_{sc}(l_0 - r_{sc}\varphi_{sc})}{2\sqrt{l^2 - (l_0 - r_{sc}\varphi_{sc}^2)}} \quad (15)$$

The denominator in (15) tends to zero when the links approach full horizontal extension, which corresponds to a kinematic singularity of the scissor [20]. The operational range is chosen to remain well below this limit. Because the scissor operates along the platform's local z-axis, it is kinematically decoupled from the tilt mechanism.

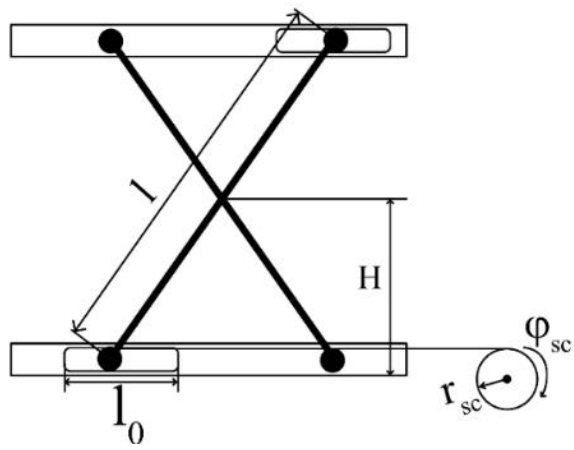

Figure 4. Schematic representation of one stage scissor mechanism

4. SIMULATION ENVIRONMENT

4.1. PyBullet Physics Engine

The simulation is implemented in Python using PyBullet [16], a physics engine that models rigid-body, contact, constraints, and gravitational loading. The comparison study of [21] confirms that PyBullet provides adequate fidelity for constrained rigid-body mechanisms of this class, with stable simulation at time steps of 1 ms. Gravity is set to $g = -9.81$ m/s²; the simulation time step is $\Delta t = 1$ ms, giving a 1 kHz update rate.

4.2. Actuator and Constraint Modelling

Each of the three motors and three springs is represented as a two-body assembly, where a cylindrical base body is fixed to the module frame, and a piston body is connected to it by a prismatic joint. The prismatic joint constrains relative motion to the actuator's local axis. A spherical joint connects the top of the piston to the platform, allowing free rotation at the attachment point and preventing the transmission of torques. This base prismatic piston spherical platform chain captures the essential constraint hierarchy of a cable-driven mechanism while remaining computationally tractable.

Each prismatic joint is actuated using a PD-based position control law that drives the piston toward its target height. The motor actuators receive target heights derived from (2), and the spring actuators receive target heights from (3). Gain values are tuned empirically and are not reported here, as they are simulation-specific heuristics rather than physical parameters of the mechanism. Figure 6 shows this chain for both actuator types. The motor and spring branches have an identical structural topology and differ only in the source equation used to determine the target height. Both branches converge at the spherical joint onto the shared platform body.

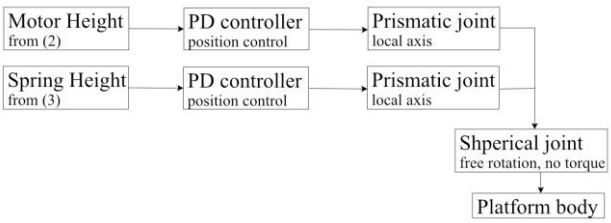

Figure 5. Block diagram of the actuator and constraint modelling chain for the motor and spring branches.

4.3. Module and Scissor Mechanism Modelling

Three custom classes were developed for Mimi platform, and are not part of the PyBullet library: Module, ScissorMechanism and SimulationController. Each class defines the structure and behaviour of its corresponding mechanical component. Object are instanitiated from these classes to construct the full simulation.

Object from the `Module` class encapsulates the platform body and six actuator objects, computing their attachment positions from the coordinate formulas. The ScissorMechanism object creates a prismatic constraint along the parent platform's local z-axis and computes the target piston position from (14) at each time step. The SimulationController is initiated at start up, stacks two modules, managing the kinematic chain from the ground to the top platform. Figure 7 show the resulting object hierarchy. The controller owns two Module instances, each of which contains its actuator objects, platform body, and a ScissorMechanism that recomputes its target piston position from (14) at every simulation step.

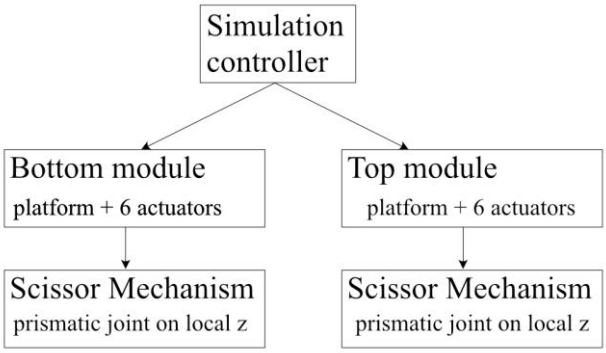

Figure 6. Object hierarchy of the Module and ScissorMechanism simulation classes.

4.4. Trajectory Visualisation and Demo Mode

A TrajectoryVisualizer object pre-computes the Bézier weight arrays (7)–(9) at initialisation and renders the travelling vector curve in real time by submitting line segments to the PyBullet debug drawing API. The curve updates every simulation step, so the user can observe the relationship between motor inputs and the interpolated trajectory continuously.

The demonstration mode drives the three motors with equal-frequency sinusoidal signals mutually offset by 120°, resulting in circular platform rotation. This mode is used for repeatable performance assessment without manual input, covering the full kinematic range of the platform within a defined time frame.

5. HARDWARE INTERFACE

5.1. Microcontroller and Communication Protocol

The DC servo motors on the physical prototype are controlled by an STM32 Nucleo-64 development board with STM32F401RE microcontroller[22]. The combination of a 32-bit ARM Cortex-M4 core, hardware PWM timers, and accessible UART peripherals makes it suitable for this purpose. During the simulation, the communication with the microcontroller was established over a UART serial link at 115200 baud with a DTR toggle reset sequence to synchronise firmware startup. Motor commands are transmitted as ASCII-encoded strings in the format (PWM_1,PWM_2,PWM_3) followed by a newline character, where each field is a pulse width in microseconds. This protocol is identical in structure to the approach used in [17] for robot open-loop validation, and its simplicity eliminates parsing overhead on the embedded side.

5.2. Motor Command Encoding

The servo motors interpret PWM pulse widths in the range *500–2500* µs as angles, with *1500* µs corresponding to the neutral ($\varphi = 0$) position. The mapping from motor angle to PWM pulse width is:

$$PWM[\mu s] = 1500 + \left(\frac{\varphi}{4.27} \cdot 500\right) \qquad (16)$$

The denominator 4.27, expressed in radians, corresponds to the full-scale angular excursion of the servo; the factor of 500 maps this range to the ±1000 µs deviation from centre. Equation (16) is computed in the `NucleoInterface` class and applied to all three motor outputs before transmission.

The STM32 firmware parses each incoming packet, extracts the three pulse width values, and writes them to the corresponding hardware timer channels. The 300 Hz output rate of the main simulation loop is well within the 50 Hz minimum update rate required by standard RC-type servo receivers, ensuring that the motors track the commanded trajectory without stale-data artefacts.

5.3. Simulation-Driven Hardware Validation

The hardware validation is achieved by sending the motor commands from the simulation environment to the Nucleo over UART, and the physical motors execute the commanded trajectories in open loop. The PyBullet simulation runs concurrently with the physical hardware, providing predicted states that can be compared against observed motion through external means. This architecture is sufficient for verifying that simulation-derived trajectories produce correct physical motion and that the communication protocol operates reliably. The internal encoders embedded in the servo motors are used exclusively by the motor driver for position holding and are not accessible to the simulation or the STM32 firmware. Consequently, no feedback path from hardware to simulation exists in the current implementation.

6. RESULTS AND DISCUSSION

6.1. Platform Tracking Under Gravity

The demonstration mode simulation was run for 60 seconds with gravity enabled and all six actuator constraints active. During the simulation, the platform completed multiple full revolutions of the travelling vector without any constraint violations or divergence of the prismatic joint targets. The weight functions (7)-(9) maintained their partition of unity property throughout, so the platform height remained within the envelope defined by the actuators' heights $Z_{m,k}$ and $Z_{c,k}$ at all times. Under asymmetric motor inputs (two motors at zero, one motor at positive deflection), the platform tilted by the expected angle, and the antagonistic opposing springs exhibited the predicted counter force, as evidenced by the piston position readings of the spring assembly.

To verify the simulation with respect to the analytical kinematic model, equation (13) was evaluated at a fixed interpolation parameter $\tau = 0.25$ across six, randomly chosen, motor input configurations spanning the operational range. At $\tau = 0.25$, the Bézier weight functions take fixed values $W_1 = 0.4375$, $W_2 = 0.7500$, $W_3 = -0.1250$, so the travelling vector height reduces to a weighted combination dominated by the antagonistic spring actuator. For each configuration, a settling time of 1 s was introduced before piston heights were sampled. The analytical value of $Vz_{,1}$ was then computed from equations (2), (3), and (13) evaluated at the set motor angles, assuming perfect motor tracking. The PyBullet value is the piston height measured after the settling period, reflecting the physical equilibrium reached by the PD controlled actuator under gravity loading. The kinematic model is exact by construction and any residual difference between the two columns in Table 1 originates entirely from the simulator. Results are summarized in Table 1. At the neutral configuration $\varphi = [0, 0, 0]$, the error was 0.03 mm, confirming that the simulation correctly encodes the kinematic model at rest. Across asymmetric configurations and the actuator heights in the range 160-245 mm, the mean absolute error was 2.6 mm, corresponding to approximately 1.2% relative error. This error is attributed to static deflections under gravity loading, as the feedforward gravity compensation was not included in the PD-controlled actuator model. PD controller gains were set empirically and are not guaranteed to minimize steady-state tracking error. The simulation introduces a bounded tracking offset that is consistent across all tested configurations.

Table 1. Analytical vs. PyBullet travelling vector height at $\tau = 0.25$, Sector 1 ($z_0 = 200$ mm, $r_k = 12.5$ mm).

φ [deg]	Analytical (mm)	PyBullet (mm)	Error (mm)
[−112, 173, 21]	217.33	214.32	3.01
[0, 0, 0]	200.00	199.97	0.03
[100, −100, 0]	189.09	187.84	1.25
[−100, 100, −100]	194.55	198.14	3.59
[50, 50, 50]	205.45	199.97	5.48
[200, −200, 100]	194.55	192.77	1.78

6.2. Scissor Lift Stability

The scissor mechanism was exercised over the range $\varphi_{sc} \in [0, 2.5]$ rad, producing height excursions consistent with (14). The Jacobian (15) indicates increasing force demand as the mechanism extends, which was reflected in the higher PD effort required near the top of the range. Across the full extension range, no lateral tilt of the scissor stage was observed, consistent with the constraining action of the linear guide rails described in Section 2.

6.3. Open Loop Hardware Validation

With the open-loop link active, the three servo motors on the physical prototype responded to commands generated by (16) within one communication cycle. The platform tilt on the physical prototype matched the simulation state within the angular resolution of visual inspection. The

primary source of discrepancy between simulation and hardware was a lag of approximately 100 ms at the start of each motion segment. Possible sources include communication latency, servo actuator dynamics, and current limiting under load. The PyBullet actuator model does not capture any of these effects. Quantifying the individual contributions requires dedicated instrumentation and is left for future work. Platform tilt angles were cross-checked against the simulation using a smartphone's built-in orientation sensor, and the readings were consistent with the simulated tilt throughout the trajectory.

6.4. Discussion

The simulation results confirm that the PyBullet rigid-body model captures the dominant kinematic behavior of the mechanism with adequate fidelity for open-loop validation. The mean absolute error of 2.6 mm across asymmetric configurations corresponds to approximately 1.2% of the operational range; the near-zero error at the neutral configuration confirms correct kinematic encoding, while the offset under asymmetric loading is consistent with the absence of feedforward gravity compensation in the PD actuator model. Feedforward gravity compensation is identified as the primary improvement to reduce this offset. Together, these results indicate that the simulation is a valid development tool for trajectory design and protocol verification. Future work will incorporate feedforward compensation based on (15) to reduce tracking error in this region.

7. CONCLUSION

This paper presented the physics-based simulation, kinematic model, and open-loop hardware validation of the Mimi modular, extensible and compliant robotic platform. The constrained quadratic Bézier interpolation scheme provides a safe travelling vector in a closed form that is directly implementable on embedded hardware. Simulation at 1 kHz in PyBullet confirmed stable tracking across the full kinematic range under gravity. Quantitative comparison of the travelling vector height against the analytical model across six input configurations at $\tau = 0.25$ yielded a mean absolute error of 2.6 mm (approximately 1.2% relative error). The remaining discrepancy was primarily attributed to static gravity sag in the PD-controlled actuator model in the absence of feedforward compensation. Open-loop hardware validation through an STM32 Nucleo-64 development board demonstrated reliable command forwarding at 115200 baud, with physical platform motion visually consistent with the simulation state. Future work will address multi-module tilt coupling at large deflections, and the integration of force sensing for contact-aware operation in agricultural and inspection tasks, as well as closed-loop HIL validation with explicit encoder or IMU feedback.

Abstract: *This work introduces a method for synthesizing thermal imagery in real time within the Unity 3D game engine (Unity Engine/Unity) Editor. The approach builds on the engine's existing light simulation mechanisms, with adjustments that approximate behaviour in the infrared domain. While grounded in real life samples, the method is largely empirical, with calibration driven by the goal of achieving visually convincing results across complete scenes, including dynamic elements and motion. A central outcome is the ability to maintain real-time performance, on the order of 60 frames per second, while remaining sufficiently lightweight to integrate into pre-existing simulation systems developed in Unity. The method is evaluated through direct visual comparison with data captured from thermal cameras, alongside a user-based visual recognition task designed to probe perceived realism. Basic distinctions between material classes, such as metals, plastics, and fabrics, are represented, and the model accounts for ambient thermal contributions influenced by solar exposure and environmental temperature. The primary constraint lies in the preparatory effort required to define thermal characteristics for individual scene elements. Despite this, the approach proves to be a practical and adaptable solution for simulation contexts, particularly in defence and industrial domains, where real-time, visually credible thermal rendering is required without imposing significant computational burden.*

Keywords: *Synthetic infrared image generation, Real-time thermal rendering, Unity Engine, Infrared radiance modelling, Sensor-aware image synthesis.*

1. INTRODUCTION

Infrared (IR) and thermal imaging have moved well beyond their historical military niche into surveillance, pedestrian and vehicle detection, industrial inspection, search-and-rescue, and robotics operating under degraded visibility.

Despite its enormous potential, the development and deployment of IR systems face a significant bottleneck - the scarcity of suitable IR data. Training robust and reliable IR systems requires large, diverse, and high-quality datasets. However, obtaining such datasets in real world is challenging due to privacy concerns, logistical issues, and the difficulty in capturing a wide range of scenarios and conditions [1].

Synthetic IR image data generation is a natural response, following the precedent set by game-engine-based synthesis in the visible domain. This paper proposes a reproducible method for generating synthetic infrared images, and potentially image sequences, using Unity version 2022. The claim is a method proposal, not a fully validated thermal-sensing solution, and not a claim of complete radiometric accuracy. The primary contribution is synthetic infrared rendering in Unity. Although not primarily a dataset-generation tool, as used in [2], the method may later support such workflows. The paper is a starting point for a broader research direction, using simple, self-contained examples to demonstrate feasibility of the core rendering-repurposing strategy rather than delivering a large-scale benchmark.

Beyond dataset scarcity, a second motivation for engine-based infrared synthesis is controllability. Physical thermal data capture is constrained by weather, time of day, sensor availability, and scene access, whereas a synthetic pipeline allows systematic variation of object temperature, emissivity, geometry, and camera viewpoint within a single reproducible scene. This controllability is particularly relevant for generating edge cases, unusual object-background temperature contrasts, or repeated scenarios with only one parameter changed at a time, none of which are easily obtained from field data collection. The cost of measured data is high, and it is difficult to obtain infrared images in various scenarios [3]. The present paper does not exploit this controllability quantitatively, since it presents only two illustrative scenes, but the underlying method is structured so that later work could vary these parameters systematically once the core rendering approach has been established as viable.

A further consideration is computational accessibility. Physically based infrared rendering, if pursued from first principles, typically requires dedicated radiometric renderers, detailed material spectral databases, and

Corresponding author: B Šmidling
E-mail: bojan.smidling@pupin.rs

DOI: 10.5937/OTEH26053S

substantial computational resources to reach acceptable frame rates. By contrast, the approach in this paper deliberately trades physical completeness for accessibility, relying on an engine that is freely available, widely taught, and already familiar to many engineers working on simulation tooling. The priority is establishing the basic approach, rather than delivering the most physically complete implementation achievable.

A final point worth stating explicitly concerns reproducibility. Since the method relies solely on standard Unity components, mesh objects, the Standard Shader's emission channel, a terrain object, and a script computing thermal radiation using Stephan-Boltzmann law per object, it can in principle be reimplemented in any recent Unity version without specialized plugins or proprietary rendering extensions. This stands in contrast to some physically based infrared renderers, which may depend on custom radiometric pipelines that are harder for other researchers to reproduce or extend. Ease of reimplementation is treated here as a practical advantage of the proposed approach, separate from its physical fidelity, and is offered as an additional argument for adopting it as a starting point for further research rather than as a claim about its ultimate accuracy.

Section 2 reviews Unity's visible-range rendering pipeline. Section 3 develops the analogy between visible and infrared rendering. Section 4 details the proposed method. Section 5 presents illustrative examples, and Section 6 concludes with limitations and future work.

2. VISIBLE RANGE RENDERING OVERVIEW

Game engine renders a scene composed of mesh-based objects, each assigned a material referencing a shader that determines how the surface responds to lighting and is rasterized into pixel values. The built-in Standard Shader used in this work exposes albedo, metallic, smoothness, and an emission channel that allows a surface to appear self-illuminated independently of external scene lighting [4].

A virtual camera defines viewpoint, field of view, and output resolution [5]. For each frame, the engine determines visible geometry from the camera viewpoint, applies lighting calculations per the active rendering pipeline, and writes resulting colour values into a two-dimensional image buffer [6]. This mature, real-time-efficient stack is precisely what motivates repurposing it for infrared rendering rather than building a separate renderer from scratch.

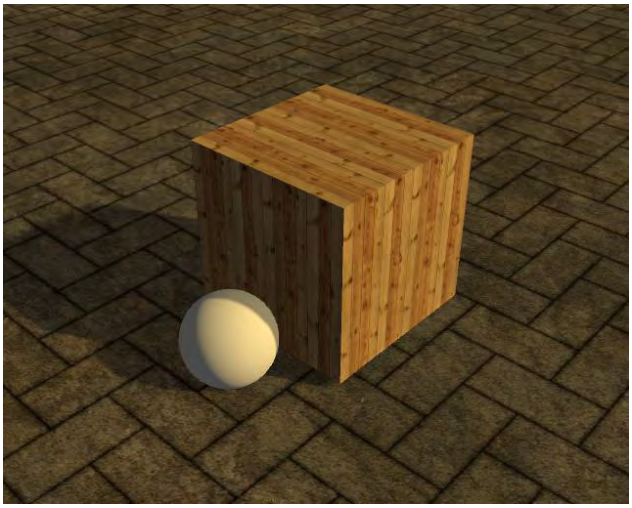

Figure 1. Example scene in visible range, concrete floor, wooden cube and brick sphere, illuminated by the Sun

3. CONNECTION AND ANALOGY OF VISIBLE AND IR RENDERING

The central idea is that the visible-range rendering stack need not be replaced, only repurposed, by changing what surface intensity represents. The same geometry, camera model, and largely the same material infrastructure are retained, but the value written to the output image is reinterpreted as an approximation of infrared emission rather than visible reflectance.

Unity does not natively render infrared radiation. Unity has no built-in concept of thermal emission or wavelength-dependent infrared material response. The method computes a simplified thermal value for each object outside Unity's native lighting model, then feeds that value into the emission property of the Standard Shader, reusing existing rasterization and display infrastructure. Emission functions purely as a rendering proxy, not as a physical model of infrared emission itself.

This distinction, between the physical thermal computation and the rendering mechanism used to display it, connects Section 2 to Section 4: once a thermal value is computed, it is injected into the existing visible-range pipeline through the emission channel, and the remainder of the pipeline proceeds exactly as for an ordinary scene. The method therefore inherits, essentially for free, Unity's existing support for real-time performance, dynamic elements, and animated characters, none of which need reimplementation.

4. METHOD

The proposed method is deliberately minimal in physical scope, covering surface temperature, surface emissivity, and a single spectral-band assumption framed as a long-wave infrared (LWIR) style approximation. Atmospheric transmission, reflected background radiation, detector calibration, sensor noise, optical blur, detector response, and angular or wavelength-dependent emissivity variation beyond the chosen band are intentionally omitted.

4.1. Thermal value computation

For a simplified broadband approximation, emitted radiant exitance is modelled using the Stefan-Boltzmann law:

$$M = \varepsilon\sigma T^4 \quad (1)$$

where M is emitted radiant exitance, ε is surface emissivity, σ is the Stefan-Boltzmann constant, and T is absolute surface temperature in Kelvin. Celsius inputs are converted to Kelvin before substitution.

Stefan-Boltzmann's law approximates total emitted thermal power integrated over all wavelengths, whereas real sensors measure band-limited radiance shaped by reflection, atmosphere, optics, and calibration. The present model is therefore a first-order thermal-appearance approximation, not a complete sensing model. Emissivity values are treated as approximate, band-specific constants per object in LWIR range, not universal material constants, since real emissivity depends on wavelength, angle, texture, and material state.

4.2. Object-level implementation

Each object is assumed to have a single, uniform temperature and emissivity across its visible surface, or each object is approximated to a diffuse reflector, which assumes the radiation reflection intensity of the target is equal in all directions, as stated in [7].. Shadows, ambient lighting, and post-processing are disabled or excluded where they would interfere with the simplified thermal logic, since they belong conceptually to the visible-light domain. In the implementation, every renderable object is parametrised by two scalar values: its surface temperature TTT (in °C, converted internally to K) and its surface emissivity ε, the latter taken from a long-wave infrared emissivity table [8]. In the example scene (**Figure 2**) the wooden cube is assigned $\varepsilon = 0.76$ at $T = 25$ °C (ambient), the concrete floor $\varepsilon = 0.90$ at $T = 25$ °C (ambient), and the brick sphere $\varepsilon = 0.94$ at $T = 40$ °C (self-heated), consistent with emissivity values reported for rough concrete, wood, and fine brick in LWIR .

The emitted radiant exitance M for each object is computed once from Equation 1, using its assigned temperature and emissivity, and serves as a purely numerical proxy for radiative power. This per-object thermal value is then mapped into a colour emission term through Equation 2:

$$EmissionColor = Color.white \cdot \frac{M(T,\varepsilon)}{M(Tmax,1)} \quad (2)$$

In the example configuration $Tmax = 100°C$, so all object emissions are normalised to the radiative output of an ideal blackbody at 100 °C. The resulting $EmissionColor$ is finally written into the _EmissionColor property of the Unity Standard Shader material for that object, ensuring that the visible emission intensity in the rendered frame is a monotonic function of the underlying thermal state while remaining independent of conventional lighting and shading passes.

Figure 2. Raw emission values image of wooden cube, concrete floor and brick sphere in LWIR mode of Unity

4.3. Terrain-level implementation

Outdoor scenes require a terrain surface, handled differently from discrete mesh objects since Unity's Diffuse Terrain shader does not directly expose an emissive parameter in the same way as the Unity Standard shader. The terrain shader takes a single RGB texture and tiles it repeatedly across the terrain. Our implementation takes a texture of grass, soil, and occasional stones, which is then converted into a thermal proxy by editing the artwork so that each material category is recoloured to a normalised grey level proportional to its emissivity, using the mapping:

$$Color_{part} = Color.white \cdot M_{part} \quad (3)$$

In effect, stone regions appear as the brightest tones, soils intermediate, and grass as the darkest, reflecting emissivity-like behaviour in the 0.90–0.98 range for typical soils and vegetation in LWIR, as stated in [8] and [9]. The resulting emissivity texture is then assigned as the albedo input to the Diffuse Terrain shader and treated as a spatially varying emissivity proxy over the terrain surface.

Since Diffuse Terrain provides no emission colour property, a dedicated directional light source is introduced to act as the terrain's thermal emission proxy. This light is restricted to the terrain via Unity's layer system, so that it illuminates only the terrain layer and no other scene objects, thereby isolating the terrain contribution from the rest of the lighting pipeline. For the terrain we set a uniform surface temperature $Tmax = 30°C$ and reuse Equation 2, to compute an emission colour $EmissionColor$. Instead of writing this value into Standard shader property _EmissionColor as in section 4.2., the $EmissionColor$ is applied directly to the C*olor* property of the terrain's dedicated directional light. The light is configured to mimic pure emission rather than conventional illumination by disabling shadows and reflections and aligning its direction to be perpendicular to the terrain surface, yielding a terrain contribution that is visually consistent with the rest of the thermal model while remaining conceptually separate from the visible-light domain.

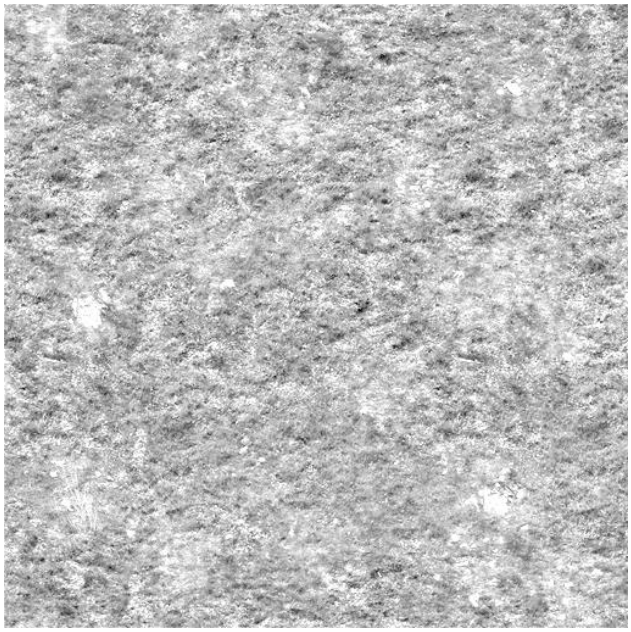

Figure 3. Emissivity texture of terrain used in example scene

4.4. Display mapping and thermal palettes

Once thermal values are computed for all objects and terrain, the scalar field is converted into a displayable image through a mapping stage. Pixel intensity is normalised using the minimum and maximum thermal values present in the current view frustum, so the coldest visible value maps to the darkest output and the hottest to the brightest. Because normalisation is per-frame, absolute brightness is not directly comparable across frames unless the underlying value range is also reported.

In the prototype implementation, the thermal field is rendered into a single render texture by Unity's camera, and a custom post-processing shader, *ReplaceColor*, is applied to this texture to perform the final colour mapping. For every pixel, *ReplaceColor* computes a normalised offset in the palette domain using its current blue-channel value (treated as the scalar thermal intensity) and the global minimum and maximum over the entire render texture,

$$offSetX = \frac{(inputTex2D.b * 255 - _minB)}{(_maxB - _minB)} \quad (4)$$

where *_minB* and *_maxB* are the minimum and maximum blue-channel values observed in the frame. *offSetX* acts as a lookup coordinate into a one-dimensional false-colour palette texture *_PalleteTex*. The final pixel colour is then obtained as

$$PixelColorValue = tex2Dlod(_PalleteTex, float4(offSetX, offSetY, 0, 0)) \quad (5)$$

where *offSetY* is a hard-coded offset selecting the active palette row (e.g. white-hot, red-hot, yellow-hot) within the palette texture. In this scheme the internal thermal output remains a single scalar intensity field, while the choice of palette texture and *offSetY* purely controls visualisation, following the behaviour of commercial thermal imaging systems where switching palettes changes only appearance and not temperature data.

The thermal output is represented internally as a single scalar intensity field. For display, it can be written as equal RGB values for grayscale output, or remapped through a false-colour palette such as white-hot, red-hot, or yellow-hot (Figure 4), following conventions common in commercial thermal software [10]. Palette choice affects only visualisation, not the underlying physical or computational content.

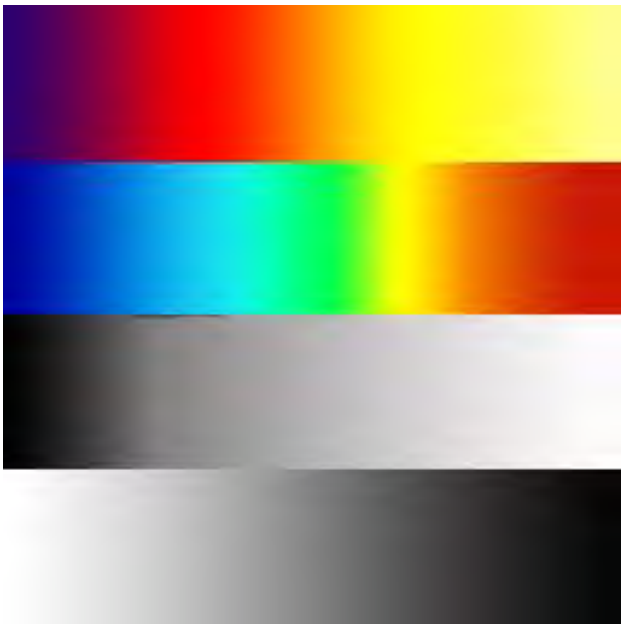

Figure 4. False colour thermal palettes, yellow hot - up, red hot - down

5. RESULTS

The examples below are illustrative demonstrations of feasibility, consistent with the paper's goal of establishing a starting point rather than a validated system. No quantitative sensor-level or task-based evaluation is performed here.

5.1. Uniform-material object scene

The first scene consists of simple geometric objects, each with a distinct material and a distinct temperature-emissivity pair, following Section 4.2. Concrete, wood, and brick surfaces were included, with object temperatures chosen to differ noticeably from one another. Under the normalisation procedure of Section 4.4., the rendered image shows visually distinguishable contrast between objects, driven entirely by Equation 1, without additional post-processing (Figure 5).

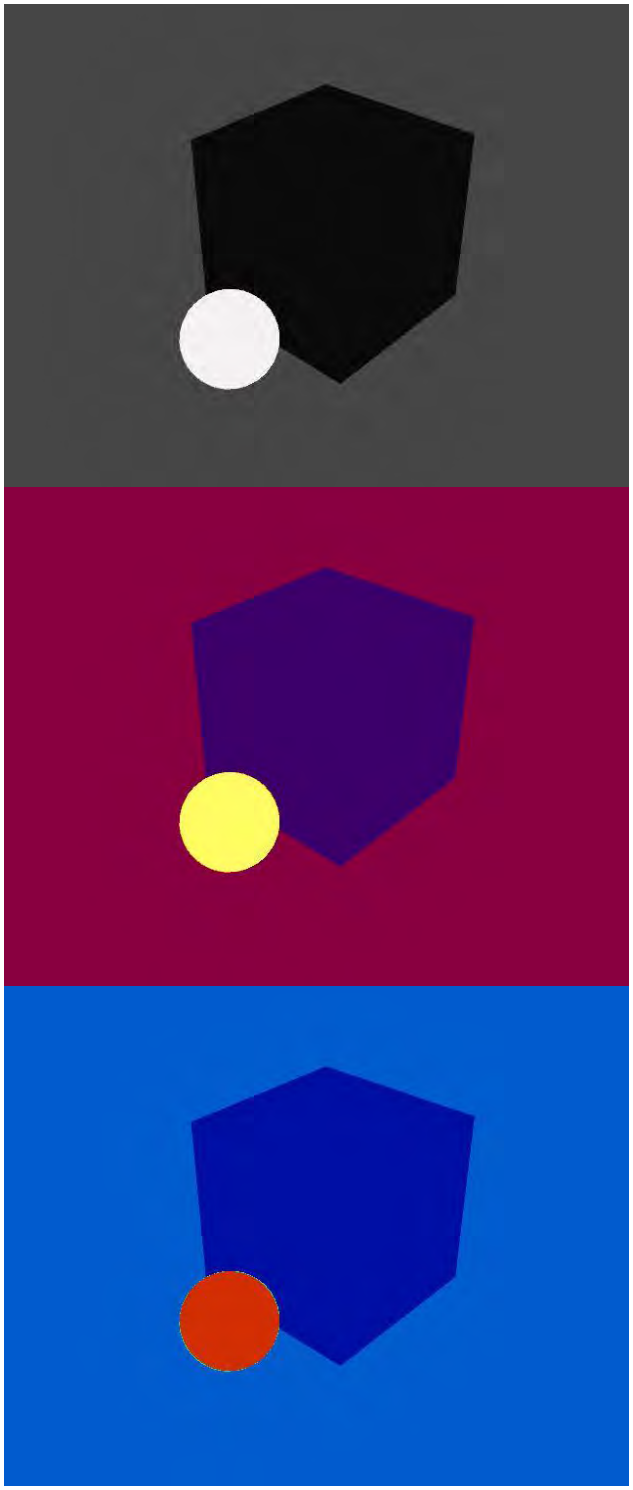

Figure 5. Synthetized LWIR image of example scene in White hot (top), Yellow hot (middle), and Red hot (bottom) colour modes, with normalization procedure

This scene isolates the core thermal computation and normalisation steps in a setting with no terrain or dynamic elements, so the basic mechanism's behaviour is not obscured by scene complexity.

5.2. Outdoor terrain scene with human figures

The second scene combines the object-level and terrain-level procedures of Sections 4.2 and 4.3. A real infrared photograph of soldiers in an open field served as a qualitative visual reference, not a ground-truth target for quantitative comparison. Soldier meshes were placed in a Unity terrain scene, assigned a common body and clothing temperature of approximately 36 degrees Celsius, converted to kelvin before use in Equation 1, together with approximate band-specific emissivity values for clothing and exposed skin of 0.88 (Fabric: Hessian, green) [8]. The terrain was treated with the thermal proxy texture and lighting workaround of Section 4.3., with grass, dirt, and stone assigned emissivity values in the 0.9 to 0.98 range and surface temperature of 30 degrees Celsius.

The rendered output shows human figures as distinctly brighter thermal forms against a cooler terrain background, qualitatively consistent with the reference photograph, where warm-bodied subjects stand out against cooler surroundings (Figure 6). This correspondence is offered strictly as evidence of plausibility, demonstrating that the method reproduces the basic figure-against-background contrast pattern typical of real thermal imagery of people outdoors, not that it reproduces exact radiometric values. Optional blur and synthetic sensor noise were identified as promising additions for improving perceptual resemblance to real thermal camera imagery, and are left for future work.

5.3. Interpretation and evaluation framing

Both scenes support plausibility only and are not sufficient to prove physical radiometric correctness. Appropriate evaluation depends on intended downstream use, and the present paper avoids committing to a single universal protocol that was not actually executed. For realism aimed at human observers, in simulation or training contexts, evaluation should rely on human judgement or structured realism review.

The image provided in [11] was used as a visual reference point (Figure 6). Top panel shows an LWIR image of several people on rough terrain, while the bottom panel shows a Unity-generated synthetic infrared image produced by the proposed method. Blur and noise were added in Photoshop to facilitate visual comparison with the reference image.

For algorithm testing or benchmarking, evaluation should rely on downstream task performance against an established benchmark protocol. Both strategies are left as future work.

6. CONCLUSION

This paper has proposed a deliberately simplified, first-order method for synthesizing infrared imagery in Unity 3D, and demonstrated through two simple examples that visible-range rendering infrastructure can be repurposed to produce structurally plausible thermal-like output. The method retains Unity's existing geometry, materials, and camera model unchanged, introducing a thermal computation stage based on a single-band (LWIR) Stefan-Boltzmann approximation, per-object temperature, and approximate emissivity, injected into the pipeline through the Standard Shader's emission property used strictly as a

rendering proxy.

The implementation is explicitly limited by object-wise uniform emissivity and temperature, a single spectral band (LWIR), and the omission of atmospheric transmission, reflected background radiation, detector calibration, sensor noise, optical blur, and angular or wavelength-dependent emissivity variation. Each of these omissions is identified as an addressable direction for future research.

Concrete extensions include material-class differentiation between metals, plastics, and fabrics through class-specific emissivity behaviour, incorporation of ambient thermal contributions from solar exposure and environmental temperature via Equation 1, and a move from qualitative plausibility toward quantitative evaluation through human-judgement studies or downstream task-based benchmarking. This work suggests that general-purpose real-time game engines are a viable and accessible foundation for synthetic infrared research, provided the physical scope and limitations of any such method are stated as clearly as they have been here.

Abstract: *Acoustic methods for the detection of propeller-driven drones are used at relatively short distances, up to a few hundred meters. The drones are relatively weak sources of sound. The appearance of acoustic disturbances in the environment significantly reduces quality of the detection and localization drones by acoustic methods. Starting assumption, in resolving of this problem, is that acoustic ambient noise has a Gaussian natural distribution. A significant reduction in the influence of ambient noise was achieved by using the so-called statistical filter, which eliminates all contributions of ambient noise if their distribution is Gaussian. The function of filtering acoustic signal, that is, the filter itself, is realized as an independent module, that is, a processor that analyzes the acoustic signal using standard statistical methods, as well as higher order statistics. To check the quality of the filter itself it is used the five core quality factors: correlation coefficient, Normalized Root Mean Square Error (NRMSE), Signal-to-Error Ratio (SER), Maximum Absolute Error (MaxAE) and Estimated Delay (τ). The analyzed acoustic signals were generated in different flight mode of the drone, such as hovering, circular movement, left-right movement and others.*

Keywords: *drone, acoustic noise, statistical filter.*

1. INTRODUCTION

Acoustic detection of drones is crucial becausee it fills critical gaps left by radar and cameras against modern drone threats, especially in complex environments. There are more significant reasons for using acoustic methods such as its passive and steatlthy nature, identification of fiber optic drones, and in addition, these acoustic methods can act as a low-power trigger for turnig on radar and high resoluton cameras only after it hears a drone nearby.

There are different ways to do make signal useful and clear, such as filters and transforms. Nowadays exists and more advanced techniques like computer programs and smart networks. This paper explores a relatively little-used method for extracting useful signals from noise, which is statistical method based on higher order statistics. In adddition to the description of the filter itself, the paper presents its application in acoustics, seismics, hydroacoustics and infrasound analysis. Several tests were performed to obtain an evaluation of quality of the filter. The five core quality factors are used: correlation coefficient, Normalized Root Mean Square Error (NRMSE), Signal-to-Error Ratio (SER), Maximum Absolute Error (MaxAE) and Estimated Delay (τ). All of these methods help us to understand how useful is this filtering method for extracting a signal from noise.

Statistical filters use well-known statistical quantities, like mean and variance to process the signal. The mean filter, for example, replaces each data point with the average of neighboring points within a specific window. By averaging nearby values, high-frequency noise is smoothed out, and the signal is effectively de-noised, see [1]. Practical explanation of moving average filters with implementation examples and applications are given in the paper Smith, Steven W. [2]. Moving average is effective at removing high-frequency noise, but may blur sharp features or sudden changes in the signal. The choice of the window size is critical; a too small window might not remove enough noise, while a too large window can lead to loss of important signal details. There are many others filtering techniques. The Gaussian smoothing involves convolving the signal with a Gaussian kernel. The Gaussian function gives more weight to central points and less weight to distant points, see [3, 4].

Wavelet technique is used for de-noising signals by thresholding the wavelet coefficients. Wavelet transform decompose the signal and transform it into wavelet coefficients at different scales and positions. These coefficients represent the signal's details at various levels of time and frequency resolution [5, 6].

Classic comprehensive treatment of statistical filtering theory is well described in the book of the author Jazwinski, Andrew H. [7]. Modern Bayesian approaches including particle filters is described by Särkkä S. [8]. Comprehensive modern treatment of statistical filters including Kalman filters [9], particle filters, and their

DOI: 10.5937/OTEH26054V

applications in tracking and estimation is described too. Particle filtering is based on sequential Monte Carlo methods for nonlinear/non-Gaussian problems such as target tracking, navigation, signal processing, finance, robotics, and others.

This paper presents the results of filtering acoustic signals, drone noise, using a statistical filter whose working principle is completely based on statistical methods. In the implementation of the filter, in addition to classical statistical procedures, such as the calculation of mean values, the so-called higher order statistics, i.e. the fourth order cumulants are used too. All the mentioned procedures are applied on signal segments – windows, with or without overlapping.

2 PRINCPLES OF THE FILTER DESIGN

Using the fourth-order cumulants (also called kurtosis in the statistical world) is a game-changer for machine noise analysis because they are "blind" to Gaussian noise and excel at detecting non-linear, impulsive signatures – exactly what failing or, standard mode of work, machine produce. Using them enables to:

- Suppress background noise (real-world acoustic sensors pick up wind, traffic, and electronic hiss-all Gaussian (random) noise. Fourth-order cumulants theoretically become zero for Gaussian noise, meaning they filter out the environment and leave only the machine unique "fingerprint".
- Reveals non-linear interactions. Machine parts, or drone propellers, interact in complex ways. The fourth-order cumulants capture phase coupling between frequencies, showing their interconnections, not just that they exist.
- Immune to synchronous noise. If propeller creates a loud, constant tone, the second-order methods see it as a big peak. But cumulants suppress these steady periodic noises, letting us to focus on the changing signatures.
- The method is robust to signal distortions. Mathematically it remains stable even if the microphone is cheap, or the signal clips slightly.

Relatively bad argument for using the fourth-order cumulants is that they require a lot of data (longer sampling time) to estimate accurately, and are computationally heavy. But for critical machinery – like drones, the early detection of its presence is worth the cost.

The flow chart diagram of the filter is shown in Figure 1. The process of statistical filtering is carried out in several steps. The first is segmentation with or without overlap. This is a significant considering that in order to successfully calculate the fourth-order cumulants, dynamically in time, a larger amount of data is required. The fourth-order cumulants are calculated over thus formed data segments, which contain information about the signatures of interest. Thus, this part of the analysis is responsible for extracting the frequencies of interest. In this way, the time-varying part of the signal was performed.

In practical applications DC signal component is also of interest. In order to preserve this component of the signal, a block named "Overall statistics of the signal segments" is created, see Fig. 1. Its basic role is to calculate the mean value of each signal segment. By adding these two branches, we get a filtered signal, or statistically filtered signal, which has information about both the DC component of the signal and all frequencies of interest of the signal.

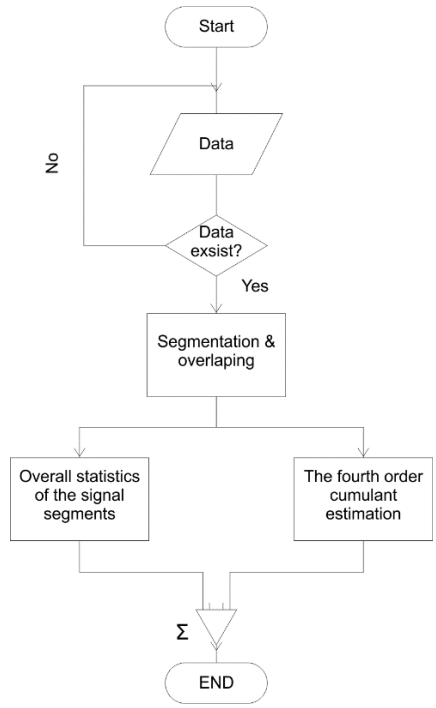

Figure 1. Flow chart diagram of the statistical filter algorithm.

The description of the statistical filter is given in the form of a block diagram, since its mathematical principles have been well known for a long time, and there is extensive literature on it. These signal analyses are very similar to the one who applies Short Time Fourier Transform (STFT), so it can be said that this approach opens up statistical domain in signal analysis. Statistical domain is just as equal the frequency domain considering that it closely connects them.

3. THE METRICS USED TO EVALUATE THE QUALITY OF THE FILTER

To check the quality of the filter itself it is used the five core quality factors: correlation coefficient, Normalized Root Mean Square Error (NRMSE), Signal-to-Error Ratio (SER), Maximum Absolute Error (MaxAE) and Estimated Delay (τ).

3.1 The Pearson correlation coefficient, ρ

The Pearson correlation coefficient, ρ, measures the linear relationship between source (X) and filtered (Y) signals:

$$\rho_{XY} = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2 \cdot \sum_{i=1}^{n}(Y_i - \bar{Y})^2}} \quad (1)$$

where n is number of the samples.

3.2 Normalized Root Mean Square Error (NRMSE)

Normalized Root Mean Square Error (NRMSE) is defined by following equation:

$$\mathrm{NRMSE} = \frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n}(Y_i - X_i)^2}}{X_{\max} - X_{\min}}. \quad (2)$$

3.3 Signal-to-Error Ratio (SER)

Signal-to-Error Ratio (SER) measures how accurately the filter reproduces the desired frequency response.

$$SER = \frac{\text{Power of the output signal that passes correctly}}{\text{Power of the signal that is missshape}} \quad (3)$$

The "error" here isn't noise or distortion from external sources – it is the deviation of the real filter from the ideal mathematical model.

A high SER means the filter behaves almost exactly as deigned. A low SER means the filter introduces significant amplitude/phase errors.

If $H_{ideal}(f)$ = desired (ideal) frequency response, and $H_{real}(f)$ = actual measured frequency response, then the error in the frequency domain is:

$$E(f) = H_{real}(f) - H_{ideal}(f), \quad (3a)$$

and SER is:

$$SER = \frac{\int |H_{ideal}(f)|^2 df}{\int |H_{real}(f) - H_{ideal}(f)|^2 df} \quad (3b)$$

In decibels (most common):

$$SER_{dB} = 10 \cdot log_{10}\left(\frac{\int |H_{ideal}|^2}{\int |E|^2}\right) \quad (3c)$$

The main factors which contributes error in filters are: passband ripple, insufficient stopband attenuation, nonlinear phase, coefficient quantization (digital filters), and component tolerances (analog filters).

In case when we have input (X) and output (Y) amplitudes directly, the gain (G) of a system is defined as, $Y_{ideal\ output} = G \cdot X_{input}$, the error is the difference between the actual output and the ideal expected output. Power of the signal that is misshape is estimated starting from error amplitude, A_{error},, which is defined as follows:

$$A_{error} = Y_{actual\ output} - Y_{ideal\ output} \quad (3d)$$

If we don't know Y_{ideal_output}, SER_{dB}, is estimated, starting from Eq. (3), by following equation:

$$SER_{dB} = 10 \cdot log_{10} \frac{\frac{1}{n}\sum_{i=1}^{n} X_i^2}{\frac{1}{n}\sum_{i=1}^{n}(X_i - Y_i)^2}. \quad (3e)$$

This definition of SER_{dB} is used in this paper.

3.4 Maximum Absolute Error (MaxAE)

Maximum Absolute Error (MaxAE) is estimated based on the following considerations:

$$max|X_{true} - X_{estimated}|$$

$$\text{or } \mathrm{MaxAE} = \max_{i=1,\ldots,n} |Y_i - X_i|. \quad (4)$$

MaxAE is the single largest deviation between the filter's actual response and the ideal response, measured across all frequencies of interest. The significance of this error is in fact that many standards specify a maximum allowed error, not an average.

3.5 Estimated Delay (τ)

The delay is estimated by finding the lag that maximizes cross-correlation:

$$\hat{\tau} = \arg\max_k |R_{XY}[k]| \quad (5)$$

where cross-correlation, R_{XY}, is estimated by

$$R_{XY}[k] = \sum_{i=1}^{n} X[i] \cdot Y[i+k], \quad (5a)$$

for $lag\ (k)$ (with appropriate zero-padding).

3.6 Signal power

The total signal power is the integral (or sum) of the squared magnitude of the frequency response:

$$P_{signal} = \int_{-\infty}^{\infty} |H(f)|^2 df$$

(6)

Power in decibels (dB):

$$P_{dB} = 10 \cdot log_{10}\left(\frac{P}{P_{ref}}\right) \quad (6a)$$

Common references: dBm (reference = 1 mW), dBW (reference = 1 W), and dB (no reference, just a ratio).

4. RESULTS OF THE ANALYSIS OF THE ACOUSTIC NOISE OF DRONES IN HOVERING MODE

The quality and capabilities of the acoustic filter were checked through the analysis of the acoustic noise of five types of drones that were in hovering mode. The results of the analysis are presented graphically, showing the real signal, the filtered signal, as well as the spectrogram of the original signal.

4.1.1 Drone DJI Matrice 210

DJI 210 Matrice 210 quadcopter is designed for industrial applications. Its total weight with batteries is 4.8 kg and overall dimensions 883 × 398 × 886 mm.

4.1.2 Drone DJI Mavic Pro

DJI Mavic Pro drone has total mass, when include gimbal cover, of 743 g, and folded dimensions 83 × 83 × 198 mm.
Maximal speed is 65 km/h.

4.1.3 Drone Parrot Anafi

Parrot Anafi is relatively small drone with overall

dimensions 244 × 67 × 65 mm and weight 320 g. Maximum horizontal speed is 15 m/s, and vertical speed 4 m/s.

4.1.4 Drone Yuneec Typhoon

Yuneec typhoon drone is hex copter (6 – rotors) designed for serial photography. Its weight is around 1695 g, and with maximum speed 13.5 m/s.

4.1.5 Drone DJI Phantom 4 Pro Plus

Total weight of this drone is 1388 g (battery and propellers are included). Maximal speed is 72 km/h, and diagonal size (excluding propellers) is 350 mm.

4.2 The quality of the filtrated data

It is possible to conclude subjectively about the quality of the performed filtering of the acoustic noise of drones by looking at the diagrams that show the source and filtered data, see Fig. 2. as their spectrograms, see Fig. 3, as well as objectively using parameters described in Section 3 of this paper. Both approaches have advantages and disadvanteges. The advantage of the first method is that it is fast and gives the first assessment of the acceptability of the solution. As for the second – analytical method, it is more objective because it is based on several statistical parameters.

Lookking at the graphs in Fig. 2, it can be concluded that the amplitudes of the filtered acoustic noisesignal are significantly smaller than the amplitudes of the raw data. This is consequence of the existence of a significant acousic noise that statistically has a Gaussian distribution.

Superior supression of Gaussian noise is performed, and therfore better SNR. The output have a significantly better SNR compared to linear filters (like FFT – based bandpass. The phase information is restored (better fidelity). Standard power – spectrum (second order) filters destroy phase information – they point out only what frequencies exist, but not when they occur. The fourth order cumulants preserve phase coupling. This means the output waveform preserves the shape of the impulses. The output is temporally accurate, which is critical for localizing drone by using sounds.

A 4th-order cumulant filter can isolate one source because it exploits statistical independence. The output is „cleaner“ in the sence that it belongs to only one physical source.

Linear filters struggle with „pink“ or „brown“ noise (common in industrial halls). The 4th-order filter outputs a signal free from this color, meaning the background sounds flat and uniform, making the fault signatures pop out visually and audibly.

If the acoustic noise itself is non-Gaussian (e.g., another drone or a hammering sound), the filter will not supress it. The output will be mix both sources.

In addition, because 4th-order cumulants amplify tails (large amplitudes), a single accidental loud bang (e.g., far and near explosions) can dominate the output temporarily ruining the signal quality. This unwanted propetry of the 4th-order cumulants can be overcome brcause the drone detection algorithm will omit these segments, bearing in mind that the drone represents a continuous source acustic noise.

In Table 1, the results of the statistical analysis of the acoustic signals of drones are systematized. Inspired by the multi-metric evaluation approaches found in literature [10], a novel aggregate Quality Factor (QF), see Eq. 6, defined as the weighted harmonic mean of individual normalized *RMSE*, *SER*, *MAE* ad estimated delay into a single percentage value, where the weights, w_i reflect the relative importance of each metric for the target application is proposed. In this case, the weighting factors were chosen as follows: w = [0.5, 0.2, 0.2, 0.1]. The greatest importance is given to the correlation factor, which is weighted by 0.5.

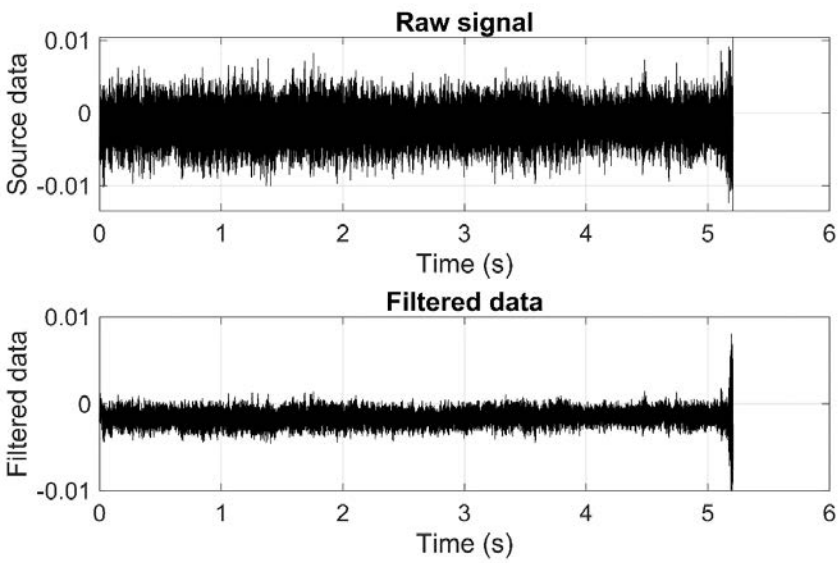

Figure 2. Raw and filtered data of the acoustic noise of DJI Matrice 210 drone in hovering mode.

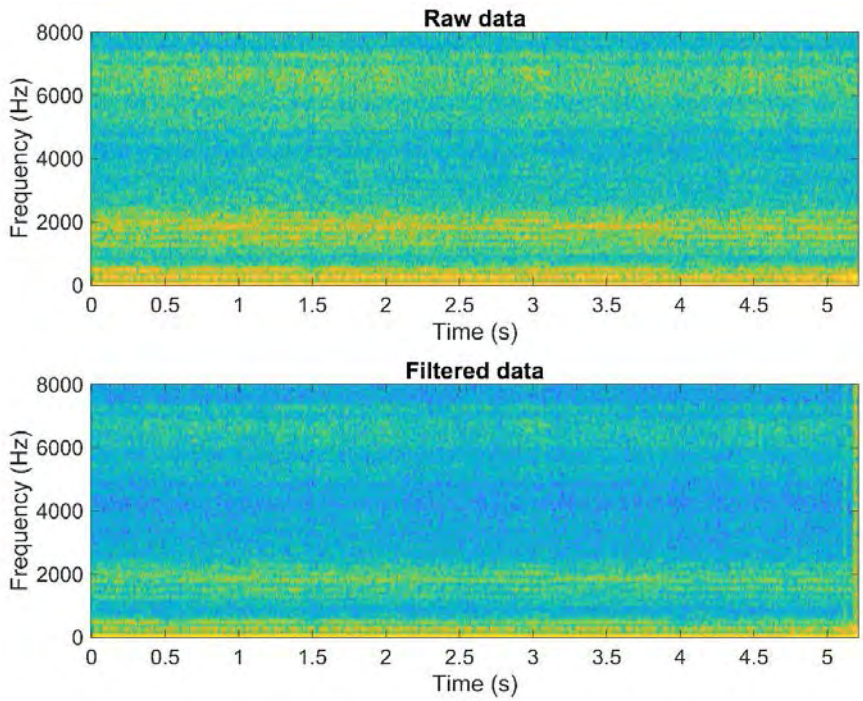

Figure 3. Spectrograms of raw and filtered data of acoustic noise of DJI Matrice 210 drone in hovering mode.

Table 1. Statistical parameters of the drone acoustic noise

+Statistical parameter that characterize source and filtered data	Type of drone				
	DJI Matrice 210	DJI Mavic Pro	Parrot Anafi	Phantom 4 Pro plus	Yuneec Typhoon
Correlation, ρ	0.9073	0.7248	0.8110	0.6960	0.8439
Error_mean	-0.0039	-0.0046	-0.0041	-0.0040	-0.0039
Error_std	0.0087	0.0068	0.0053	0.0069	0.0054
NRMSE	0.0378	0.0837	0.0807	0.0711	0.0574
SER_dB	13.4172	15.0861	16.0887	14.3544	15.7793
Max_Abs_Error (MaxAE)	0.1204	0.0619	0.0663	0.0595	0.0713
Delay_samples	27	33	30	45	46
Delay_seconds	0.0032	0.0040	0.0036	0.0054	0.0055
Signal_power	0.0020	0.0022	0.0018	0.0017	0.0017
Error_power	8.9689e-05	6.6790e-05	4.4406e-05	6.3199e-05	4.4115e-05
RMSE	0.0095	0.0082	0.0067	0.0079	0.0066
MAE	0.0070	0.0064	0.0052	0.0063	0.0052
Normalized_max_error	0.4798	0.6344	0.8034	0.5324	0.6158
Quality_score (%) (QF)	64.6052	55.2098	57.8653	57.0072	62.7528
Sampling_frequency (Hz)	8333	8333	8333	8333	8333

$$QF = w_1 \cdot \rho + w_2 \cdot (1 - \mathrm{NRMSE}) + w_3 \cdot \frac{\mathrm{SER}}{60} + w_4 \cdot \left(1 - \frac{\mathrm{MaxAE}}{0.1}\right) \tag{7}$$

By removing the Gaussian noise from the drone's acoustic noise, the result is that the spectrogram of the filtered signal, see Fig. 3, has become visually clearer, and the spectral components that originate from the operation of the drone's electric motors and its propellers are only clearly highlighted and dominate. The Gaussian noise (color disappeared in noisy areas) while preserving non-Gaussian signals (like machinery vibrations, or coms). The spectrogram's time-frequency resolution is unchanged, but the amplitude/color scale now represents non-Gaussian, not absolute power. Because 4th-order

filters are phase-blind, the spectrogram does not show phase coupling (bispectral peaks vanish).

As it well known the spectrogram is only interpretable if the signal is stationary over the window length; otherwise, time-varying cumulants distort the color scale. Therefore it is necessary to show the original spectrogram side-by-side, see Fig. 3, otherwise, the filtered version is meaningless without a baseline.

Finally, the 4th-order filter suppresses Gaussian noise but amplifies any non-Gaussian interference (e.g., clicks or transients), so it is necessary to inspect the spectrogram for artificial harmonic streaks caused by outliers, not real signals. These facts regarding filters based on 4th-order cumulants point to the need to integrate this filtering principle into algorithms that will identify these outliers in the signal end reduce their impact.

5. DISCUSION

It is well known that for acoustic based detection technology of the drones distinguishing is the distinctive features of acoustic patterns from ambient noise, and other acoustic sources. The noise spectrum consists of line spectra and their interconnecting components, where harmonic frequencies appear as distinct spectral lines. The primary goal is that acoustic signatures of drones become clearly differentiated from interference signals and ambient noise. Additional difficulty of the acoustic drone signature investigation is scenario un-homogeneity and ambient noise variability.

According obtained results, which are generated by application of statistical filtration method, which is based on different statistical procedures, such as classic statistical parameters and using higher order statistical methods on overlapped windows of the signal, relatively good results are performed. In all cases QF factor is greater from 50%, see Table 1. Signal to noise is significantly improved. Spectral lines that belongs to the drone activity are preserved as well. The raw acoustic data signal is converted into more appropriate form for further analytical purposes.

Implementation of the statistical filtration method in acoustic drone detection algorithms is significant preprocessing step, dedicated to extracting relevant features and reducing noise ambient interference.

Ambient noise compromise drone detection capabilities. Undoubtedly denoising plays an important role in drone acoustic detection. There are other approaches to reducing the impact of ambient noise such as methodology based on the linear shrinkage – subsequence projection – power spectral density filter (LSP) that employs covariance matrices and enhanced Wiener filtering, achieving effective noise suppression within a 135 m radius, see [11].

6. CONCLUSION

The paper shows the application of a statistical filter in the pre-processing of the raw acoustic signals, which originate from five types of drones in the hover mode. A significant increase in the signal-to-noise ratio was achieved, while retaining all the spectral components which originate from drone's activities.

The proposed statistical method of signal filtering largely eliminates the Gaussian noise, which makes up a significant part of the acoustic signal, since higher order statistics, i.e. cumulants of the fourth order, are implemented in the filter itself.

Nowadays deep learning techniques performed substantial advancements in drone acoustic detection. That deep learning architectures includes convolutional neural networks, recurrent neural networks, convolutional recurrent neural networks, and others. Used method for filtration of the raw acoustic noise drone's data can well serve to create better database for training advanced neural networks.

Abstract: *Hydrogen is not a conventional chemical, biological, radiological or nuclear warfare agent, yet its rapid diffusion, broad flammability range and very low ignition energy make an uncontrolled release a consequential secondary hazard at energy, transport, defence and research facilities. This critical review connects advanced hydrogen-sensitive materials with the operational requirements of CBRN reconnaissance and incident command. Palladium-based nanostructures remain the reference platform, while alloying, nanoscale confinement and porous supports mitigate hysteresis, poisoning and slow kinetics. Metal–organic and covalent organic frameworks serve as active phases, selective layers, nanoparticle hosts and precursors to porous oxides, but fast percent-level response and low-ppm detection must not be conflated. Recent machine-learning-assisted sensing improves compensation, early inference and source localization; evidence for autonomous discrimination of malicious releases from routine venting nevertheless remains limited. A defensible CBRN architecture therefore combines qualified sensors, environmental and process context, uncertainty-aware analytics, redundant communications and robotic standoff mapping while retaining deterministic alarm and shutdown logic.*

Table 1. Selected advanced hydrogen-sensing results and their operational interpretation.

Platform	Mode / T	H_2 condition	Dynamic result	Robustness evidence	Operational caveat
Pd(II)@CrPy MOF [1]	Chemiresistive / RT	0.25–1 vol%	5–7 s response	Selective in tested gases	Fast, but not a ppm-level device
MOF-derived ZnO@GC [2]	Chemiresistive / 50 °C	Detectable to 10 ppm	Tens-of-seconds scale	Humidity/selectivity examined	Promising early warning; heating and recovery remain
Pd@amic-PT COF [3]	Chemiresistive / RT	1 vol%	5.3 / 3.5 s response/recovery	Reported stable vs RH and interferents	Percent-level benchmark; limited field ageing data
Pd@Pt/SnO_2 [4]	Chemiresistive / 25–50 °C	1000 ppm	1 s response; 9–31 s recovery	Laboratory selectivity tests	Excellent speed; poisoning/long-term duty require qualification
$Pd_{80}Co_{20}$ metasurface [5]	Optical / RT	LOD 2.5 ppm; t at ~1000 ppm	~0.85 s response	Ageing, temperature and interferents tested	Spark-free optical readout; nanofabrication/readout complexity
Ta–Pd thin film [6]	Optical / RT	Seven pressure decades	Sub-second with capping layer	Hysteresis suppressed by composition	Wide range; package and gas-matrix validation needed
Pd/WSe_2 [7]	Chemiresistive / 65 °C	LOD 10 ppb	10 min exposure protocol	40 cycles; 15–80% RH tested	Exceptional LOD does not imply sub-second alarm
Nanoplasmonic + NN [8]	Optical + AI / heated	LOD 100 ppm	Spectral inference	Synthetic air, 80% RH	Strong node-level evidence; not threat classification

LOD values, response definitions, flow rates and test atmospheres differ among studies; the table supports qualitative comparison, not direct ranking. RT: room temperature; NN: neural network.

1. INTRODUCTION

Hydrogen infrastructure is expanding from established chemical and refining sites to electrolyzers, storage modules, pipelines, refuelling stations, ports, vehicle depots and distributed backup-power installations. Hydrogen is colourless and odourless, diffuses rapidly through small openings and, in air, is flammable in range approximately 4–75 vol%. Its minimum ignition energy is about 0.017–0.02 mJ [9]. These properties demand detection well below the lower flammability limit (LFL). A commonly used safety alarm level is 25% of the LFL, corresponding to about 1 vol% H_2, although site-specific codes and hazard analyses govern the final set-point [10,11].

The CBRN relevance requires careful definition. Molecular hydrogen is not normally classified as a toxic chemical warfare agent. It becomes important to CBRN organizations because they routinely operate in uncertain, multi-hazard environments where an accidental or intentional hydrogen release may create fire, explosion, structural damage, access denial or secondary dispersion of hazardous material. The same response architecture like remote reconnaissance, hazard mapping, warning and reporting networks, protected decision-making and evidence preservation, can incorporate hydrogen channels alongside chemical, radiological, meteorological and imaging payloads. European capability priorities explicitly identify the integration of advanced CBRN sensors into small autonomous vehicles and drones [12].

This review evaluates advanced hydrogen-sensitive materials through that operational lens. The central question is not which material has the lowest laboratory LOD, but which combination of material, transducer, packaging, calibration, network and decision logic provides timely and trustworthy action under humidity, temperature swings, interferents, loss of communications and adversarial ambiguity.

2. REVIEW SCOPE AND PERFORMANCE REQUIREMENTS

A targeted critical review of peer-reviewed experimental papers, recent perspectives and official performance guidance available through July 2026 was undertaken. Priority was given to studies reporting concentration range, response/recovery behaviour, operating

temperature, humidity or interferent testing, stability, and integration with wireless or data-driven systems. Cross-study numerical ranking was avoided where authors used different definitions of response, LOD, carrier gas, flow, exposure time or baseline correction.

ISO 26142 defines performance and test requirements for stationary hydrogen detection apparatus, including accuracy, response time, stability, measuring range, selectivity and poisoning; it does not prescribe system installation or control logic [10]. For CBRN use, these product metrics are necessary but insufficient. An operational specification should also address: (i) t_{90} at safety-relevant concentrations rather than only at the LOD; (ii) recovery and latching behaviour after a large exposure; (iii) humidity, oxygen, CO, hydrocarbons, sulfur species, aerosols and decontamination chemicals; (iv) calibration transfer between nodes; (v) intrinsic or explosion safety; (vi) power autonomy and communications loss; and (vii) confidence reporting and raw-data retention. Long-term drift and poisoning often dominate real availability even when initial sensitivity is exceptional [13–16].

3. ADVANCED MATERIAL PLATFORMS

3.1 Palladium, platinum and alloy nanostructures

Palladium remains the reference hydrogen-recognition material. H_2 dissociates on Pd, atomic hydrogen enters interstitial sites and PdH_x formation changes resistance, work function, lattice dimensions and optical permittivity. Nanowires, nanoparticles, discontinuous films, nanogaps and plasmonic arrays amplify one or more of these changes [14,15]. The same Pd–H phase transition can generate hysteresis, mechanical fatigue and slow recovery. Surface adsorption of CO, sulfur-containing species, water or hydrocarbons blocks catalytic sites, while oxygen changes surface kinetics. Therefore, selectivity is not an intrinsic constant: it is a function of alloy composition, morphology, capping layer, operating temperature and gas matrix.

Alloying Pd with Au, Ag, Cu, Co, Ni or Pt can suppress the α/β-hydride transition, accelerate kinetics or reduce poisoning. Luong et al. engineered Pd nano-patchy metasurfaces and reported a 2.5 ppm LOD; $Pd_{80}Co_{20}$ responded in about 0.85 s at approximately 1 mbar H_2 with optical readout [5]. Ta–Pd thin films achieved a hysteresis-free optical response over seven pressure decades and sub-second dynamics when paired with a suitable capping layer [6]. Bimetallic Pd@Pt/SnO_2 combined dissociation catalysis with semiconductor resistance modulation, producing a 1 s response to 1000 ppm H_2 at 25–50 °C [4]. A 2025 catalytic-plasmonic Pt nanoparticle design further illustrates the move toward high-humidity optical operation [17]. Optical transduction is attractive in explosive zones because the sensing head can be electrically passive and interrogated remotely, but the optical source, spectrum acquisition, fouling and alignment still require engineering qualification.

Reliability research is shifting from one-time performance to maintainability. Kim et al. traced degradation of a wireless Pd-nanowire node to carbon-containing surface contamination and restored nearly 100% of initial performance using a 200 °C, 10 min thermal refresh after two months of contamination [18]. This is operationally important: self-diagnostics and scheduled regeneration may be more valuable than a marginal improvement in pristine LOD. However, regeneration consumes energy and may be incompatible with an active hazardous atmosphere, so it must be inhibited during an alarm and managed as a maintenance function.

3.2 MOFs, COFs and framework-derived materials

Porous frameworks offer molecular-scale control over pore size, surface chemistry and guest–host interactions. Their role in hydrogen sensing falls into four categories that should be reported separately: a conductive MOF/COF as the active chemiresistor; a porous selective overlayer on another transducer; a scaffold that disperses Pd/Pt and mediates charge transfer; or a sacrificial precursor that is converted into a porous oxide/carbon composite [19,20]. Labeling all four simply as “MOF sensors” obscures the actual recognition and transduction mechanisms.

A direct example is Pd(II)-decorated conductive chromium–pyrazine MOF (Pd(II)@CrPy), which responded selectively in 5–7 s, but over 0.25–1 vol% H_2—not at 1–10 ppm [1]. By contrast, MOF-derived ZnO@graphitic-carbon microcubes detected down to 10 ppm and were evaluated under humid conditions, but their dynamic times were on the order of tens of seconds and they required mild heating [2]. Montoro et al. showed that calcination temperature and precursor identity control the selectivity of MOF-derived CuO, NiO and ZnO, with ZnO favouring H_2 [21]. These studies support MOFs as design tools for porosity and dispersion, but not a universal claim of simultaneously achieving single-ppm detection and an 8 s response.

COFs provide greater covalent stability and π-conjugated charge-transport pathways. Thokala et al. used a redox-active polyimide COF to reduce and anchor Pd nanoparticles without an external reducing agent. The resulting Pd@amic-PT chemiresistor operated at room temperature and showed 5.3/3.5 s response/recovery at 1 vol% H_2, with reported tolerance to humidity and interferents [3]. This is a compelling architecture for low-power nodes, yet percent-level tests do not establish low-ppm performance, multi-year stability or resistance to CBRN decontaminants. Framework stability against water, acids/bases, radiation, mechanical shock and thermal cycling must be assessed after device fabrication, not inferred from powder characterization alone.

3.3 Metal oxides, two-dimensional materials and hybrid interfaces

Semiconducting oxides such as SnO_2, ZnO, WO_3, In_2O_3 and TiO_2 are mature, inexpensive and readily

miniaturized, but conventional devices often require heating and respond to many reducing gases [13,14]. Noble-metal sensitization lowers the operating temperature and accelerates charge transfer, while porous or heterojunction structures increase active area. Pd@Pt/SnO_2 is an instructive example of catalytic and electronic sensitization acting cooperatively [4]. For battery-powered robotics, the duty cycle of microheaters—not only peak heater power—should be included in the mission energy budget.

Two-dimensional semiconductors can translate local catalytic events into large conductance changes. A Pd-decorated WSe_2 device detected 10 ppb H_2 at 65 °C and retained a measurable response at 80% RH [7]. Yet the protocol used 10 min H_2 exposures and 5 min purges. The result demonstrates remarkable analytical sensitivity, but it is not evidence of a 10 ppb, sub-second safety alarm. This distinction between LOD and safety response time is essential when selecting a CBRN payload.

3.4 Transduction, packaging and mission-oriented selection

Recognition chemistry cannot be evaluated independently of transduction. Chemiresistive devices are compact and compatible with low-cost electronics, but the complete node must control contact resistance, baseline drift, heater duty cycle and electromagnetic susceptibility. Optical devices permit an electrically passive sensing head and can exploit wavelength, intensity or spectral-shape changes; their penalties are source and detector complexity, optical fouling and alignment. Catalytic and thermal-conductivity devices provide robust complementary channels at higher concentrations, whereas electrochemical cells may offer useful low-concentration response but introduce electrolyte life, orientation and replacement constraints [13,14,16]. A heterogeneous node that combines physically different channels is often more defensible than multiple copies of a single high-sensitivity material because common-mode interferents are less likely to produce concordant signals.

Packaging determines the exposure actually seen by the material. Hydrophobic membranes, particulate filters, flame arrestors and selective overlayers can protect a sensing film, yet every added diffusion barrier changes response and recovery. Sample pumps improve placement flexibility but add power, acoustic signature, tubing adsorption and a new failure mode. Consequently, system response should be measured from gas arrival at the device inlet to authenticated alarm output, including transport, filtering, analogue settling, digital filtering, edge inference and communication latency. Calibration records should include gas matrix, humidity, temperature, pressure, flow and certified-mixture uncertainty. For fielded CBRN equipment, built-in test must distinguish an intact electronic channel from a chemically responsive sensing surface; electrical continuity alone cannot reveal catalyst poisoning or blocked pores.

Mission profile should therefore govern material choice. Fixed protection at a hydrogen plant prioritizes rapid and repeatable behaviour near safety-relevant fractions of the LFL, low false-alarm burden and maintainability. Portable early-warning instruments may value ppm capability, low mass and low standby power, but still require an unambiguous high-level alarm channel. A moving robot needs response and recovery times commensurate with vehicle speed and sampling height; otherwise its concentration map is spatially displaced by sensor memory. Long-duration unattended nodes prioritize drift compensation, energy per measurement and remote health reporting. No single LOD, response time or sensitivity value captures these trade-offs, and technology rankings should be stated for a defined concept of operations rather than as universal material league tables.

4. FROM SENSOR SIGNAL TO REAL-TIME THREAT ASSESSMENT

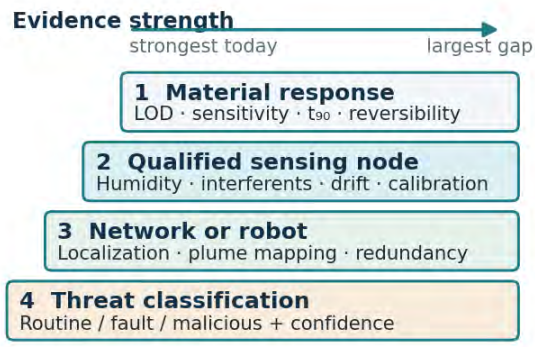

Figure 2. Evidence ladder: strong material results do not automatically validate an autonomous CBRN decision.

Machine learning is most defensible when it solves a clearly bounded sensor problem. Tomeček et al. processed the full spectrum of a heated nanoplasmonic sensor with dense neural networks or transformers and obtained a 100 ppm LOD in synthetic air at 80% RH [8]. Martvall et al. used a long short-term transformer ensemble model to predict the eventual plasmonic response in oxygen-free inert gas, accelerating the reported response by up to a factor of 40 while outputting prediction uncertainty [22]. These studies demonstrate humidity compensation, use of rich spectral features and early prediction; they do not demonstrate attribution of malicious intent.

At network level, data fusion can detect, quantify and localize releases. A recent hydrogen-refuelling-station study fused simulated concentration histories with wind speed and direction in a temporal convolutional network. After sensor-layout optimization, the model reported a mean source-location error of 0.54 m using 60 s sequences from 135 virtual sensors [23]. A four-node Zigbee system with a hydrogen/CO/alkane/smog array and an optimized back-propagation network reported correlation coefficients above 0.997 and mean relative errors below 0.25% in laboratory tests [24]. Both are promising, but the former depends on CFD-generated data and the latter used a small controlled dataset. Domain shift—from one geometry, sensor lot, weather regime or release type to another—remains a central safety risk.

A real-time CBRN assessment should therefore separate four outputs: detection ("is H_2 present?"), quantification ("what concentration and rate of change?"), localization ("where is the likely source and plume?"), and attribution ("is the pattern consistent with normal venting, a component fault or a deliberate act?"). Attribution requires contextual features that a gas sensor cannot provide: process state, valve commands, maintenance schedule, access-control events, video/acoustic evidence, wind field, node agreement and event history. The model should expose confidence and out-of-distribution status. A high hydrogen alarm must trigger deterministic ventilation, isolation or evacuation regardless of the classifier's interpretation; AI can prioritize investigation but must not suppress a safety trip.

Validation must match the level of the claimed decision. Randomly splitting adjacent time samples between training and test sets overstates generalization because neighbouring samples share the same release, weather and sensor history. A stronger design withholds complete incidents, facilities, sensor lots and environmental regimes, then reports sensitivity, specificity, false alarms per operating hour, time-to-decision and calibration of confidence. Simulation and CFD are valuable for generating rare geometries and hazardous release cases, but final performance should be anchored to blind physical trials. Threat attribution should be treated as human-supervised evidence fusion: the algorithm may rank hypotheses and identify inconsistent observations, while the incident commander retains authority and the system preserves raw data, model version and rationale for after-action review.

5. CBRN DEPLOYMENT ARCHITECTURE

For fixed critical infrastructure, a layered network is preferable to reliance on a single "best" material. Fast safety nodes should be located at credible release points and high-level accumulation zones, supported by environmental sensors and at least one complementary transduction principle. Optical or passive heads are advantageous in ignition-sensitive zones; chemiresistive or electrochemical nodes provide compact redundancy. Gateways should time-synchronize data, buffer raw signals during communication loss and use authenticated, encrypted links. Alarm thresholds, maintenance state and model version must be auditable.

For reconnaissance, a UGV can carry a calibrated H_2 sensor, RH/temperature, airflow, pressure/acoustic leak indicators, visible/thermal cameras and SLAM positioning. A UAV can rapidly survey elevated or inaccessible points, but rotor wash distorts light-gas plumes and must be included in sampling strategy. Mobile robots have already demonstrated gas-source localization by combining concentration sensing with LIDAR-based mapping in hazardous indoor simulations [25], and defence planning identifies autonomous platforms as a route to CBRN standoff sensing [12]. The hydrogen-specific next step is controlled, full-scale validation against known releases, obstacles, ventilation states and robot trajectories.

Operational reporting should preserve three layers: an immediate safety message (concentration, alarm state and protective action), a tactical map (estimated source, plume, uncertainty and sensor health), and a forensic record (time-stamped raw data, calibration, platform position and chain of custody). This structure supports both emergency response and later investigation without overloading the first responder with material-level sensor details.

6. EVIDENCE GAPS AND RESEARCH PRIORITIES

First, standardized tests must move beyond dry single-gas chambers. Candidate materials should be evaluated at 0.1–2 vol% H_2 for safety dynamics and at lower concentrations for early warning, across realistic RH/temperature cycles, oxygen levels, CO, methane, ammonia, sulfur compounds, aerosols and decontamination vapours. Report t_{10}, t_{50} and t_{90}, recovery after overload, false-alarm rate, drift and energy per measurement. Second, framework-based devices require packaged-device durability data: adhesion, pore blockage, radiation response, vibration and cleanability. Third, datasets for AI must include different sensor lots, facilities, seasons, routine vents, faults and controlled adversarial scenarios. External validation should be performed before claiming threat classification.

Fourth, sensor placement and mobile sampling should be co-designed with plume physics. CFD and digital twins are useful for rare-event coverage, but models must be anchored to full-scale releases and quantify uncertainty. Fifth, networks need graceful degradation: local alarms during gateway loss, self-test, cross-node plausibility checks, signed firmware and a manual fallback. Finally, field trials should use operational metrics—time to reliable alarm, source-location error, false dispatches, time saved in exclusion-zone mapping and responder dose/risk reduction—rather than laboratory sensitivity alone.

The literature supports fast MOF/COF-based devices and separate low-ppm MOF-derived devices, but not a general "1–10 ppm in 8 s" MOF benchmark. It supports AI-enhanced hydrogen quantification and localization, but no directly comparable peer-reviewed field study located in this review established 95% threat-versus-routine classification within 30 s or a 60% response-time improvement across transport hubs and critical infrastructure. These values are better presented as prospective validation targets until a traceable dataset and protocol are available.

7. CONCLUSIONS

Advanced hydrogen detection is progressing from sensitive materials toward context-aware safety systems. Pd-based nanostructures and alloys currently offer the strongest combination of rapid recognition, tunability and compatible electrical or optical transduction. MOFs and

COFs add selective transport, high-area supports and designable electronic pathways, while MOF-derived oxides bridge framework chemistry with established semiconductor sensing. The decisive CBRN advance, however, will not come from one material. It will come from qualified heterogeneous nodes, multimodal fusion, reliable communications, robotic standoff mapping and transparent decision logic. AI is already useful for compensation, accelerated inference and localization; malicious-intent classification remains an open, evidence-limited task. A safety-first architecture should keep threshold alarms and shutdown deterministic, using AI to add localization, context and uncertainty—not to replace fail-safe protection.

Abstract: *The accurate estimation of aircraft airspeed and altitude using Pitot–static systems is essential for reliable flight control and navigation. Conventional estimation methods, such as the Extended Kalman Filter (EKF), inherently rely on a single dynamic model and may exhibit degraded performance in the presence of sensor degradation and time-varying measurement disturbances. This motivates the development of estimation algorithms capable of accommodating multiple operating conditions.*

This paper investigates an Interacting Multiple Model (IMM) estimator for air-data parameter reconstruction from the Pitot–static measurements. The estimator combines multiple Extended Kalman Filters, each associated with a specific sensor operating condition, including nominal operation, pressure bias, and sensor drift. A mathematical model of the Pitot–static system is developed, incorporating sensor dynamics, measurement noise, bias, and drift effects. The IMM algorithm is implemented in the MATLAB environment and evaluated under representative aircraft flight scenarios.

The performance of the proposed IMM estimator is evaluated through Monte Carlo simulations and compared with that of a conventional EKF estimator. The obtained results demonstrate that the IMM algorithm achieves improved estimation accuracy in the presence of sensor bias and drift while maintaining reliable estimation of flight parameters under different operating conditions. The obtained results indicate the applicability of IMM-based estimation for the improvement of ADC robustness against sensor degradation, while maintaining reliable air-data parameter estimation.

Keywords: *Air Data Computer, Pitot–static system, Extended Kalman Filter, Interacting Multiple Model, Air-data estimation.*

1. INTRODUCTION

The Pitot–static system represents a critical measurement subsystem in an aircraft, providing air-data information required for flight control, navigation, and other avionics functions. Modern aircraft and unmanned aerial vehicles increasingly employ Micro-Electro-Mechanical Systems (MEMS) sensors to perform pressure and temperature measurements due to their compact size, the low power consumption, and compatibility with digital processing architectures. The measurements of static pressure, total pressure, and outside air temperature are processed by the Air Data Computer (ADC) to determine fundamental flight parameters, including airspeed, altitude, vertical speed, and air density [1], [2].

Regardless of these advantages, MEMS-based air-data measurements remain sensitive to several error sources that directly affect estimation accuracy. The most relevant error sources include measurement noise, temperature dependency, sensor bias, long-term drift, nonlinear sensor characteristics, and dynamic effects which are introduced by the pneumatic response of the Pitot–static installation. Furthermore, environmental influences such as vibration, moisture, and partial blockage of the sensing system may degrade measurement quality and reduce the reliability of the estimated air-data parameters [3].

The Air Data Computer integrates measurements from Pitot–static and temperature sensors by employing digital processing and estimation algorithms in order to provide reliable air-data information for aircraft systems. Previous studies have demonstrated the importance of analytical modeling of Pitot–static sensor faults and the estimation-based approaches for the improvement of fault tolerance and reduction of measurement degradation impact [4]–[6]. Among available estimation techniques, the EKF estimator is widely used in nonlinear state estimation applications because of it's capability to handle nonlinear system models with moderate computational complexity. However, the EKF estimator is generally designed around a predefined system model and may experience degraded performance when measurement characteristics or system behavior change due to sensor degradation or abnormal (i.e. unexpected) operating conditions.

To overcome the limitations associated with single-model estimation, multiple-model approaches have also been investigated for systems that are characterized by varying operating conditions. Among these, the IMM algorithm

Corresponding author: V. Sokolović;

DOI: 10.5937/OTEH26056S

represents an established framework for the adaptive state estimation. The IMM algorithm employs several parallel estimators associated with the different system models and updates model probabilities according to consistency between the predicted and the measured outputs, with a goal to facilitate adaptation to changes in system behavior [7]. The theoretical foundation of the IMM approach was introduced by Blom and Bar-Shalom for the systems with Markovian switching parameters, while the subsequent developments extended these multiple-model estimation techniques for variable-structure systems [8], [9].

Previous studies have shown that IMM-based estimators can improve robustness in systems affected by the model uncertainty and changing measurement conditions [10], [11]. Comparative investigations of multiple-model EKF approaches have also shown that estimator performance strongly depends on correct model definition, transition probability selection, and process noise tuning [12].

Although IMM-based algorithms have been extensively investigated in applications such as maneuvering target tracking, navigation, and multi-sensor data fusion, their application to Pitot–static air-data estimation with the explicit representation of sensor bias and drift effects has received considerably less attention. In particular, the development of IMM-based estimators that explicitly incorporate sensor bias and drift models within the air-data measurement process has received less attention. Therefore, this represents an important research direction since these degradation mechanisms may directly affect the accuracy and the reliability of ADC outputs.

The main contribution of this work is the development and evaluation of an IMM-based estimator specifically adapted for Pitot–static air-data processing with explicit representation of pressure sensor bias and drift. The proposed approach employs a bank of Extended Kalman Filters representing different sensor operating conditions, including nominal operation, pressure measurement bias, and sensor drift. A mathematical model of the Pitot–static system is developed that incorporates pneumatic sensor dynamics, measurement noise, pressure measurement bias, and drift characteristics. The proposed estimator is implemented in MATLAB and evaluated through Monte Carlo simulations, while its performance is compared with a conventional EKF estimator. The obtained results provide a methodological basis for a further development of robust Air Data Computer estimation algorithms that are capable to maintain improved accuracy under the degraded sensor conditions.

2. PITOT–STATIC SYSTEM MODEL AND SIMULATION FRAMEWORK

2.1. Mathematical Model of the Pitot–Static System and Air-Data Parameter Computation

A mathematical model of the Pitot–static system was established to generate reference air-data parameters and simulate sensor measurements corresponding to ADC operation. The developed model establishes a relationship between flight conditions, atmospheric parameters, and the outputs of the pressure and temperature sensors. The atmospheric parameters were calculated according to the International Standard Atmosphere model [13]. The air temperature at a given altitude is thus defined as:

$$T = T_0 - Lh, \tag{1}$$

where T_0 represents the standard temperature at sea level, L is the temperature lapse rate, and h is the flight altitude. The static pressure is then calculated using the barometric equation:

$$p_s = p_0 \left(\frac{T}{T_0} \right)^{\frac{g}{RL}}, \tag{2}$$

where p_0 denotes the standard sea-level pressure, R is the specific gas constant of air, and g represents gravitational acceleration. Based on this, the air density is obtained from the ideal gas relationship:

$$\rho = \frac{p_s}{RT_{at}}. \tag{3}$$

The total pressure measured by the Pitot tube is defined as the sum of static and dynamic pressure:

$$p_t = p_s + \rho \frac{V^2}{2}, \tag{4}$$

where V denotes the true airspeed value. The air-data parameters used for estimator evaluation are calculated from the simulated measurements, while the altitude is obtained from the inverse barometric relationship:

$$h = \frac{T_0}{L} \left[1 - \left(\frac{P_s}{p_0} \right)^{\frac{RL}{g}} \right]. \tag{5}$$

The dynamic pressure is determined as difference of total and static pressure, while the airspeed is calculated as:

$$V = \sqrt{\frac{2q}{\rho}}. \tag{6}$$

The vertical speed is obtained by using the numerical differentiation of the estimated altitude:

$$V_z = \frac{dh}{dt}. \tag{6}$$

The calculated air-data parameters are subsequently used as the reference quantities in order to adequately evaluate the performance of the EKF and IMM estimators.

2.2. Sensor Measurement Model and Representation of Operating Modes

The accuracy of a Pitot–static measurement system is influenced by several non-ideal effects, including sensor response delay, measurement noise, systematic offsets,

and long-term variations. In this work, a specific sensor measurement model was developed to represent different operating conditions required for IMM-based estimation.

The dynamic response of the pressure measurement channels was represented by a first-order system:

$$p_{dyn}(k) = p_{dyn}(k-1) + \frac{\Delta t}{\tau}\left(p_{true}(k) - p_{dyn}(k-1)\right), \quad (7)$$

where p_{true} represents the ideal pressure value, p_{dyn} is the dynamically filtered sensor output, τ represents the sensor response time constant, and Δt is the sampling interval.

The measured pressure value is defined as:

$$p_{meas} = p_{dyn} + b + d + n, \quad (8)$$

where b represents sensor bias, d represents sensor drift, and n denotes a measurement noise. The measurement noise is modeled as a zero-mean Gaussian process, and the sensor bias is represented as a slowly varying offset:

$$b(k) = b(k-1) + w_b(k), \quad (9)$$

where $w_b(k)$ represents the bias process noise. The long-term sensor drift is modelled by using a random-walk process:

$$d(k) = b(k-1) + w_d(k), \quad (10)$$

where $w_d(k)$ represents the drift process noise.

The IMM-based models differ not only due to the process noise covariance tuning but also due to the assumed sensor degradation dynamics. To enable IMM operation, three sensor operating modes are defined:

- Model 1 – Nominal operating mode, which represents normal sensor operation, and includes measurement noise and dynamic response effects only;
- Model 2 – Bias mode, which represents the sensor condition that is characterized by a constant pressure measurement offset. In simulation used in this work, the pressure bias of 50 Pa is introduced in the time period between 200 s and 300 s; and
- Model 3 – Drift mode, which is used in this work to represent the gradual sensor degradation after 350 s of simulation time. The drift component is generated using a random-walk process in order to reproduce slowly varying sensor characteristics.

The beforehand defined operating modes provide a physical interpretation of the IMM model set and enable adaptive selection between different sensor conditions.

2.3. Simulation Configuration and Measurement Data Generation

An appropriate MATLAB-based simulation environment was developed to evaluate the proposed IMM estimator. A simulation process includes the flight trajectory model, atmospheric calculations, Pitot–static sensor dynamics, measurement noise, and the sensor degradation scenarios. The total time duration of each simulation is $T_{sim} = 600$ s with the sampling interval defined as $\Delta t = 0.01$ s. The used flight trajectory consists of several climb, level-flight, and descent segments, where altitude and airspeed variations are independently defined according to the selected flight profile.

Based on the generated flight conditions, reference values of altitude, airspeed, temperature, static pressure, and total pressure are calculated. The pneumatic response of the Pitot–static system is represented by first-order dynamics with a different time constants for the pressure channels $\tau_{ps} = 0.1$ s for the static pressure channel and $\tau_{pt} = 0.5$ s for the total pressure channel. The measurement noise is introduced as a Gaussian process with the following standard deviations $\sigma_{ps} = 10$ Pa, $\sigma_{pt} = 5$ Pa and $\sigma_T = 0.5$ K.

The generated sensor measurements are then additionally processed using a second-order Butterworth low-pass filter with a cutoff frequency of 2 Hz to reduce a high-frequency measurement disturbances.

The resulting measurement data are then used as inputs for the both EKF and IMM estimators. Their performance is evaluated under the nominal conditions and during the sensor degradation scenarios that involve bias and drift effects.

The Figure 1 illustrates the simulated and reference Pitot–static sensor outputs used as input data for the evaluation of the EKF and IMM estimators.

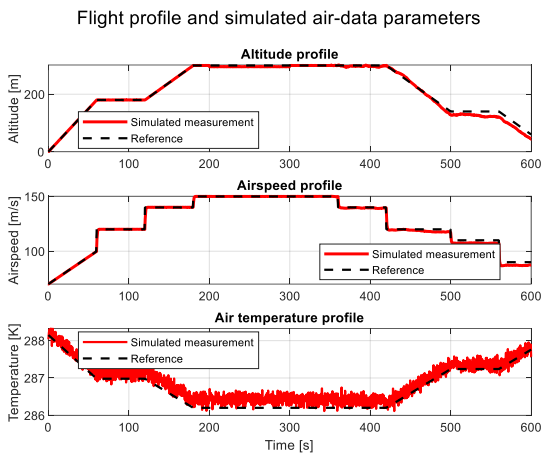

Figure 1. Flight profile and simulated reference air-data parameters used in the Pitot–static system model

3. EXTENDED KALMAN FILTER AND INTERACTING MULTIPLE MODEL ESTIMATION ALGORITHM

3.1. Extended Kalman Filter Formulation for Air-Data Estimation

The Extended Kalman Filter (EKF) is used as a baseline estimator for the evaluation of performance improvement achieved by using the proposed IMM approach. The EKF provides the nonlinear state estimation by linearizing the process and measurement models around the current

operating point. In this work, the estimation is performed directly using Pitot–static pressure measurements, while derived air-data parameters are then obtained from the estimated states. This approach avoids additional filtering of calculated quantities and thus preserves the physical relationships between altitude, airspeed, and atmospheric parameters.

The state vector of the EKF is defined as:

$$\mathbf{x}_k = [h_k \quad V_k \quad T_k \quad b_{p_s,k} \quad b_{p_t,k}], \tag{11}$$

where h_k represents altitude, V_k is airspeed, T_k is air temperature, while b_{ps} and b_{pt} denote the biases of the static and the total pressure sensors, respectively. The nonlinear state transition model is expressed as:

$$\mathbf{x}_k = f(x_{k-1}) + \omega_k, \tag{12}$$

where w_k represents the process noise with covariance matrix **Q**. The flight parameters are assumed to remain constant within a single sampling interval, while the pressure sensor biases are modeled as slowly varying stochastic processes $b_{ps,k} = b_{ps,k}+w_{bps}$ and $b_{pt,k} = b_{pt,k}+w_{bts}$. The measurement vector is defined using the directly available Pitot–static sensor outputs:

$$\mathbf{z}_k = [p_{s,k} \quad p_{t,k} \quad T_k], \tag{13}$$

and the nonlinear measurement equation is given by:

$$\mathbf{z}_k = h(x_k) + \upsilon_k, \tag{14}$$

where v_k represents zero-mean Gaussian measurement noise with covariance matrix **R**.
The EKF prediction step is performed according to:

$$\begin{aligned} \hat{\mathbf{x}}_{k|k-1} &= f(\hat{\mathbf{x}}_{k-1}), \\ \mathbf{P}_{k|k-1} &= \mathbf{F}_k \mathbf{P}_{k-1} \mathbf{F}_k^T + \mathbf{Q}, \end{aligned} \tag{15}$$

where $\mathbf{F}_k$ is the state transition Jacobian matrix. Since the selected process model assumes that the flight parameters remain constant within the same sampling interval, while sensor biases follow a random-walk process, the state transition matrix is approximated by the identity matrix. The measurement update is calculated using the Kalman gain:

$$\mathbf{K_k} = \mathbf{P}_{k|k-1}\mathbf{H}_k^T \left[\mathbf{H}_k \mathbf{P}_{k-1} \mathbf{H}_k^T + \mathbf{R_k}\right]^{-1} \tag{16}$$

where $\mathbf{H}_k$ represents the measurement Jacobian matrix defined as:

$$\mathbf{H}_k = \begin{bmatrix} \frac{\partial p_s}{\partial h} & 0 & 0 & -1 & 0 \\ \frac{\partial p_t}{\partial h} & \frac{\partial p_t}{\partial V} & \frac{\partial p_t}{\partial T} & 0 & -1 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix} \tag{17}$$

where $\frac{\partial p_t}{\partial h} = \frac{\partial p_s}{\partial h} + \frac{1}{2}V^2 \frac{\partial \rho}{\partial h}$, $\frac{\partial \rho}{\partial h} = \frac{1}{RT}\frac{\partial p_s}{\partial h}$ and $\frac{\partial p_s}{\partial V} = \rho V$, $\frac{\partial p_s}{\partial h} = -\frac{g}{RT} p_s$,

The updated state estimate is obtained as:

$$\hat{\mathbf{x}}_k = \hat{\mathbf{x}}_{k|k-1} + \mathbf{K}_k(\mathbf{z}_k - h(\mathbf{x}_{k|k-1})), \tag{18}$$

while the covariance matrix is updated according to:

$$\mathbf{P_k} = (\mathbf{I} - \mathbf{K_k}\mathbf{H}_k)\mathbf{P}_{k|k-1}. \tag{19}$$

The EKF estimator described above represents the single-model estimation approach used as a reference for the comparison with the proposed IMM estimator.

3.2. Interacting Multiple Model Estimator Configuration

The IMM estimator is introduced as an extension of the single-model EKF approach described in the previous section. Unlike the conventional EKF, which assumes a fixed system behavior, the IMM algorithm employs a bank of parallel EKF estimators with the different process noise characteristics in order to represent possible (i.e. here observed) sensor operating conditions.
In this work, three beforehand defined operating modes of the Pitot–static system are considered, which correspond to the nominal operation, sensor bias, and sensor drift conditions. In each mode the EKF formulation presented in Section 3.1 is employed, while a different process noise covariance matrices $\mathbf{Q}_1$ $\mathbf{Q}_2$, and $\mathbf{Q}_3$ are assigned in order to adjust the estimator sensitivity to the corresponding sensor behavior.
The IMM model set is therefore defined as:

$$\mathbf{M} = \{M_1 \quad M_2 \quad M_3\}, \tag{20}$$

where each model has an associated EKF estimator and model probability μ_i. The transition between operating modes is described by the Markov transition probability matrix:

$$\mathbf{\Pi} = \begin{bmatrix} \pi_{11} & \pi_{12} & \pi_{13} \\ \pi_{21} & \pi_{22} & \pi_{23} \\ \pi_{31} & \pi_{32} & \pi_{33} \end{bmatrix}, \tag{21}$$

where π_{ij} represents the probability of transition from model i at the previous time step to model j at the current time step.

At each sampling instant, the IMM estimator performs state interaction, model-conditioned EKF filtering, model probability update, and fusion of individual estimates. In the interaction step, the initial conditions for each EKF are obtained by combining the state estimates and the covariance matrices from all models according to their previous probabilities and the Markov transition matrix. The predicted probability of model j is calculated as:

$$c_j(k) = \sum_{i=1}^{N} \pi_{ij}\mu_i(k-1), \tag{22}$$

where μ_i(k−1) denotes the probability of model i at the previous time step. Corresponding mixing probabilities are determined by:

$$\mu_{ij}(k) = \frac{\pi_{ij}\mu_i(k-1)}{c_j(k)}. \tag{23}$$

These probabilities are used to compute the mixed initial state and covariance for each EKF prior to the prediction and correction steps described in Section 3.1. After the EKF update, the consistency of each model with the current measurements is evaluated using the innovation vector and innovation covariance. The likelihood function of the j-th model is calculated as:

$$\Lambda_j(k) = \frac{1}{\sqrt{(2\pi)^m |S_j(k)|}} \exp(D),$$
$$D = -\frac{1}{2} v_j^T(k) S_j^{-1}(k) v_j(k), \tag{24}$$

where $v_j(k)$ is the innovation vector, $S_j(k)$ is the innovation covariance matrix, and m denotes the dimension of the measurement vector. The model probabilities are then updated according to Bayes' rule:

$$\mu_j(k) = \frac{\Lambda_j(k) c_j(k)}{\sum_{i=1}^{N} \Lambda_i(k) c_i(k)}. \tag{25}$$

Finally, the overall IMM estimate is obtained as the weighted combination of the individual EKF estimates:

$$\hat{\mathbf{x}}_{IMM}(k) = \sum_{i=1}^{N} \mu_j(k) \hat{x}_j(k), \tag{25}$$

while the corresponding covariance matrix is computed as

$$\mathbf{P}_{IMM}(k) = \sum_{i=1}^{N} \mu_j(k) \mathbf{E},$$
$$\mathbf{E} = \mathbf{P}_j(k) + \left(\hat{\mathbf{x}}_j(k) - \hat{\mathbf{x}}_{IMM}(k)\right)\left(\hat{\mathbf{x}}_j(k) - \hat{\mathbf{x}}_{IMM}(k)\right)^T. \tag{26}$$

The resulting model probabilities provide an indication of the most likely sensor operating condition at the each sampling instant, while weighted state estimate combines the advantages of all candidate models. Consequently, the here proposed IMM estimator preserves the estimation accuracy during the nominal operation, and also improves robustness under sensor bias and drift conditions.

The numerical values of the process noise covariance matrices, transition probability matrix, and initial model probabilities used in the simulations are presented in the following section.

4. SIMULATION RESULTS AND DISCUSSION

For the statistical evaluation of the proposed IMM estimator, 100 Monte Carlo simulation runs have been performed under the nominal operating conditions as well as in the presence of sensor bias and sensor drift, using different realizations of process and measurement noise. The simulation parameters adopted throughout this study are summarized in Table 1.

Table 1. Simulation parameters

Parameter	Value
P_0	diag(10^2,10^2,1^2,50^2,50^2)
R	diag(10^2,5^2,0.5^2)
Q_1	diag(0.5^2,0.2^2,0.05^2,0.01^2,0.01^2)
Q_2	diag(0.5^2,0.2^2,0.05^2,1.5^2,1.5^2)
Q_3	diag(0.5^2,0.2^2,0.05^2,0.05^2,0.05^2)
μ_0	$[0.98,0.01,0.01]^T$
Π	[0.995 0.004 0.001; 0.010 0.985 0.005: 0.005 0.010 0.985]

Figure 2 shows that both estimators accurately follow the reference altitude and velocity during nominal operation. However, in the presence of sensor degradation, the IMM estimator achieves better agreement with the reference values compared with the EKF. Unlike the single-model EKF estimator, the IMM estimator adapts the estimation process according to the most probable sensor operating condition, and thus reduce the influence of bias and drift effects.

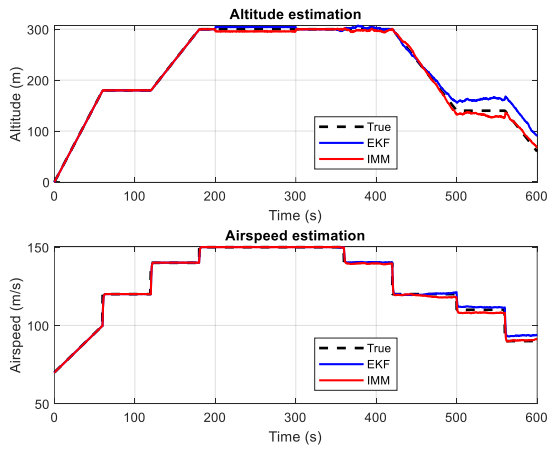

Figure 2. Comparison of EKF and IMM estimates

The Monte Carlo simulation results presented in Figure 3 confirm the robustness of the proposed IMM estimator. For all the analyzed parameters, here proposed IMM approach achieves the lower root mean square error (RMSE) values when compared with the EKF estimator, with the most significant improvements being obtained in case of the altitude estimation.

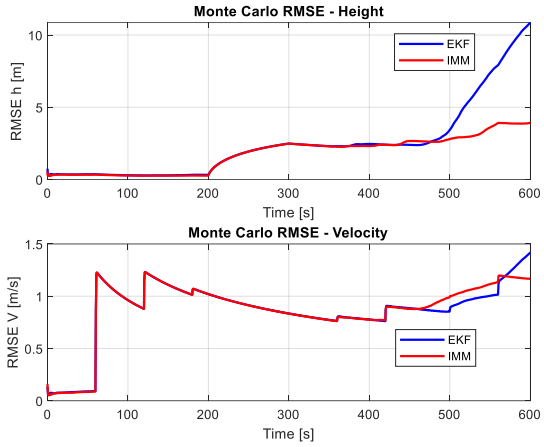

Figure 3. RMSE comparison obtained from Monte Carlo simulations

The quantitative comparison that is presented in Table 2 confirms the advantages of here proposed IMM estimator over the conventional EKF estimator approach. The lower RMSE values are achieved for all analyzed parameters, which indicates the improved estimation accuracy while algorithm stability is also maintained. It shuld be stressed, that the most significant improvement is observed in the case of altitude estimation, which confirms effectiveness of here observed multi-model approach under the sensor degradation conditions.

Table 2. RMSE comparison

State	EKF RMSE	IMM RMSE	Improvement
Altitude (m)	2.4433	1.7859	26.9%
Airspeed (m/s)	0.8669	0.7742	8.3%

5. CONCLUSION

This paper presents an air data parameter estimator based on the IMM algorithm and a bank of EKFs for the different operating regimes of a pitot-static system. The proposed approach includes nominal operation, sensor bias, and drift models, with the adaptive mode selection based on the estimated model probabilities.

The observed nonlinear Pitot–static system model include sensor dynamics, measurement noise, bias, and drift effects that were used for estimator evaluation. The obtained Monte Carlo simulations results show that the IMM approach reduces estimation errors compared with the conventional EKF while preserving stable operation under degraded sensor conditions. Our future work will focus on incorporating additional degradation models and validation of the proposed approach by using real-time experimental flight test data.

Abstract: *The increasing usage of Unmanned Aerial Systems in critical areas requires robust Counter Unmanned Aerial Systems solutions to maintain security and operational integrity. This paper investigates the impact of sequential sensor data fusion on the classification accuracy of Unmanned Aerial Systems signals within the Radio Frequency domain for real-time inference. Given the hardware constraint of a single Radio Frequency receiver, we propose a tailored fusion architecture that integrates sequential data acquired over time. Utilizing Radio Frequency spectrograms as the primary input, various sensor fusion methods were evaluated in combination with simple Convolutional Neural Networks. To ensure compatibility with our deep learning models, particularly under the constraints of Radio Frequency sensors that are often affected by low Signal-to-Noise Ratio and spectral interference in dense environments, the proposed fusion methods produce post-processed spectrograms that retain the original input dimensions. This design enables seamless integration into pre-trained deep learning pipelines without necessitating architectural modifications, while also addressing conditions that may otherwise contribute to elevated false-positive rates. The proposed methods were benchmarked against multiple pre-recorded validation datasets specifically designed to simulate real-world scenarios. The results demonstrate that specific temporal sensor fusion approaches significantly enhance prediction accuracy and overall decision-making robustness, providing a more stable decision boundary compared to baseline models without data fusion. Ultimately, the proposed approach offers a computationally efficient technique to improve inference reliability without additional overhead hardware or extensive model fine-tuning. By effectively mitigating stochastic noise and signal fading, this method reduces false alarm rates by up to 15%, suggesting that incorporating time-domain sensor fusion as a preprocessing layer is a scalable, cost-effective solution for real-time drone classification in complex Radio Frequency environments.*

Keywords: *classification, drone, convolutional neural network, fusion, radio frequency, sensors.*

1. INTRODUCTION

The development of Unmanned Aerial Systems (UAS) or colloquial “drones” and the technology they use is progressing at an incredible pace, while the reduction in their price and the simplification of their use contribute to their increasing availability and accessibility. As a result, there has been a need for protection against malicious drones that seek to damage critical structures in some way. This is how Counter Unmanned Aerial Systems (CUAS) emerged, which, with the help of sensor systems and Artificial Intelligence (AI) algorithms, detect and identify drones and react appropriately in order to neutralize the threat [1].

Most AI algorithms developed for this application rely primarily on individual sensor inputs, such as images, whereas real-time scenarios in which sensors continuously generate large volumes of image data are typically not sufficiently addressed [2]. When used in real-time, detection algorithms often give too many decisions per unit of time, and the end-user does not benefit from that. Moreover, such decisions are imperfect because of the detection algorithms themselves, which have a certain accuracy over trained datasets that are generally not large and diverse enough due to unavailability of adequate training data and the very nature of the problem. This is strictly connected with the characteristics of Radio Frequency (RF) environment often affected by low Signal-to-Noise Ratio (SNR), spectral interference and propagation of electromagnetic waves [3], [4], [5].

The research subject includes the introduction of automatic data fusion into a system with a single sensor for detection and identification of drones in the RF domain. Multiple early and late fusion techniques were tested through experimental research (spectrogram merging, hard and soft fusion), and the corresponding results are presented offering the tailored approach for this specific problem. Each of the fusion approaches are explained in the Methodology chapter of the paper. The main goal is to increase the reliability and accuracy of drone detection and identification CUAS systems that

Corresponding author: D. Mikanović;
E-mail: darko.mikanovic@mod.gov.rs
DOI: 10.5937/OTEH26057M

leverage already trained Convolutional Neural Network (CNN) models for predictions.

There are several advantages of using optimal sensor fusion techniques. The reliability and accuracy of drone detection and identification are increased with very little overhead and using the available prediction models as-is. The number of decisions made per unit of time is brought closer to the optimum for the end-user. An optimal sensor fusion is also a good starting point for more advanced data fusion approaches that include other types of fusion, such as post-prediction late fusion, that can increase the accuracy and reliability of detection systems even more.

The limitation of the sensor fusion approach is that it cannot improve the predictions accuracy by much on its own without other data fusion layers, though incorporating sensor fusion along with advanced feature fusion or late fusion methods tend to bring the best results.

The main contribution of this work consists of several facts: improvement of the classification accuracy in CNN models with temporal data fusion approaches, examination of the classification accuracy in 2,4GHz frequency band, testing the possibility of detecting multiple drones operating at the same time, and novel benchmark for examining the classification accuracy of drone classification in RF domain.

The rest of the paper is organized as follows: chapter Literature presents the recent research in this area specifically solving this problem, chapter Methodology presents the system model and explains to the reader how the experiments are performed, chapter Results presents the obtained results with discussion, and finally chapter Conclusion concludes the study.

2. LITERATURE

2.1 RF Domain and Spectrogram Analysis for UAS Classification

The rapid proliferation of UAS within critical airspace underscores the immediate necessity for dependable CUAS technologies [6]. Traditional drone monitoring techniques—primarily dependent on visual recognition, electro-optical sensors (cameras), and acoustic arrays—exhibit severe performance drop-offs when subjected to high ambient noise, physical occlusions, and adverse weather conditions [4], [7], [8]. To bypass these vulnerabilities, RF sensing has emerged as an indispensable modality, offering an all-weather, long-range, non-line-of-sight strategy by intercepting telemetry and control packets exchanged between a drone and its ground control station [9]. Recent trends favor Deep Learning (DL) and AI pipelines over hand-crafted statistical extractions to interpret these signal environments [7], [10], [11]. Specifically, by applying the Short-Time Fourier Transform (STFT), researchers transform one-dimensional raw time-series data or In-phase and Quadrature (I/Q) samples into two-dimensional visual spectrogram layouts [3], [5], [12], [13]. This processing stabilizes signal variance, preserves underlying temporal-spectral fluctuations, and maps the physical channel behaviors directly into joint time-frequency domains optimal for CNN feature backbones [3], [5], [11].

2.2 Multi-Sensor and Cross-Modality Data Fusion Architecture

While 2D DL models yield high accuracy profiles under pristine configurations, real-world RF landscapes remain prone to multipath scattering, intermittent fading, and deliberate or stochastic spectral noise, inflating false-positive metrics [3]. To reinforce system robustness, cross-modality data fusion frameworks have been widely engineered. For instance, multi-sensory CUAS architecture combining heterogeneous sensors—such as radars, electro-optical sensors (cameras), acoustic arrays, and RF sensors—leverage complementary physical properties to yield substantial improvements in drone verification accuracy, spatial classification, and real-time tracking efficiency [7], [10], [14], [15], [16]. Within specific dual-stream frameworks, DL models have been successfully fused with parallel convolutional channels to combine raw acoustic waveforms with RF signatures, illustrating high tracking efficacy across heterogeneous clusters [4], [9]. Furthermore, multi-modal network schemes are frequently supported by advanced algorithmic backbones, such as contrastive learning Siamese topologies or Kalman filters, to reliably identify unauthorized payloads and stealth drone threats under highly complex electromagnetic interference [3], [11], [17].

2.3 Single RF sensor Preprocessing Paradigms and the Temporal RF Fusion Gap

Despite the high detection performance guaranteed by multi-sensor deployment, the physical implementation of distributed, multi-modal hardware remains heavily constrained. Deploying physical radar arrays alongside synchronized electro-optical sensors (cameras) and acoustic arrays introduces severe system configuration complexity, excessive computational workloads, and aggressive calibration costs [9]. Consequently, modern methodologies are actively pivoted toward data reconstruction and virtual feature fusion frameworks capable of extracting hidden or multi-feature temporal streams inside a single-sensor hardware pipeline [12]. Synthesizing sequential temporal segments or multi-scale data profiles prior to or within intermediate convolutional layers provides a highly stable decision boundary, maximizing the model's macro-precision and robustness without scaling hardware boundaries [5], [12].

However, to the best of our knowledge, analysis of existing CUAS literature reveals a stark architectural dichotomy. Current state-of-the-art data fusion solutions are overwhelmingly dependent on either multi-modal hardware configurations (fusing RF with radar [1], [4], [7], [8], [10], [14], [15], [16], [17], vision [9], [18], or acoustics [4]) or concurrent multi-channel array nodes [3]. There remains a severe scarcity of scientific research evaluating sequential, time-domain data fusion

architectures engineered specifically for single-receiver RF infrastructures. Most single-sensor designs still rely on isolated, single-frame spectrogram inferences that lack temporal context and fail during deep signal fading or transient interference bursts. This critical research gap establishes a clear demand for lightweight, computationally efficient preprocessing frameworks capable of dynamically aggregating temporal RF states into standardized dimensions, optimizing classification accuracy without demanding overhead hardware or resource-intensive model fine-tuning.

3. METHODOLOGY

3.1 Fusion Architecture

The proposed system (Figure 1) processes RF spectrograms produced by a single receiver through two independently pre-trained CNN classifiers, one for counting drones (Model 1) and the other for identifying a single drone (Model 2). These models were also used in paper [13], where they are described in detail. Model 1's classes are: 0 drones, 1 drone, 2 drones and 3 drones; model 2's classes are: Lightbridge (0), OcuSync20 (1) and OcuSync40 (2). Model 2's predictions are relevant only when model 1 outputs 1 drone as the prediction. Combining both models' predictions, the proposed data fusion approach has 6 possible decisions to make:

- No drones (model 1: 0),
- Lightbridge (model 1: 1, model 2: 0),
- OcuSync20 (model 1: 1, model 2: 1),
- OcuSync40 (model 1: 1, model 2: 2),
- Two drones (model 1: 2),
- Three drones (model 1: 3).

Spectrograms are recorded in advance and grouped into four different scenarios which are used in this research for fusion evaluation and they will be explained in the Experimental setup section and presented in the Results and discussion chapter. Two families of data fusion are considered: early (sensor) fusion, which merges several successive spectrograms into a single input prior to classification, and late (hard and soft) fusion, which combines the classifiers' outputs over several consecutive predictions. Sensor and late fusion can also be combined, and every technique is configurable in terms of how many spectrograms or predictions are aggregated. Each fusion technique will be described in the following sections.

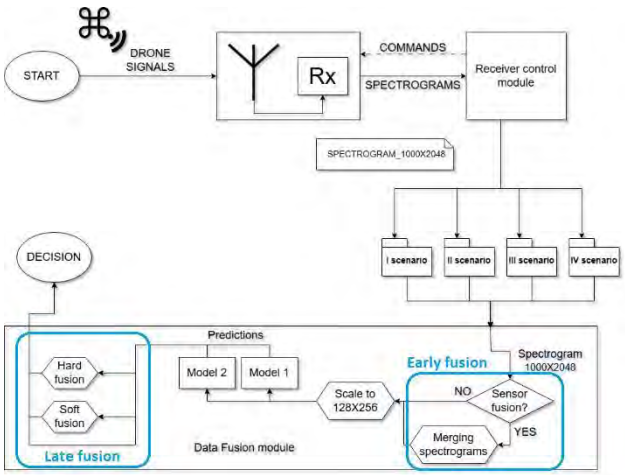

Figure 1. Methodology

3.2 Sensor (Early) Fusion

Since only a single RF sensor is available, sensor fusion here is limited to merging successive spectrograms from that sensor into one spectrogram matching the models' input size. Three merging methods were implemented: vertical concatenation of successive spectrograms followed by rescaling, which compresses drone signal patterns along the time axis while preserving their width — the primary feature distinguishing drone types (Figure 2); pixel-wise logical OR of the aligned spectrograms, which preserves the original dimensions but accumulates noise and interference from every merged frame (Figure 3); and pixel-wise logical XOR, intended to reduce this noise accumulation relative to OR at the cost of a more fragmented resulting signal (Figure 4). Vertical concatenation showed the best results among these three methods in qualitative tests in the 2,4GHz frequency band use case, where the accuracy is increased only slightly when compared to late fusion approaches.

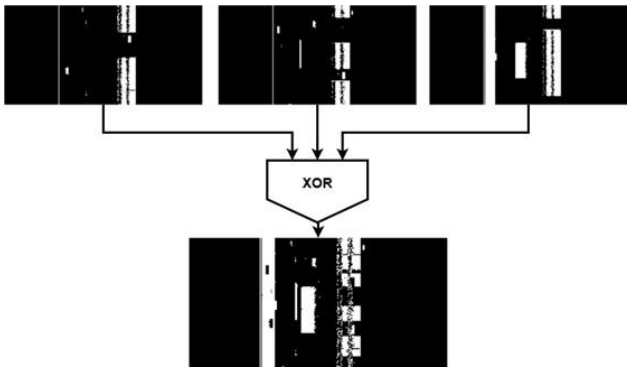

Figure 4. Sensor Fusion – XOR operation

3.3 Score-Level Fusion: Soft Fusion

Soft fusion combines the probability vectors produced by a classifier over several consecutive spectrograms by summing them element-wise and selecting the class with the highest cumulative probability. The soft fusion additionally folds the previous decision window's summed vector into the current sum, scaled by an empirically obtained factor k = 0.25. This makes fusion outcomes more resistant to short-lived state changes, at the cost of slightly slower adaptation in environments where drones frequently appear or disappear, and is therefore best suited to relatively stable operating environments.

3.4 Decision-Level Fusion: Hard Fusion

Hard fusion instead combines the discrete class predictions made over several consecutive spectrograms, using at least three predictions to avoid frequent ties. Under the majority voting rule, the final decision is the class occurring most often within the prediction window (e.g., for predictions [0, 1, 0, 2, 2, 0], the majority voting outcome is class 0). Another rule that is implemented is the longest sequence rule, where the final fusion decision is the class that makes the longest consecutive sequence in the prediction window (e.g., for predictions [0, 0, 1, 1, 1, 0, 0], the longest sequence outcome is class 1). Residual ties are resolved through a configurable secondary rule.

3.5 Experimental Setup

To emulate realistic operating conditions, all recordings were made indoors, where sporadic 2,4GHz interference from other wireless devices is present, and drone signals were intentionally attenuated by placing the drones at a distance from the receiving antenna. Manual band switching between 2,4GHz and 5,8GHz and drone activation/deactivation were used to simulate dynamic scenarios. Four scenarios were each recorded once, so that every fusion configuration is evaluated on identical data: (I) a single Lightbridge drone featured in 108 spectrograms; (II) a single OcuSync40 drone featured in 72 spectrograms; (III) two drones (Lightbridge and OcuSync20) in 108 spectrograms; and (IV) three drones (Lightbridge, OcuSync20 and OcuSync40), 252 spectrograms – each scenario including drone-free intervals. Sensor fusion was limited to merging at most four spectrograms, and late fusion windows were capped at nine consecutive predictions, reflecting the real-time constraint of at most one fusion decision every three seconds at an acquisition rate of three spectrograms per second.

4. RESULTS AND DISCUSSION

Table 1 summarizes, for each scenario, the classification accuracy obtained without fusion and the best-performing early and late fusion configurations identified during testing. Fusion decisions are compared against ground truth at the timestep granularity determined by the corresponding fusion window. Early fusion results in scenarios II and III are omitted because no early fusion configuration could achieve the accuracy of models without fusion due to scenarios' nature. N_{sp} is the number of successive spectrograms used for sensor fusion.

Table 1. Classification accuracy by scenario

Scenario	No fusion	Best early fusion	Best late fusion
I	85.19%	89.81% ($N_{sp} = 2$)	**98.15%** (hard, 4 predictions)
II	91.67%	–	**97.22%** (soft, 3 predictions)
III	96.30%	–	96.30% (soft, 3 predictions)
IV	80.95%	84.52% ($N_{sp} = 3$)	**89.29%** (hard, 4 predictions)

The used scenarios and relevant results are illustrated using plots in the upcoming figures. The blue strip is used to mark the ground truth, that is, the true state at the given time in the scenario. Red dots represent models' predictions without any fusion influence. Models' predictions tend to fluctuate frequently when no fusion method is used to compensate. Finally, the golden stars represent fusion's decisions. The stars appear less frequently than the red dots, since fusion algorithms take several predictions from model's to make a single decision. Number of taken predictions is a configurable parameter.

Scenario I, characterized by pronounced interference, benefited most from fusion: sensor fusion via concatenation of two successive spectrograms raised accuracy from 85.19% to 89.81% (Figure 5), while decision-level hard fusion with four predictions using the majority voting rule reached 98.15% (Figure 6).

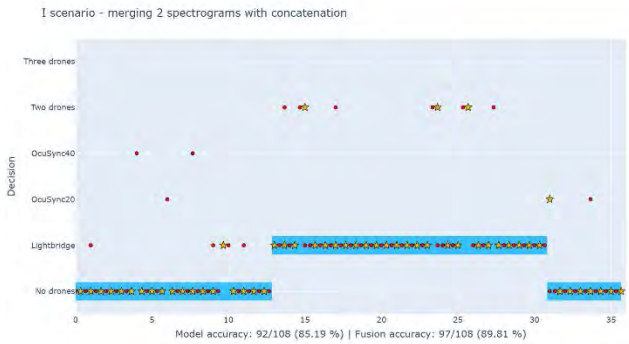

Figure 5. Scenario I – Early fusion

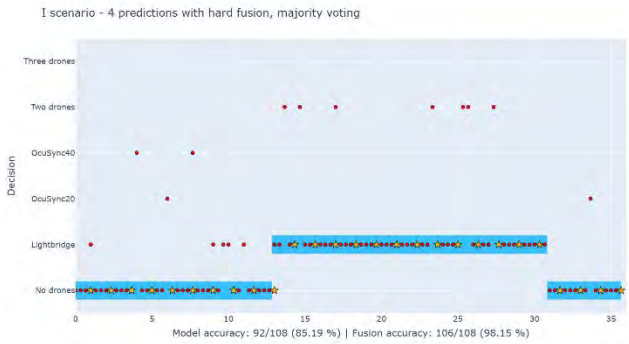

Figure 6. Scenario I – Hard fusion

In the cleaner scenarios II (Figure 7) and III (Figure 8), sensor fusion could not improve the unfused models' accuracy. Soft fusion over three predictions matched or exceeded the unfused baseline in these scenarios (97.22% and 96.30%, respectively) while producing visibly more stable decision sequences than the individual model predictions, which fluctuated at several points despite comparable aggregate accuracy.

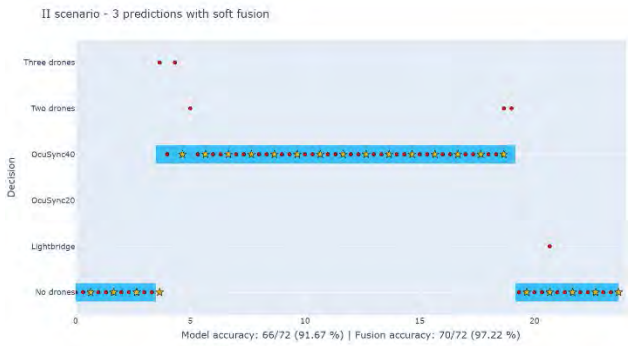

Figure 7. Scenario II – Soft fusion

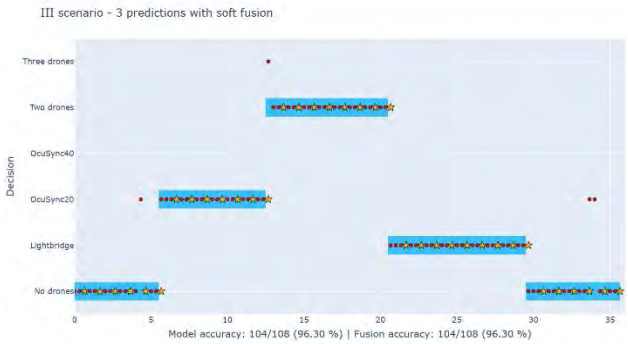

Figure 8. Scenario III – Soft fusion

In the most complex scenario IV (Figures 9 and 10), involving three drones and frequent state changes, hard fusion over four predictions using the longest sequence rule improved accuracy from 80.95% to 89.29%.

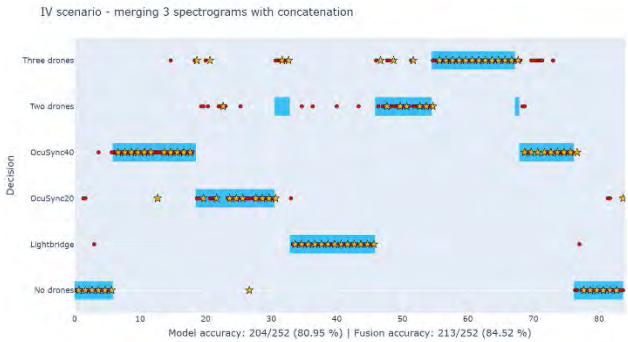

Figure 9. Scenario IV – Early fusion

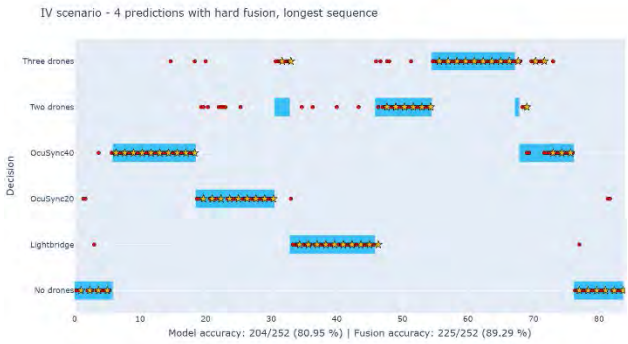

Figure 10. Scenario IV – Hard fusion

Across all scenarios, late fusion consistently outperformed sensor fusion alone, confirming that pairing sensor fusion with a late fusion stage, rather than relying on sensor fusion in isolation, is necessary to obtain the largest accuracy gains. Models used should also have certain amount of accuracy so the fusion algorithms can work out a reliable decision using model's predictions as a baseline.

5. CONCLUSION

This work evaluated sensor and late data fusion for single-receiver RF drone classification with CNN models across four realistic multi-drone scenarios. Sensor fusion alone provided only marginal accuracy gains in the 2,4GHz frequency band. Late fusion, in contrast, improved classification accuracy by up to 13% over the

unfused baseline and produced markedly more stable decisions over time, while also allowing the decision-making frequency to be tuned to the target application.

These findings support time-domain fusion as a lightweight, hardware-free preprocessing layer for improving the precision and reliability of real-time RF-based drone classification. As a result, the predictions that are shown to users in real time became stable and more useful, without fluctuations and excessive output. Future work includes extending the sensor system with additional RF or complementary sensors, fine-tuning the CNN models directly on fused spectrograms, and evaluating further soft and hard fusion strategies.

Abstract: *The wide implementation of Global Navigation Satellite Systems has declared these technologies critical assets in both military operations and civilian infrastructure. Consequently, Global Navigation Satellite Systems have become a critical target for Electromagnetic Spectrum Operations. Traditional centralized jamming systems, however, are often inadequate in complex and dynamic electromagnetic environments and in large geographic areas due to weaknesses such as single-point failures, increased latency, and restricted signal range. To overcome these limitations, there is a need for autonomous, distributed jamming architectures capable of adapting to dynamic electromagnetic environments. This paper proposes a decentralized approach powered by Federated Learning to enable a swarm of jamming agents to collaboratively learn and execute electronic attack. Federated Learning was selected to reduce communication overhead and enable effective coordination among multiple agents in complex, large-scale environments where synchronization is essential for neutralizing dynamic military targets. To evaluate system performance, we observed the Jamming-to-Signal Ratio at the Global Navigation Satellite Systems receiver point, ensuring the effectiveness of the distributed electronic attack strategy. Our results show that this approach provides excellent adaptability in non-stationary, high-mobility scenario compared to traditional centralized jamming strategies. Exploiting the collective intelligence of multiple autonomous agents and improving the Jamming-to-Signal Ratio at the target receiver, the proposed approach achieves higher operational efficiency and resilience against counter-jamming measures. The Federated Learning framework sets up a scalable and robust foundation for future multi-agent coordination in military electromagnetic spectrum operations.*

Keywords: *agents, artificial intelligence (AI), electromagnetic spectrum operations (EMSO), Federated Learning (FL), Global Navigation Satellite Systems (GNSS), Jamming-to-Signal Ratio (JSR).*

1. INTRODUCTION

Electromagnetic Spectrum Operations (EMSO) include coordinated combat military actions to profile, exploit, and protect the electromagnetic environment, combining electronic warfare (EW) with spectrum management. The primary purpose of EMSO is to achieve superiority and unrestricted access to the electromagnetic spectrum (EMS) for friendly forces while at the same time denying its use to foes. In modern multi-domain conflicts, this is obtained by enabling precision electronic attack (EA), covered and secure communication, and early warning capabilities. However, modern EMSO cope with severe limitations due to the extreme congestion of the radio frequency (RF) environment, the proliferation of commercial off-the-shelf (COTS) software-defined radios (SDR), and the vulnerability of centralized EW architectures [1].

Crucial and specific aspect of successful EMSO is the exploitation of possibly weakens point which are Position, Navigation, and Timing (PNT) signals, most notably the Global Navigation Satellite System (GNSS) [2]. The primary military purpose of GNSS, that engages satellite constellations such as GPS, GLONASS, Galileo, and BeiDou, is to serve as the primary and global tool for giving precise, real-time spatial and temporal information. The critical limitation of GNSS comes from its extreme vulnerability to electronic interference [3], [4], both intentional and unintentional. Unintentional interference arises from civilian infrastructure, space weather phenomena, or RF cosmic radiation and harmonic emissions from nearby communication equipment, which inadvertently degrade sensitivity of GNSS receiver (GNSS RX). Intentional interference stands for a deliberate tactical deployment and engagement of EA assets. From an EMSO perspective, GNSS jamming and spoofing offers profound tactical benefits by creating localized denial-of-service (DoS) zones for PNT signals [4].

In response to these general threats, modern defensive doctrines have integrated advanced GNSS protection mechanisms, complicating the EMSO scene [5]. Current military GNSS RXs are increasingly equipped with anti-jamming capabilities, such as spatial-temporal anti-jamming processing (STAP) [6], Controlled Reception Pattern Antennas (CRPA) [7], and multi-constellation fallback algorithms. While these electronic protection (EP) techniques enhance PTN resilience, they turn the EMS into

Corresponding author: B. Sazdić-Jotić;
E-mail: boban.sazdic.jotic@vs.rs
DOI: 10.5937/OTEH26058S

a highly dynamic, asymmetric environment. For offensive EMSO, traditional high-power, centralized jamming stations or jammer (JX) are no longer fully effective, as protection techniques can nullify static interference sources [7].

To overcome these sophisticated defense techniques, this paper proposes a distributed autonomous GNSS jamming framework based on artificial intelligence (AI). Rather than relying on a single vulnerable JX, the proposed architecture coordinates a swarm of geographically distributed, low-cost and low-power JX capable of executing synchronized jamming [1], [8]. To navigate dynamic RF environments, each JX employs Reinforcement Learning (RL) to autonomously adapt its position and power based on real-time feedback. To address communication limits and data privacy constraints, a Federated Learning (FL) framework [9] is integrated across the swarm, allowing jammers to collaboratively optimize a global model by exchanging compact weight updates instead of raw telemetry [10], [11], [12].

The integration of RL and FL for distributed GNSS jamming offers key EMSO advantages:

- **Resilience.** Spatial distribution eliminates single points of failure, protecting against hard-kill threats.
- **Adaptability.** RL-driven local control allows real-time optimization of position and power against dynamic electronic protection (EP) upgrades.
- **Anti-Jam Evasion.** Multiple low-power JXs effectively bypass modern protections like Controlled Reception Pattern Antennas (CRPA).
- **Communication Efficiency.** FL preserves bandwidth and privacy by exchanging compact model weights instead of raw telemetry.

Conversely, architecture faces operational challenges, including swarm convergence complexity, heterogeneity penalties during federated aggregation (due to varying hardware/communication limits), and the requirement for strict synchronization between JXs to prevent mutual self-interference.

The rest of this paper is organized as follows: chapter 2 presents the literature review, chapter 3 shows the architectural design of the proposed approach, chapter 4 shows the results and discussion, and chapter 5 summarizes the core findings of the study.

2. LITERATURE

2.1. GNSS OVERVIEW

Technologies of GNSS have become a crucial part of modern infrastructure, with broad applications in transportation, telecommunications, scientific research, and numerous civilian and military systems. In recent years, GNSS is again in the focus because of the recent military conflicts around the world. Official GPS interface specification documents [13] provide the basis for understanding the structure of PTN signals, message formats, and the characteristics of individual frequency bands. Additionally, authors in [14] addressed GNSS modernization and analyzed the development of new signals and services, as well as improvements in positioning accuracy. New ideas are presented in [15] giving attention to multi-constellation GNSS RXs, which provide greater positioning reliability and availability in complex environments. Finally, authors in [16] investigated the application of AI to improve GNSS performance, particularly in position estimation and signal-quality analysis.

2.2. GNSS INTERFERENCE (JAMMING & SPOOFING)

Signals of GNSS reach the Earth's surface at extremely low power levels, generally below the GNSS RX thermal-noise floor, which makes it particularly vulnerable to various forms of interference and deliberate attacks. Jamming [17] and spoofing [5] are widely regarded as the most serious EA threats to reliable GNSS operation. In addition, review studies in [18], [19], analyze the effects of interference on GNSS RX performance using parameters such as automatic gain control (AGC), carrier-to-noise density ratio (C/N0), signal spectral characteristics, and in-phase/quadrature (I/Q) samples. Additionally, authors in [20] introduced distributed systems for detecting and localizing interference sources, as well as to sensor networks for monitoring large geographical areas. Modern approaches in [21] increasingly employ AI algorithms for the automatic detection and classification of different interference types. Although many existing algorithms achieve high detection accuracy, most rely on centralized data processing, which represents a limitation in distributed GNSS systems.

2.3. REINFORCEMENT LEARNING AND FEDERATED LEARNING

The integration of RL approaches in the domain of GNSS technologies represents a fundamental innovation in modern EMSO, particularly under conditions of intentional jamming and spectrum vulnerability [22], [23]. By interacting with dynamic EMS, intelligent autonomous unmanned systems can adopt alternative navigation strategies and mitigate GNSS loss [24]. This capability enables systems to adapt to unpredictable spatial variations without requiring predefined, static scenarios. Moreover, FL is a modern distributed AI approach that enables collaborative model training without exchanging raw data among agents. In communication networks, edge computing, and distributed systems, FL has been successfully applied to distributed spectrum sensing, interference classification, and jammer recognition [25]. In the GNSS domain, recent studies demonstrate the potential of FL for spoofing-attack detection [26], GNSS interference classification [27], and the development of personalized models for different receivers and operating environments.

Despite substantial progress, the application of RL and FL in EMSO for distributed GNSS jamming remains underexplored, especially in scenarios involving autonomous JXs and real-time data processing. This research gap provides the primary motivation for the solution proposed in this paper.

3. METHODOLOGY

This chapter defines the proposed simulation model for analyzing and improving the AI distributed jamming of GNSS RX in the context of EMSO. The system model combines RL algorithm for the autonomous positioning of *N* JXs organized in a swarm with a simple FL framework to collaboratively watch and evaluate the cooperative EA effects. The simulation model defines a two-dimensional square, Region of Interest (ROI), $\mathcal{A}$, centered at the coordinate origin, and defined by the set:

$$\mathcal{A} = \{(x, y) \in \mathbb{R}^2 | -D/2 \le x \le D/2, -D/2 \le y \le D/2 \quad (1)$$

where *x* and *y* are planar coordinates, and $D \times D$=20×20 km are ROI dimensions (empirically chosen for operational EMSO level).

3.1. ROI CONFIGURATION AND RASTERIZATION

The ROI is discretized using a raster grid with a resolution step of Δ=0.025 km (empirically chosen for operational EMSO level), defining a finite matrix of possible positions where the swarm of JXs can exist in. To stand for real EMSO deployment limits, the ROI is divided along the *y*-axis into two distinct operational zones:

- **Area of Interest (AOI)** is a foe territory and the part of ROI, resolute for deployment and maneuvering of one enemy GNSS RX:

$$\text{AOI} \cap \mathcal{A}, \forall x \ge 0 \quad (2)$$

- **Area of Responsibility (AOR)** is a friendly territory and the part of ROI, resolute for deployment and maneuvering of swarm of JXs:

$$\text{AOR} \cap \mathcal{A}, \forall x < 0 \quad (3)$$

The fixed GNSS RX is positioned at $\mathbf{x}_{\text{RX}} = [0, 5]$, while JXs can maneuver in the AOR. At time step *t*, the position of *i*-th (*i* =1,2, …, *N*=10) JX is $\mathbf{x}_{i,t} = [x_{i,t}, y_{i,t}]$. At the beginning of simulation (*t*=0), the JXs start the mission from separate positions and can move inside the AOR maneuvering boundary ($\forall x \le -5$). Such constraints show the real EMSO conditions and help to simulate the swarm jamming keeping the minimum distance from GNSS RX.

3.2. RADIO PROPAGATION MODEL

The research focuses particularly on GNSS L1 frequency band (1575.42 MHz), which power level ($P_{\text{GNSS,RX}}$) at the whole ROI randomly fluctuated in the range from -125 dBm to -130 dBm that is simply presented with Normal Gaussian distribution. The jamming signal arriving at the targeted GNSS RX position is modeled using a Free Space Path Loss (FSPL) propagation model:

$$L_i = 20\log_{10}(d_{i,t}) + 20\log_{10}(f) + 32.45 \quad (4)$$

where L_i is signal propagation loss from *i*-th JX to the targeted GNSS RX, $d_{i,t} = \|\mathbf{x}_{i,t} - \mathbf{x}_{\text{RX}}\|_2$ is the Euclidean 2D distance between the *i*-th JX and the targeted GNSS RX in km, *f* is GNSS RX frequency in MHz, and 32.45 is FSPL constant. To guarantee a successful EA, the cumulative Jamming-to-Signal Ratio (*JSR*) at the GNSS RX position must satisfy a predefined effectiveness threshold, which is set to γ_{JSR}=20.005 dB. The critical threshold value (γ_{JSR}) for effective EA can be observed through the cumulative power:

$$P^{\gamma}_{\text{J,RX}} = P_{\text{GNSS,RX}} + \gamma_{\text{JSR}} \quad (5)$$

$$p^{\gamma}_{\text{J,RX}} = 10^{\frac{P^{\gamma}_{\text{J,RX}}}{10}} \quad (6)$$

Next, assuming all JXs transmit with the same power, the required uniform power per JX is:

$$p_t^{\text{JX}} = \frac{p^{\gamma}_{\text{J,RX}}}{\sum_{i=1}^{N} g_i} \quad (7)$$

$$P_t^{\text{JX}} = 10\log_{10}(p_t^{\text{JX}}) \quad (8)$$

where P_t^{JX} is resulting jamming signal at the GNSS RX position and $g_i = 10^{(G_{JX}+G_{RX}-L_i/10)}$ is the linear path gain from *i*-th JX towards the GNSS RX, where G_{JX} is antenna gain of each JX, G_{RX} is antenna gain of GNSS RX and L_i is defined in equation (4). It is important to note that P_t^{JX} is power term used inside the reward function explained in chapter 3.1.

3.3. OPTIMIZATION VIA RL

Building upon the foundational concepts proved in our prior work [28], the problem of finding the best spatial distribution of the JXs is solved by engaging Proximal Policy Optimization (PPO) [29] due to its superior stability and clipped objective constraints in non-stationary multi-agent settings.

State Space (*s*). Comprises the current coordinates of all JXs in the AOR with the boundary restriction, alongside the current estimated *JSR* derived from direct feedback loops. The PPO agent was implemented using an actor–critic neural-network architecture. For each JX, the input state is a four-dimensional normalized vector composed of the current JX spatial coordinates, the required uniform JX power, and the estimated joint JSR at the GNSS RX:

$$s_{i,t} = \left[\frac{x_{i,t}}{D/2}, \frac{y_{i,t}}{D/2}, \frac{P_t^{\text{JX}}}{50}, \frac{JSR_t}{50}\right] \quad (9)$$

Action Space (*a*). Defines the permitted directional steps of the agent on the raster grid across the four primary basic directions (North, South, East, West) with a discrete step size of Δ_d, or a possibility to remain stationary:

$$a_{i,t} = [N(\uparrow), S(\downarrow), E(\rightarrow), W(\leftarrow), Stay(\cdot)] \quad (10)$$

Reward Function (*r*). The reward function was designed to guide the swarm of JXs toward spatial configurations that satisfy the required *JSR* at the GNSS RX while minimizing the required uniform JX power. Each JX receives a local reward composed of a shared power-efficiency term, a local distance-improvement term, a *JSR* tracking penalty, an invalid-action penalty, and a pairwise separation penalty. The power-efficiency term encourages configurations that reduce the uniform transmit power needed to achieve the target joint *JSR*. The distance-reduction term encourages each JX to move toward the RX within the allowed rasterized maneuvering region. The *JSR* tracking term penalizes deviations from the required *JSR*, while the invalid-movement action and JX-to-JX separation penalties enforce motion feasibility and

discourage unrealistic JX co-location. A compact form of the reward function is:

$$r_{i,t} = w_P(\Delta P_t) + w_d \Delta d_{i,t} - w_J e_{JSR,t} - w_B(I_{i,t}^{invalid}) - w_S(S_t) \quad (11)$$

where the power-efficiency reward is product of scaling factor (w_P=3.0) and power difference ($\Delta P_t = P_{t-1}^{JX} - P_t^{JX}$); the distance-reduction reward is product of scaling factor (w_d=0.75) and distance difference ($\Delta d_{i,t} = \frac{d_{i,t-1} - d_{i,t}}{\Delta}$); the *JSR* tracking penalty is product of scaling factor (w_J=0.05) and *JSR* mismatch ($e_{JSR,t} = \frac{|JSR_t - \gamma|}{\max(|\gamma|,1)}$); the invalid movement penalty is product of scaling factor (w_B=0.05) and invalid movement (when JXs try to leave the allowed maneuvering region); the JX-to-JX separation penalty is product of scaling factor (w_S=0.10) and JXs co-location or unwanted clustering. The scaling factors are empirically chosen during the training process.

The PPO network consists of a shared fully connected backbone with two hidden layers, each having 96 neurons and hyperbolic tangent (Tanh) activation functions. The actor head maps the hidden representation to logits over the five discrete raster actions (a). A categorical distribution is then formed from these logits to sample the JX movement action. In parallel, the critic head maps the same hidden representation to a scalar state-value estimate used for advantage estimation. The PPO network parameters are optimized using the Adam optimizer with a learning rate of $\alpha=3\times10^{-4}$. Training uses the clipped PPO objective (ε=0.2), generalized advantage estimation with ζ=0.97 and λ=0.95, a value-loss coefficient of 0.50, an entropy coefficient of 0.02, and gradient-norm clipping at 0.50. The PPO network training was implemented in PyTorch using a custom JX swarm environment rather than the OpenAI Gymnasium interface. Evaluation is performed with 1000 steps and greedy-polish mechanism. The proposed environment directly represents the multi-JX raster movement problem, RF link-budget evaluation, JSR computation, reward calculation, and movement constraints.

3.4. FL FRAMEWORK FOR JAMMING EFFECTIVENESS MONITORING

Centralized data aggregation between JXs in EMSO could be disrupted due to bandwidth constraints, communication masking, or the deployment of electronic counter-counter measurement (ECCM) assets. To mitigate this weakness, we propose an FL framework consisting of the distributed JXs as local FL clients. The purpose of the FL framework (FL-PPO) is to allow the JXs to improve their PPO policies without sending raw local trajectories, observations, rewards, or full training data to a central controller - aggregator. At the beginning of each federated round (r), the aggregator JX broadcasts the current global actor's weights ($\theta_i^{(r)} \leftarrow \theta^{(r)}$) to the other JXs. Each JX then performs local PPO training using its own local states, actions, rewards, and *JSR* feedback. After local training, i-th JX obtains updated local weights ($\theta_i^{(r,local)}$). Instead of sending the full local model or raw training data, each JX computes a compact weight increment. Moreover, only increment ($\Delta\theta_i^{(r)} = \theta_i^{(r,local)} - \theta^{(r)}$) is transmitted to the aggregator JX. Although the framework is federated, it still uses central aggregation. The difference from conventional architecture is that the central aggregator is one of the JX stations. The selected aggregator JX performs five main operations:

- **Global model initialization**. At round r=0, the aggregator JX initializes the global PPO actor model ($\theta^{(0)}$).
- **Weight-increment collection**. After local PPO training, each JX sends only its compact update ($\Delta\theta_a^{(r)}$) to the aggregator JX.
- **Compact update compression**. The weight increments are compressed before transmission with top-k FP16 compression.
- **Federated averaging**. The aggregator JX periodically executes a Federated Averaging routine to compute the updated global model parameters:

$$\Delta\theta_{golbal}^{(r)} = \frac{1}{N}\sum_{i=1}^{N} \Delta\theta_i^{(r)} \quad (12)$$

The aggregator JX reconstructs the sparse updates, computes their average, and the global model is then updated and broadcasted back to the JXs. This decentralized pipeline yields system robustness, enables collaborative observation of the ESM, and accelerates the convergence rate of the RL agents toward globally the best spatial coordination within highly fluid EMSO conditions.

4. RESULTS AND DISCUSSION

This section presents the simulation results, which were conducted to analyze the efficacy of jamming, and the prediction of the best locations for distributed JXs (two JXs, five JXs and ten JXs towards one GNSS RX). The results show that the proposed approach can be used for AI distributed jamming of GNSS RX in the context of EMSO. The FL-PPO framework can achieve stable convergence toward the best locations, with *JSR* values consistently supported within the specified threshold. Visual analysis of the agent's trajectories reveals that the model avoids EMS inefficient regions, focusing instead on positions that help the best *JSR*. Results of the optimal positions of two JXs with FL-PPO framework when GNSS RX is asymmetrically positioned are shown in Figure 1.

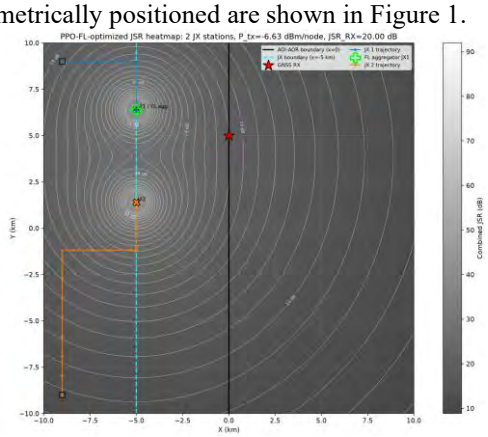

Figure 1. Optimal position of two JXs with FL-PPO when GNSS RX is asymmetrically positioned

The trajectories shown in Figure 1 demonstrate how the JXs focus on maneuvering toward the GNSS RX coordinates, optimizing their positions to maximize the *JSR* while minimizing transmit power. Results of the optimal positions of five JXs with FL-PPO framework

when GNSS RX is asymmetrically positioned are shown in Figure 2.

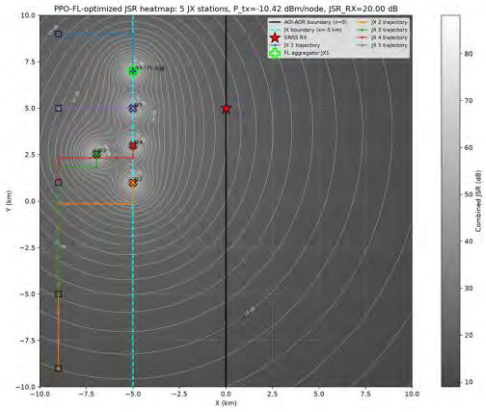

Figure 2. Optimal position of five JXs with FL-PPO when GNSS RX is asymmetrically positioned

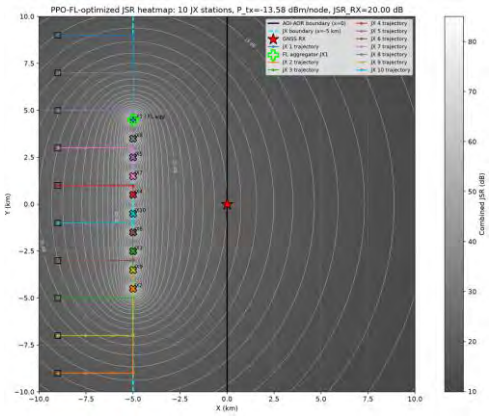
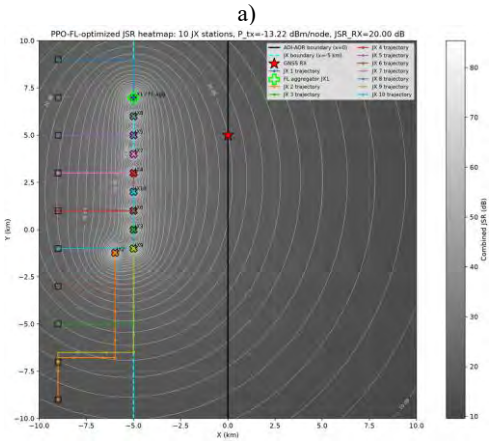
It can be noticed that the higher density of JX trajectories occurs near the GNSS RX which confirms the FL-PPO framework adaptation when GNSS RX is asymmetrically positioned. Figures 1 and 2 show that the asymmetric setup shifts optimal JX locations toward the displaced GNNS RX, proving the proposed approach dynamically adapts to varying GNSS RX geometries rather than converging to fixed configurations. The improvement in the proposed approach can easily be seen with scenario when ten JXs are engaged, that is presented in Figure 3.



a)



b)

Figure 3. Optimal spatial distribution of ten JXs using FL-PPO: a) GNSS RX at the ROI center, and b) GNSS RX asymmetrically positioned at (0,5).

Figure 3 illustrates the optimized spatial deployment of ten JXs under two GNSS RX placement scenarios using the FL-PPO framework. It can be noticed that the spatial distribution contours confirm that individual JXs autonomously place themselves to avoid overlapping redundancies, ensuring a uniform *JSR* coverage over the GNSS RX position. During evaluations of edge cases (JXs were initialized at the border of the ROI), the FL-PPO framework successfully guided isolated JXs toward the globally optimal positions. The results demonstrate that the FL-PPO framework balance effectively from small configurations to larger JX's swarms, successfully satisfying joint *JSR* while minimizing transmit power through cooperative spatial positioning. These properties of the FL-PPO framework support findings and emphasize that RL models can outperform traditional heuristic and deterministic search algorithms in situations with expansive search domains or dynamically changing conditions [12], [22]. This can be supported by quantitative comparison shown in Table 1.

Table 1. Quantitative comparison.

Method	N JX	RX	P_t^{JX}/JX, [dBm]	Mean $d_{i,t}$ [km]	"greedy-polish" steps
PPO	2	(0,0)	-6.67	5.5901	18
		(0,5)	-6.39	6.0443	78
FL-PPO		(0,0)	-6.67	5.5917	63
		(0,5)	-6.63	5.6801	104
PPO	5	(0,0)	-10.59	5.7153	97
		(0,5)	-10.31	6.0822	221
FL-PPO		(0,0)	-10.59	5.7153	200
		(0,5)	-10.42	5.9085	206
PPO	10	(0,0)	-13.58	5.7332	146
		(0,5)	-13.17	6.2686	212
FL-PPO		(0,0)	-13.58	5.7330	180
		(0,5)	-13.22	6.1712	222

Table 1 demonstrates that FL-PPO framework achieves same or better spatial optimization and jamming effectiveness to centralized PPO, especially in the scenario when GNSS RX is asymmetrically positioned. Despite its advantages, the FL-PPO framework introduces a minor heterogeneity penalty. Specifically, in the ten JXs swarm scenario, the FL-PPO framework required 23% more total evaluation steps to achieve a stable spatial convergence when GNSS RX is symmetrically positioned, and 5% when GNSS RX is symmetrically positioned. Such delay in global model synchronization is an expected trade-off, attributed to the periodic nature of the federated weight aggregation phase compared to the continuous, immediate centralized updates.

5. CONCLUSION

This paper introduced a FL-PPO framework for autonomous distributed GNSS jamming using PPO-based local control and a peer-selected aggregation JX. By exchanging only compact model-weight increments rather than raw trajectory data, the architecture eliminates central dependence while maintaining communication efficiency. Simulation results confirm that both PPO and FL-PPO frameworks successfully adapt jammer deployment to target geometries—converging symmetrically for centered GNSS receivers and shifting dynamically toward asymmetric placements to minimize transmit power while

satisfying target JSR constraints. While the FL-PPO framework introduces a slight delay in convergence compared to a centralized PPO, it provides critical advantages in tactical EMSO: immunity to single-point communication failures and the ability to dynamically adapt to asymmetric target geometries. Furthermore, scalability tests demonstrate that the FL-PPO framework effectively coordinates larger swarms. The primary contribution lies in merging distributed spatial optimization with federated weight-sharing for communication-constrained environments. Future work will incorporate terrain-induced multipath propagation, dynamic jamming power and receiver mobility over predefined trajectory, network latencies, and hardware-in-the-loop validation.

Abstract: *Acoustic signal analysis serves as an essential approach for detecting drones operated via optical fibers, which evade conventional radio-frequency detection methods. Nonetheless, achieving reliable acoustic-based detection poses notable challenges due to the pronounced sensitivity of classification models to environmental noise and low signal-to-noise ratios. While deep transfer learning has emerged as a powerful tool for audio classification, the choice of optimal time-frequency representation remains a critical factor in model performance. This paper presents a comparative evaluation of spectrogram- and bispectrum-based transfer learning for drone audio classification. Utilizing a comprehensive dataset of drone and non-drone acoustic signals, raw audio data is transformed into standard 2D spectrograms and higher-order bispectrum representations, which are then classified using three pre-trained models: ResNet-18, ResNet-50 and ViT Base 16. The results of this analysis suggest that higher-order spectral analysis provides a more robust and dependable feature representation in case of smaller model architectures, while larger networks struggle to generalize on the nonlinear features of the bispectrum and favor spectrogram representations.*

Keywords: *audio signal classification, drone classification, transfer learning, spectrogram, bispectrum.*

1. INTRODUCTION

The detection and classification of Unmanned Aerial Vehicles (UAVs), commonly known as drones, has become a matter of critical importance, namely for airspace surveillance and perimeter security. Existing counter-UAV systems employ several detection methods, including radar, radio-frequency (RF) monitoring, electro-optical and infrared imaging, and acoustic sensing. Each of these methods has its limitations – passive RF systems depend on the presence of detectable electromagnetic emissions and may be affected by interference from other wireless devices, whereas optical systems generally require an unobstructed view of the target and adequate illumination or atmospheric visibility [1]. These limitations motivate the investigation of complementary detection techniques.

The emergence of fibre-optic-controlled UAVs further illustrates the limitations of systems that depend on detecting or disrupting wireless command links. In such platforms, command and video signals are transmitted through a physical fibre-optic cable rather than a conventional radio link. Consequently, RF detectors designed to identify command-and-control transmissions may be ineffective [2]. Acoustic sensing is therefore of interest as a passive and comparatively low-cost method that does not depend on the UAV's communication protocol. It instead exploits the characteristic sounds generated by rotating propellers, electric motors, and associated mechanical components [3]. Its practical performance, however, is affected by propagation distance, microphone characteristics, wind, reverberation, and competing environmental sounds [4].

Machine Learning (ML)-based acoustic UAV detection commonly begins by converting a time-domain recording into a representation that exposes its spectral and temporal structure. Frequently used representations include short-time Fourier transform spectrograms, Mel-frequency spectrograms, filterbank energies, and Mel-frequency cepstral coefficients (MFCCs) [1], [3], [5]. A magnitude or power spectrogram describes the local distribution of signal energy across time and frequency, but it omits the phase of the complex STFT coefficients. In addition, additive noise contributes energy to the same time-frequency representation and may obscure the tonal and harmonic components associated with rotor and motor operation.

Higher-order spectral analysis offers a complementary representation of these signals. In particular, the bispectrum describes third-order statistical dependencies and can reveal quadratic phase coupling among frequency components [6], [7]. Such coupling may provide information about harmonic and nonlinear interactions that is not represented explicitly in an ordinary power spectrum. Moreover, for additive Gaussian noise that is statistically independent of the signal, third-order cumulants vanish in

DOI: 10.5937/OTEH26059M

expectation. Bispectral estimation can therefore reduce the expected contribution of Gaussian noise [6], [7]. Most frequently used methods for estimating this bispectral structure include parametric approaches based on autoregressive moving-average (ARMA) models [8].

The selection of a suitable classifier is also influenced by the quantity and diversity of the available training data. Convolutional Neural Networks (CNNs), including residual architectures such as ResNet, incorporate local spatial structure through convolution and have been widely adopted for time-frequency image inputs [9]. Transformer architectures, including the Vision Transformer and the Audio Spectrogram Transformer, use self-attention to model relationships between patches or time-frequency regions over longer ranges [5], [10]. However, the original success of vision transformers depended substantially on large-scale pretraining, and training such models from scratch can be difficult when only a limited dataset is available. Data-efficient training, transfer learning, augmentation, and regularization can mitigate this limitation [10], [11]. Thus, model performance in small datasets depends not only on architecture capacity, but also on initialization and training strategy.

2. LITERATURE

Acoustic UAV detection has predominantly been formulated as an environmental sound-classification problem using short-time spectral representations. Jeon et al. [12] compared Gaussian mixture models, CNNs, and Recurrent Neural Networks (RNNs) using MFCC and Mel-spectrogram features, including evaluation with recordings made in an urban street environment. Bernardini et al. [13] adopted a more traditional pipeline, combining temporal and spectral descriptors—such as short-time energy, spectral centroid, spectral roll-off, and MFCCs—with a support vector machine (SVM) model. Al-Emadi et al. [14] evaluated CNN, RNN, and Convolutional Recurrent Neural Network (CRNN) architectures using spectrogram representations and investigated synthetic data generation as a means of enlarging the available UAV-audio dataset. Other studies have explored model and feature fusion: Casabianca and Zhang [15] combined the outputs of multiple deep networks operating on Mel-spectrograms, whereas Dong et al. [16] fused decisions obtained from Log-Mel-spectrogram and MFCC-based classifiers. Collectively, these studies demonstrate the feasibility of learning drone acoustic signatures from time-frequency representations.

Nevertheless, the robustness of acoustic UAV detectors remains sensitive to propagation distance, environmental noise, microphone characteristics, UAV type, and differences between training and deployment conditions. Tejera-Berengué et al. [4] explicitly examined the effects of distance and recording environment on several conventional and deep-learning classifiers. More recent work has similarly emphasized cross-dataset generalization and the value of pretraining and noise augmentation [17]. Thus, it is safe to say that many published results are obtained from relatively limited, augmented, or closely matched datasets, and that reliable performance in previously unseen acoustic environments remains an open challenge.

As mentioned, most existing acoustic UAV classifiers rely on second-order signal representations (power spectra, STFT spectrograms, Mel-spectrograms), while bispectral representations have been investigated primarily for radar and RF signal classification rather than acoustic detection. For example, Liu et al. [18] combined bispectral slices with a neural classifier to recognize low signal-to-noise (SNR) UAV radar-signal modulations. In the available literature analyzed for this study, no peer-reviewed work was found that combines UAV acoustic bispectra with pretrained vision architectures. Parametric bispectrum estimation is itself well established. Raghuveer and Nikias developed an autoregressive approach in which model parameters are estimated from third-order recursion equations, providing a parametric alternative to conventional Fourier-based bispectrum estimators [5].

3. METHODOLOGY

In this section, we describe the framework utilized to classify drone audio signals and evaluate the performance of the model. Section 3.1 describes the dataset used in this study, along with the necessary preprocessing steps. Following the data description, Section 3.2 introduces the feature extraction pipeline. We give a brief explanation of spectrograms and bispectral representations of audio signals, used to capture temporal, spectral and higher-order statistical variations. In Section 3.3, the process of model training and evaluation is outlined, focusing on the method of transfer learning and the implemented cross-validation evaluation strategy.

3.1 Dataset

The dataset used for this research was taken from the HuggingFace hub [19]. It consists of ~180k .wav files with sampling rate of 16kHz, and each file belongs to one of the two categories: DRONE or NO_DRONE. Because of the substantial volume of the dataset and the resulting computational costs, we extracted an approximately balanced subset for the purpose of this study.

Since the original files are of varying lengths, they were segmented into 1-second snippets to satisfy the fixed-input requirements of neural network training process. This can result in the appearance of snippets containing no valuable information, which is why the resulting dataset was filtered using a percentile-based root mean square (RMS) energy threshold. With this, we acquired a subset consisting of ~3500 audio signals.

As it can be concluded from the class names, the DRONE class includes audio signals which contain various drone sounds in different operating environments. The samples were aggregated from multiple data sources, primarily capturing the acoustic profiles of various multirotor UAVs, with commercial quadcopters being the most dominant. On the other hand, the audio files in the NO_DRONE class represent a variety of sounds, including traffic, animal noises, chatter of people, etc. and were specifically pulled from environmental audio datasets. In some of the files, multiple different sounds are combined. For example, audio files from DRONE class may include distant traffic,

wind and outdoor ambient noise in the background.

3.2 Feature extraction

One of the most important steps before starting the ML model training process is selecting the right features to appropriately represent the data we want to classify. When working with audio files, there is a possibility of extracting features from the time domain (mean, standard deviation, zero-crossing rate, etc.), but this has ultimately proven to be inferior to the frequency-domain approach.

Figures 1 and 2 show examples of spectra of signals from our two different classes. As we can see in the DRONE signal spectrum, there is a series of regularly spaced, distinct peaks which correspond to the harmonic comb structure. This pattern can be attributed to the drone's electric motors and rotating propeller blades.

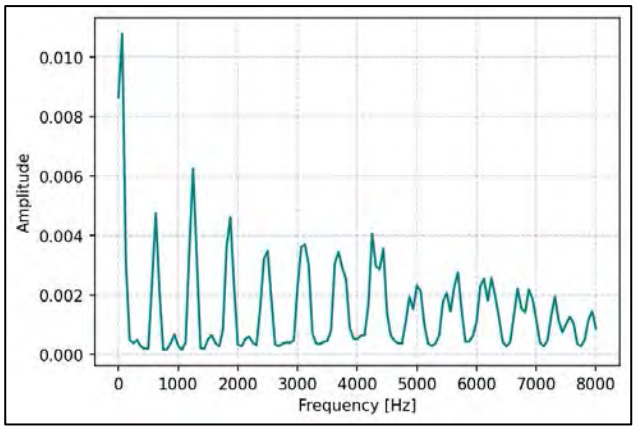

Figure 1. Spectrum of a DRONE signal

The difference between these two types of signals is clear when comparing figures 1 and 2. The NO_DRONE signal's energy is concentrated in the lower frequencies and undergoes a rapid decay past 1000Hz. The lack of mechanical periodicity here is obvious and the spectrum's appearance is highly characteristic of ambient background noise.

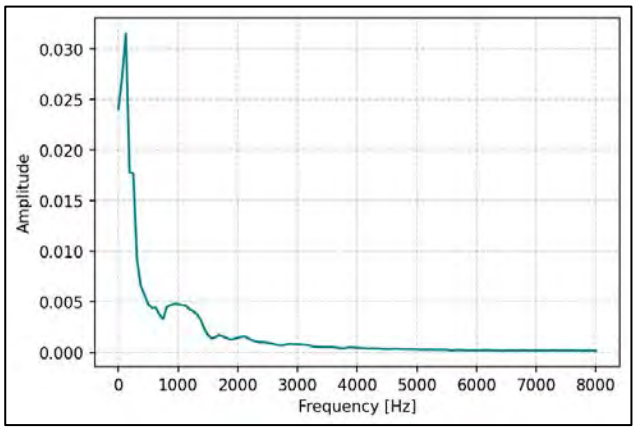

Figure 2. Spectrum of a NO_DRONE signal

Spectrogram is one of the most commonly used time-frequency representations of a signal. We use the Discrete Short-Time Fourier Transform (DSTFT) to calculate the frequency-domain representation of an audio file, given by the formula:

$$X[m,k] = \sum_{n=0}^{N-1} x[n+mR]w[n]e^{-j\frac{2\pi}{N}kn} \qquad (1)$$

In equation (1), $X[m,k]$ is the complex-valued STFT coefficient at time index m and frequency bin k, $x[n+mR]$ is the $(n+mR)$-th sample of the original audio sequence, $w[n]$ is the window function, R is the hop size, and N is the total number of samples. The spectrogram can then be calculated as:

$$S[m,k] = |X[m,k]|^2 \qquad (2)$$

While they are highly effective for extracting stationary characteristics, they cannot fully capture complex, non-linear dynamics often present in audio signals.

Figures 3 and 4 show examples of spectrograms of signals from the two different classes.

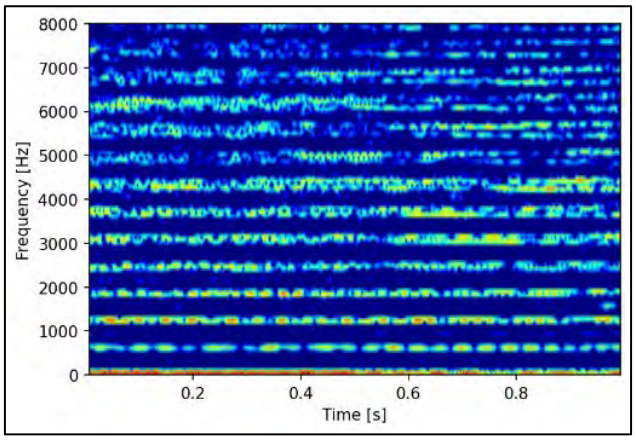

Figure 3. Spectrogram of a DRONE signal

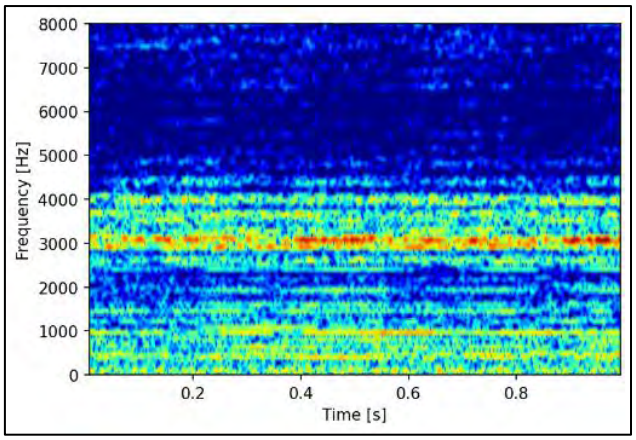

Figure 4. Spectrogram of a NO_DRONE signal

From these two representations, we can draw the same conclusions as we did when looking at figures 1 and 2. In the case of DRONE signal, we can see multiple "stripes" in the spectrogram which are the result of drone's motors and rotating blades. On the other hand, the NO_DRONE signal spectrogram has no such patterns and its values are noticeably lower for frequencies past ~4kHz.

Because of spectrogram's limitations, we calculated the bispectrum (third-order cumulant spectrum). The advantage of the bispectrum is in its ability to preserve phase information and detect non-linear interactions

between frequency components. Mathematically, the bispectrum is defined as the Fourier transform of its third-order cumulant sequence. Again, we use the DFT to practically calculate the bispectrum of a signal:

$$B[k_1, k_2] = E\left[X[k_1]X[k_2]X^*[k_1 + k_2]\right] \quad (3)$$

where $X[k1]$ and $X[k2]$ are the DFT coefficients at the frequency bins $k1$ and $k2$, respectively, X^* is the complex conjugate of the DFT coefficient at the sum $[k_1 + k_2]$ frequency bin, and E is the expectation operator. Because the resulting bispectrum is complex-valued, we calculate the absolute magnitude to extract a real-valued matrix suitable for neural network training.

Alternatively, the bispectrum can be calculated using Autoregressive Moving Average (ARMA) coefficients, and this is a parametric method that we used for this research. The method relies on modeling the audio signal as an ARMA process, estimating the coefficients and calculating the transfer function. Without going into the mathematics of this approach, the bispectrum is calculated as:

$$B[k_1, k_2] = \gamma_3 H(k_1)H(k_2)H^*(-k_1 - k_2) \quad (4)$$

In the previous equation, H and γ_3 are the transfer function and parameter obtained from the ARMA estimation. Determining the ARMA model order is tricky, but if done right, the resulting bispectrum will have higher frequency resolution and less smoothing issues (which are inherent to windowing functions) than is the case when calculating spectrograms.

For the research done in this paper, we used MatLAB to perform automatic ARMA model order selection [20] and the corresponding bispectrum matrices calculation, which we then loaded into Python prior to the model training. Spectrograms were calculated directly in Python. Figures 5 and 6 show examples of the resulting bispectra.

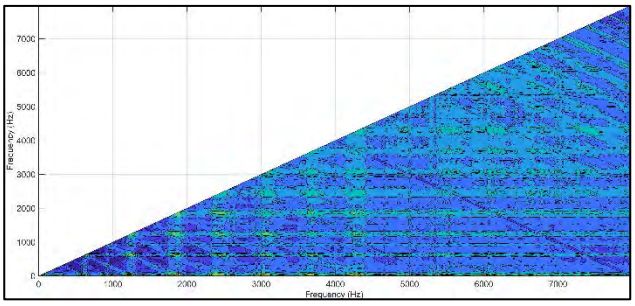

Figure 5. Bispectrum of a DRONE signal

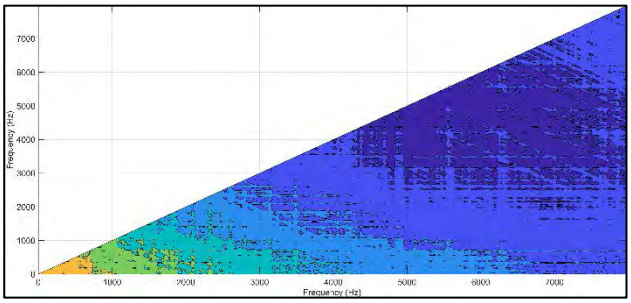

Figure 6. Bispectrum of a NO_DRONE signal

As can be seen in figures 5 and 6, because of bisepctrum's symmetrical nature and in order to lower the computational costs, we only kept the right-triangular matrix information for each bispectrum. Also, the bispectral magnitudes were converted to a logarithmic scale, which provided better results than linear scaling.

In these figures we can notice the same acoustic signatures we observed by analyzing the spectra. When looking at the bispectrum of a DRONE signal, we notice the intersecting vertical and horizontal lines which effectively form a grid pattern. This is the result of drone's deterministic, mechanical parts – rotating motors and blades.

The NO_DRONE signal's bispectrum shows strong phase coupling only in the low-frequency range. Signals from this class include various environmental sounds that are highly localized in both time and frequency, which explains why they are present as small, isolated phase coupling clusters in the bispectrum. As they lack the deterministic nature of drone signals, it makes perfect sense that there are no grid-like patterns visible, with only the dark blue color dominating the high-frequency range.

3.3 Model training and evaluation

As mentioned before, we opted for transfer learning with three pretrained models for our analysis: ResNet-18, ResNet-50 [9] and ViT Base 16 [10]. Instead of training a completely new neural network from scratch, transfer learning refers to using an already trained network and slightly adjusting it for a specific task. With this approach, we can be sure that the model has already learned common important features and we only need to fine-tune it, which also significantly reduces the amount of parameters it needs to learn and the resources it uses during that process.

Expectedly, this then poses a question: how many layers should we retrain (fine-tune) when using transfer learning? The models we selected vary significantly in the number of trainable parameters. ResNet-18 and ResNet-50 consist of roughly 12M and 26M parameters, respectively. On the other hand, ViT Base 16 is considerably larger, including around 85M trainable parameters. Considering the size of our dataset, we opted for the next approach: for ResNet-18 and ResNet-50, we made only deeper residual blocks trainable (layer3 and layer4 in PyTorch implementation). In case of ViT Base 16 model, the final six encoder blocks (blocks 6-11) were unfrozen for fine-tuning. The final fully connected layer is the same in all three cases — it includes a layer mapping the backbone features to a 128-dimensional space, followed by a ReLU activation function and a dropout layer ($p = 0.4$) to combat overfitting. For the optimizer we used AdamW, with learning rates ranging from 10^{-3} to 10^{-5}, depending on the depth of the layers.

One of the biggest concerns when it comes to training neural networks is their resulting generalization ability. It is not correct to focus solely on training accuracy and loss, because of possible overfitting. That is why we split the entire dataset into training and validation subsets and monitor the model's performance on both. To get an even better idea of our model's ability to generalize, we can use k-fold cross-validation. This method involves splitting the dataset into k subsets, using one subset for validation and the remaining $(k - 1)$ subsets for training. This process is

repeated k times and the resulting metrics are averaged. In this paper, we use 10-fold cross-validation (90% of the data is used for training and 10% for validation) to calculate our model's accuracy on the OOF (out-of-fold) samples (samples that were in the validation subset in each fold). Furthermore, the technique called Early Stopping is used during training in each fold. We observe validation loss with the patience parameter set to 3, meaning that if the loss did not achieve a new minimum after 3 epochs, the training process is terminated and the last best model weights are recorded and used for evaluation.

4. RESULTS

In this section, we evaluate the classification performances of our three selected models across two distinct feature extraction paradigms: the non-parametric STFT spectrogram and the parametric ARMA bispectrum. All models were trained and evaluated using the partial fine-tuning technique and 10-fold cross-validation, as described in the previous section. Because we used cross-validation for model training and evaluation, classification performance is quantified with mean accuracy (along with standard deviation), calculated on the OOF (out-of-fold) samples. Table 1 presents this metric for all mentioned experimental configurations.

Table 1. Classification results

	ResNet-18	ResNet-50	ViT Base16
Spectrogram	96.66 (±1.20)	96.46 (±0.89)	95.50 (±0.92)
Bispectrum	**96.92 (±0.78)**	96.05 (±1.19)	93.20 (±1.93)

We can draw several interesting conclusions looking at the results presented in Table 1. Firstly, ResNet-18 achieved the best classification performance, with bispectrum representations as inputs. The lowest standard deviation also makes this model the most consistent. This is particularly interesting because ResNet-18 has the smallest architecture here.

On the other hand, while it yields worse results than ResNet-18, ResNet-50 outperforms ViT Base 16 for both feature extraction methods. Especially intriguing is the fact that both ResNet-50 and ViT Base 16 achieve higher accuracy with spectrogram inputs. It could be argued that one of the reasons for these outcomes is the size of the dataset. An insufficient number of samples can cause models with large number of parameters (like ResNet-50 and especially ViT) to start learning specific details in training data that are not descriptive and/or represent noise. This ultimately leads to worse generalization ability and can only be remedied by increasing the dataset size. The explanation why larger models favor spectrograms in this experiment is not easy to explain. Spectrograms preserve the temporal information of the signal, while the ARMA bispectrum completely eliminates the time component in favor of focusing on frequency interactions. Because of their complex architectures and massive parameter numbers, large models may end up struggling trying to generalize on the bispectrum's nonlinear features.

We can take a look at the confusion matrix and ROC curve for the best-performing model, ResNet-18. Figure 7 shows the confusion matrix for said model.

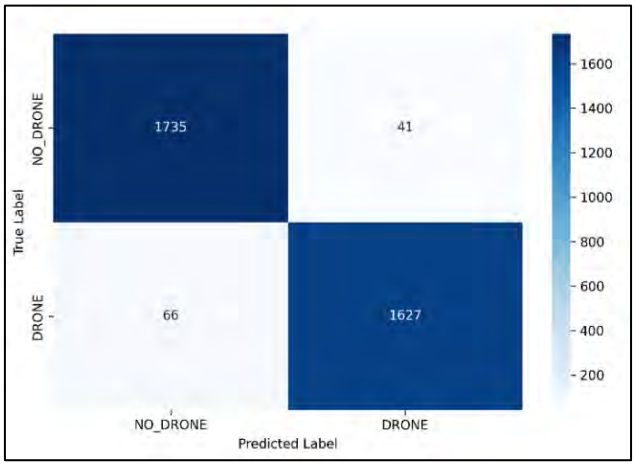

Figure 7. Classification matrix for ResNet-18

The matrix was obtained by aggregating all the OOF predictions, which is why the number of samples in the matrix is equal to the dataset size. As can be seen from the figure, classification performance is roughly symmetrical; the model achieves high precision and recall, indicating that there is no bias toward one specific class. The number of False Negative cases is higher than the number of False Positives, which is unfavorable for this specific task of drone classification.

Figure 8 shows the ROC curve for the best-performing model. The model achieved an Area Under the Curve (AUC) of 0.994. Because this metric was calculated based on out-of-fold (OOF) predictions across all ten folds, it provides a robust estimate of the model's classification performance and generalization ability.

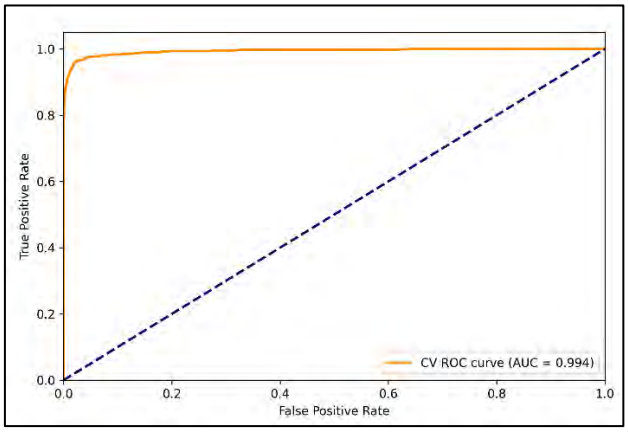

Figure 8. ROC curve for ResNet-18

5. CONCLUSION

In this paper, we performed a comparative evaluation of various transfer learning paradigms, focusing on audio drone classification. We utilized three different model architectures – ResNet-18, ResNet-50 and ViT Base 16. The networks were cross-examined across two distinct feature spaces: non-parametric STFT spectrograms and parametric ARMA bispectra.

The experiments revealed some unexpected results. The smallest model, ResNet-18, consistently outperformed

larger models, in both feature spaces. This best-performing model yields a ROC curve with the AUC of 0.994, with symmetrical classification performance. Non-parametric STFT spectrograms proved more valuable for larger networks, which is especially evident in the case of ViT Base 16. This model achieves a significantly higher accuracy when accepting spectrograms as inputs than is the case with bispectrum data.

It should be mentioned that the primary limitation of current research is the size of the dataset used. For large model architectures (notably ViT Base 16 in this case), data count is of critical importance. Consequently, the logical next step in this research would be the expansion of the dataset. With this, new experiments can be performed, which would help in determining whether large deep learning models can learn to better generalize on ARMA-calculated bispectrum inputs.

Based on the currently obtained results, another research direction involves investigating the usage of smaller model architectures (because of their superior performance) and performing testing with audio signals of drones operating in real-world environments.

Abstract: *Object detection is a fundamental component of road-scene perception systems used in autonomous driving, where visual data are often compressed to meet storage and bandwidth constraints. While image compression reduces transmission costs, it may introduce distortions that adversely affect detection accuracy. This study investigates the impact of JPEG compression on seven recent YOLO models (YOLOv5m, YOLOv7, YOLOv8m–YOLOv12m), evaluated on visible (VIS) and long wave infrared (LWIR) images from the M^{3}FD dataset. A balanced subset containing daytime and nighttime scenes is used, and ten compressed versions are generated with quality factor (QF) values ranging from 50 to 5. Results show that YOLOv12m achieves the highest global performance for VIS images, particularly during the day, while YOLOv10m excels under low-light conditions. For LWIR data, YOLOv8m performs best overall, with YOLOv12m showing advantages at night. Detection performance decreases gradually for QF values from 50 to 20, but drops sharply below QF=20, highlighting the importance of maintaining moderate image quality. Across intersection over union (IoU) thresholds, LWIR maintains more stable mAP than VIS, demonstrating its robustness under varying illumination. These findings provide quantitative insights into how JPEG compression and imaging modality affect modern YOLO detectors, informing reliable deployment under bandwidth and storage constrained environments.*

Keywords: *road scene object detection, multispectral image, JPEG compression, YOLO.*

1. INTRODUCTION

Autonomous driving systems depend on accurate object detection to perceive complex road scenes, including pedestrians, vehicles, and other traffic participants [1]. These systems rely on visual data for safe navigation and real-time decision making under diverse environmental and lighting conditions. The growing deployment of intelligent transportation systems has vastly increased visual data volumes, straining storage and transmission bandwidth. To mitigate this, image compression techniques such as JPEG are widely used, albeit at the cost of introduced distortions that may affect downstream tasks [2]. Deep learning-based object detection has become a cornerstone of computer vision, enabling machines to locate and classify objects of interest [3]. Because detection is directly tied to image content, compression-induced artifacts can alter edges, textures, and fine details critical for reliable recognition, particularly in adverse conditions like low illumination.

In recent years, YOLO (You Only Look Once) models have achieved notable success across computer vision tasks, including detection, segmentation, and pose estimation [4]. They offer an excellent speed-accuracy trade-off via single-pass inference. YOLO is widely adopted in surveillance, autonomous driving, robotics, medical imaging, and augmented reality [5]. The family has evolved through multiple generations, each addressing prior limitations through architectural innovations, parameter optimization, and improved training methodologies [6], yielding substantial gains in accuracy and efficiency while preserving real-time performance.

Numerous studies have assessed JPEG compression's impact on deep learning-based detection and classification. Dodge and Karam [7] examined effects of Gaussian blur, noise, contrast changes, and JPEG/JPEG2000 compression on classification models, finding CNNs particularly sensitive to blur and noise, with notable accuracy degradation. In [8], authors showed that compression artifacts degrade CNN-based object detectors' accuracy. Similarly, [2] analyzed JPEG compression on RetinaNet and Faster R-CNN, reporting pronounced detection drops at high compression levels.

Bayerl et al. [9] studied remote sensing image compression (JPEG, JPEG2000) on classification, showing that mismatched compression settings between

Corresponding author: B. Pavlović;
E-mail: boban.pavlovic@va.mod.gov.rs
DOI: 10.5937/OTEH26060P

training and inference cause substantial accuracy loss. In [10], authors evaluated HEVC compression on object tracking using YOLOv3 and SORT, finding that quantization significantly affects tracking performance while motion search range does not, and derived a regression model linking compression strength to accuracy. In [11], the robustness of several YOLO detectors to common distortions in remote sensing was evaluated, including Gaussian noise, JPEG/JPEG2000 compression, and blur. All distortions degraded accuracy, with YOLOv9 most robust and YOLOv7 and YOLOv10 most sensitive.

Despite these efforts, the robustness of YOLO detectors on infrared imagery, especially compared to visible (VIS) images under compression, remains insufficiently explored. Most existing studies focus on RGB data, leaving JPEG compression effects on long-wave infrared (LWIR) largely unexamined. Moreover, comparative VIS–LWIR analyses are limited, despite their distinct statistical and perceptual properties, which may lead to different responses to compression artifacts affecting textures and object boundaries. To fill this gap, this paper analyzes seven YOLO models – YOLOv5m [12], YOLOv7 [13], YOLOv8m [4], YOLOv9m [14], YOLOv10m [15], YOLOv11m [6], and YOLOv12m [16] – using a balanced test set from the M^3FD dataset, containing equal VIS and LWIR images split evenly between daytime and nighttime conditions. Both modalities are compressed with JPEG quality parameters from 50 down to 5 to systematically evaluate compression impact on detection performance.

The remainder of this paper is structured as follows. Section 2 describes the methodology, covering the dataset, YOLO models, and JPEG compression process. Section 3 presents experimental results with analysis and discussion. Section 4 summarizes key findings and outlines future research directions.

2. METHODOLOGY

2.1. Dataset description

In this study, VIS and LWIR images were used from the M^3FD [17] dataset, which is widely adopted for evaluating object detection performance in driving scenarios. A total of 440 VIS images and 440 LWIR images were selected to represent diverse driving environments. For each modality, 220 images correspond to daytime scenes and 220 images to nighttime conditions, ensuring a balanced evaluation across lighting scenarios. The selected images include typical road scenes containing pedestrians (referred to as person), cars, and buses, which are the three object categories considered in this study. The selected set covers both urban and suburban environments and includes variations in object scale, occlusion, and background complexity, providing a challenging and realistic benchmark for assessing detection performance under compression.

Table 1. Distribution of object instances in the selected subset across daytime, nighttime, and combined scenarios

Class	Daytime vision	Nighttime vision	All-day/night vision
Person	117	206	323
Car	219	220	439
Bus	147	10	157
All	**483**	**436**	**919**

Figure 1 shows images from both modalities - visible and infrared based on both daytime and nighttime conditions. The selected examples illustrate how a single image can contain representatives of multiple classes, as well as multiple samples within the same class. Additionally, it can be observed that objects may be close or far away, which would test the robustness of the detectors themselves. Objects may be visible in one modality but not visible in the other (see the presence of a person in nighttime conditions in LWIR, and their absence in VIS).

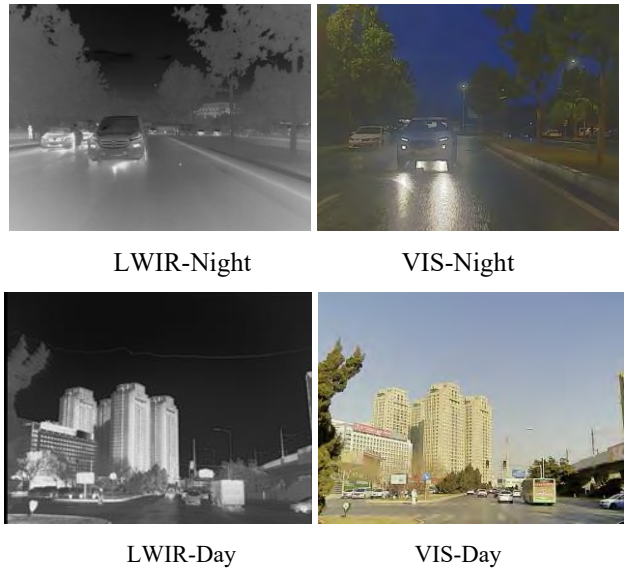

Figure 1. Example images from visible and infrared modalities based on daytime and nighttime conditions

2.2. YOLO models

Seven YOLO models are selected in this study (YOLOv5, YOLOv7–YOLOv12) to provide a comprehensive comparison across different design stages and performance trade-offs. YOLOv5m [12] introduced a stable anchor-based design using CSPDarknet53 with FPN and PANet for multi-scale features extraction. YOLOv7 [13] enhanced this design with E-ELAN and improved scaling strategies to better balance accuracy and speed. YOLOv8m [4] adopted an anchor-free framework, incorporating C2f modules and a decoupled head to improve gradient flow and detection precision. YOLOv9m [14] further improved training stability through programmable gradient information and employed the GELAN backbone for higher efficiency. YOLOv10m [15] focused on real-time performance by introducing a fully NMS-free pipeline with dual label assignment to reduce latency while improving accuracy. YOLOv11m [6] extended these developments with advanced attention mechanisms, such as C2PSA, C3K2 modules, and the SPPF block to better capture spatial

context while maintaining fast inference. The latest version, YOLOv12m [16], continues this evolution by refining architectural efficiency and training strategies to improve accuracy, robustness, and deployment flexibility.

2.3. JPEG compression

JPEG is a widely used lossy image compression method that reduces image size while maintaining acceptable visual quality [18]. It works by transforming the image into the frequency domain using the Discrete Cosine Transform (DCT), which separates visual information into low- and high-frequency components. Low frequencies capture most of the image structure, while high frequencies represent fine details and noise. The resulting DCT coefficients are then quantized to remove perceptually less important information, achieving significant data reduction. JPEG is valued for its strong balance between compression efficiency, visual fidelity, and low computational cost, enabling fast encoding and decoding. The compression level is controlled by a quality factor (QF) ranging from 1 to 100, where higher values correspond to lower compression and better image quality. In this study, JPEG compression was applied at 10 levels by varying the QF from 5 to 50 in steps of 5 using the MATLAB *imwrite* function.

3. RESULTS AND DISCUSSION

3.1 Experimental setup

The experimental setup was conducted on a Windows 11 operating system, running on an Intel® Core™ i7-12650H processor (2.30 GHz) with 16 GB of RAM, and an NVIDIA RTX 3050Ti GPU with 4 GB of memory. All algorithms were implemented using the PyTorch framework (version 2.0.1) and accelerated with the CUDA Toolkit (version 11.8).

In this study, all YOLO models are evaluated using pretrained weights from the MS-COCO dataset [19], which contains 80 object classes, including those selected from the M^3FD dataset. Each model is tested on the original image subsets as well as on ten JPEG-compressed versions generated by varying the QF. The evaluations are conducted separately for VIS and LWIR modalities and further divided into daytime and nighttime conditions to analyze the influence of illumination, providing a comprehensive comparison of detection performance across compression levels, imaging modalities, and lighting scenarios.

To assess the robustness of the YOLO models, widely adopted evaluation metrics were employed, including precision (P), recall (R), and mean average precision (mAP). The mAP was computed across intersection over union (IoU) thresholds ranging from 0.5 to 0.95 in increments of 0.05, following the MS-COCO evaluation protocol. Additionally, the mean average precision at IoU = 0.5 ($mAP_{0.5}$), consistent with the PASCAL VOC metric, was reported [20].

3.2 Global detection performance

Table 2 presents the quantitative comparison of YOLOv5, YOLOv7–YOLOv12 on the VIS-Day, VIS-Night, and both VIS subsets in terms of precision (P), recall (R), $mAP_{0.5}$, and mAP averaged across the ten JPEG compression levels from 50 to 5 with step of 5. The best result for each metric within a given subset is highlighted in **bold**.

For the VIS-Day subset, YOLOv12m achieves the highest precision (0.8055) and mAP (0.4625), indicating superior detection accuracy under daytime conditions. YOLOv7 attains the best recall (0.6462), while YOLOv7 and YOLOv12m provide the strongest $mAP_{0.5}$ performance, with YOLOv7 slightly higher (0.7073). Overall, YOLOv12m demonstrates the most balanced and robust performance in this subset.

In the VIS-Night subset, performance degradation is observed across all models due to challenging illumination conditions. YOLOv5m and YOLOv12m obtain the highest precision (0.4375 and 0.4372, respectively), while YOLOv10m achieves the best recall (0.2325), $mAP_{0.5}$ (0.26), and mAP (0.1517), highlighting its improved robustness in low-light scenarios.

Table 2. Detection results across daytime, nighttime, and both scenarios for VIS test set

Subset	Metric	YOLOv5	YOLOv7	YOLOv8	YOLOv9
VIS-Day	P	0.7221	0.7720	0.7657	0.7221
	R	0.6283	**0.6462**	0.6268	0.6305
	$mAP_{0.5}$	0.6736	**0.7073**	0.6905	0.6870
	mAP	0.4286	0.4496	0.4533	0.4458
VIS-Night	P	**0.4375**	0.3651	0.3980	0.4243
	R	0.2001	0.2052	0.2174	0.1823
	$mAP_{0.5}$	0.2438	0.2247	0.2492	0.2257
	mAP	0.1342	0.1235	0.1448	0.1310
VIS	P	0.7110	0.7068	0.7319	0.6646
	R	0.5276	**0.5332**	0.5285	0.5103
	$mAP_{0.5}$	0.5774	0.5808	0.5882	0.5573
	mAP	0.3705	0.3784	0.3918	0.3691

Subset	Metric	YOLOv10	YOLOv11	YOLOv12
VIS-Day	P	0.7687	0.7445	**0.8055**
	R	0.6207	0.6304	0.6349
	$mAP_{0.5}$	0.6853	0.6847	0.7048
	mAP	0.4480	0.4438	**0.4625**
VIS-Night	P	0.3891	0.3555	0.4372
	R	**0.2325**	0.1899	0.2070
	$mAP_{0.5}$	**0.2600**	0.2139	0.2462
	mAP	**0.1517**	0.1233	0.1425
VIS	P	0.7227	0.7149	**0.7754**
	R	0.5286	0.5027	0.5233
	$mAP_{0.5}$	0.5822	0.5590	**0.5908**
	mAP	0.3878	0.3699	**0.3951**

For the complete VIS set, YOLOv12m consistently outperforms other models, achieving the highest precision (0.7754), $mAP_{0.5}$ (0.5908), and mAP (0.3951). The highest recall is obtained by YOLOv7 (0.5332), though YOLOv12m remains competitive.

These results confirm that recent YOLO versions, particularly YOLOv12m and YOLOv10m, benefit from architectural and training improvements, delivering consistent performance gains over earlier versions, especially in terms of mean average precision, while maintaining competitive recall and precision across varying illumination conditions.

Table 3 presents performance comparison of YOLOv5m, YOLOv7, YOLOv8m–YOLOv12m on the LWIR-Day, LWIR-Night, and both LWIR subsets in terms of precision, recall, $mAP_{0.5}$, and mAP, averaged over ten JPEG compression levels.

	$mAP_{0.5}$	0.3913	0.3683	0.3524
	mAP	0.2232	0.2043	0.1948
LWIR -Night	P	0.4407	0.4623	0.4637
	R	0.3911	0.4012	**0.4245**
	$mAP_{0.5}$	0.4239	0.4182	**0.4383**
	mAP	0.2631	0.2552	**0.2726**
LWIR	P	0.5219	0.5295	0.5384
	R	0.4247	0.4154	0.4108
	$mAP_{0.5}$	0.4897	0.4522	0.4657
	mAP	0.3014	0.2709	0.2838

For the LWIR-Day subset, YOLOv8m clearly outperforms the other models, achieving the highest precision (0.5153), recall (0.4229), $mAP_{0.5}$ (0.4460), and mAP (0.2612). This indicates that YOLOv8m provides the most accurate and reliable detections under daytime conditions.

In the LWIR-Night subset, YOLOv12m attains the best overall performance, with the highest recall (0.4245), $mAP_{0.5}$ (0.4383), and mAP (0.2726). The highest precision is obtained by YOLOv5m (0.4641), closely followed by YOLOv12m (0.4637). These results show that YOLOv12m offer improved robustness in nighttime LWIR scenarios, where thermal contrast is more pronounced.

For the complete LWIR set, YOLOv8m consistently achieves the best results across all metrics, including precision (0.5853), recall (0.5057), $mAP_{0.5}$ (0.5351), and mAP (0.3370). This confirms its strong generalization capability across both day and night thermal conditions.

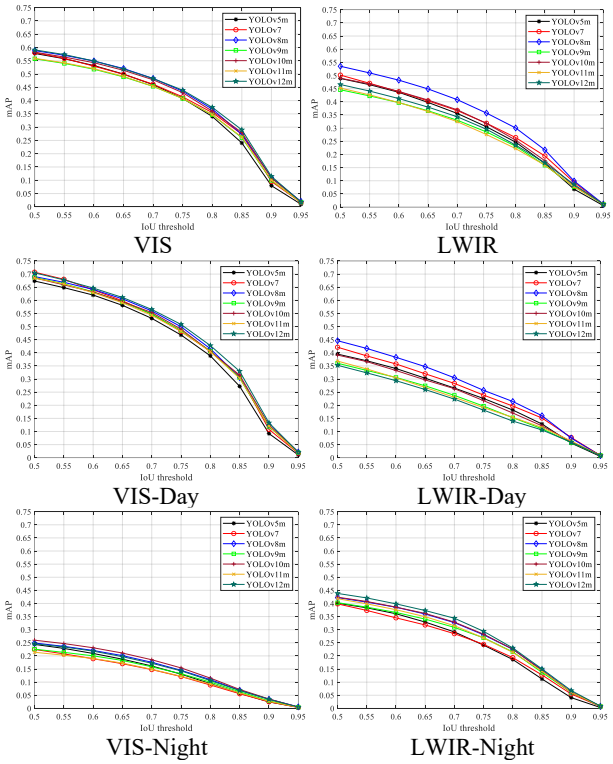

Figure 2. mAP as a function of the IoU threshold (0.5–0.95) for VIS and LWIR modalities under day and night conditions, averaged over ten JPEG compression levels (QF = 50 to 5)

The obtained results demonstrate that YOLOv8 delivers the most consistent and superior performance on LWIR data, particularly in the complete and daytime subsets, while YOLOv12m shows notable advantages under nighttime conditions.

3.3. Detection performance across IoU thresholds under JPEG compression

Figure 2 illustrates the variation in detection performance, measured in terms of mAP, as a function of the IoU, which ranges from 0.5 to 0.95 in steps of 0.05, for both visible and LWIR modalities under daytime and nighttime conditions. For each IoU threshold, the mAP is computed and then averaged over ten JPEG compression levels.

Across all configurations, the mAP decreases monotonically as the IoU threshold increases, reflecting the stricter localization requirement imposed by higher IoU values. For the VIS modality, daytime scenes consistently achieve higher mAP values than nighttime scenes at all IoU thresholds, while the performance gap becomes more pronounced at higher thresholds, indicating reduced localization accuracy under low-light conditions.

For the LWIR modality, there is a smaller gap between mAP curves in day and night scenarios. This behavior suggests that thermal imagery provides more consistent object localization under varying illumination conditions. Nevertheless, a clear performance drop is still observed.

3.4 Detection performance under varying JPEG compression levels

Figure 3 illustrates the mAP results of different YOLO object detection models under JPEG compression across QF values from 50 to 5 with step of 5, for both VIS and LWIR modalities under overall, daytime, and nighttime conditions.

Across all scenarios and YOLO models, a consistent trend is observed regarding image compression. From QF=50 to QF=20, the models remain relatively stable, demonstrating robustness to moderate compression. The mAP shows a gradual decline with a gentle slope, indicating only minor performance degradation. However, when the quality factor drops below 15, the curves exhibit a sharp "knee," with detection performance decreasing steeply as QF approaches 5. This indicates that maintaining a quality factor above 20 is essential to preserve reliable detection under compressed conditions.

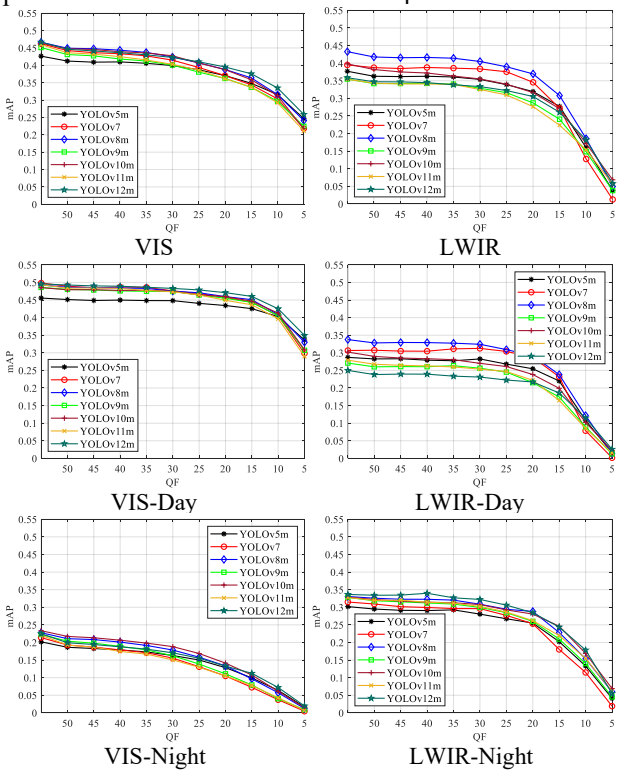

Figure 3. mAP results of YOLO models under JPEG compression across QF values for VIS and LWIR images under different lighting conditions

In comparing the models, clear differences in performance emerge. YOLOv12m and YOLOv8m consistently outperform the others across most modalities, starting from higher baselines at QF=50 and maintaining their lead as image quality decreases. The exception is VIS under nighttime conditions, where YOLOv10m achieves superior mAP values at QF levels above 20. The remaining YOLO models occupy the mid-range and frequently exchange positions. They generally outperform YOLOv5m for the visible modality and LWIR under nighttime conditions, but lag behind YOLOv8m and YOLOv12m in overall performance.

Analyzing performance across modalities reveals clear differences between VIS and LWIR images. During daytime, VIS cameras dominate, achieving mAPs near 0.50, while LWIR-Day lags behind at 0.30–0.35. This confirms that visual data provides richer texture and detail under sufficient illumination. At night, the situation reverses. VIS-Night performance drops sharply, with even the best models reaching only about 0.23 mAP, illustrating the limitations of standard cameras in low light environments. In contrast, LWIR-Night, maintains robust performance, peaking around 0.34 mAP, exceeding VIS-Night and approaching to LWIR-Day scenario. These findings indicate that thermal imaging offers consistent detection across day and night, whereas visible-light cameras are highly sensitive to lighting conditions.

3.5 Class-wise detection performance under JPEG compression

Figure 4 presents a detailed class-wise analysis of detection performance for the person, car, and bus categories. The mAP is averaged over ten JPEG compression levels.

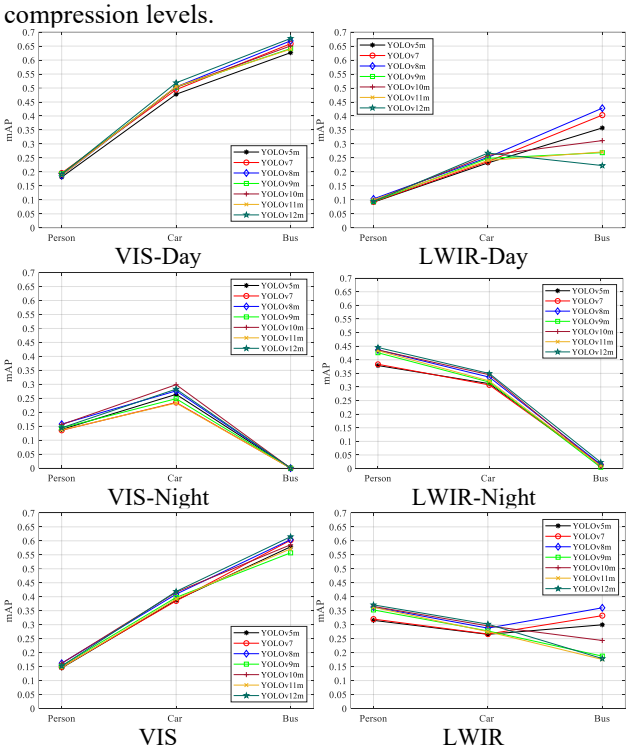

Figure 4. Class-wise detection performance in term of mAP for person, car, and bus, averaged over ten JPEG compression levels, for VIS and LWIR under daytime and nighttime conditions

In the VIS modality, daytime conditions outperform nighttime conditions for all classes, with the performance gap being most pronounced for the bus class. This indicates that YOLO detectors rely heavily on texture and color that are significantly affected by both low-light conditions and JPEG compression. The global VIS results follow the same trend as daytime conditions, confirming the dominant influence of illumination on visible-spectrum detection.

For LWIR modality, nighttime demonstrates the highest robustness for class person. The performance difference between LWIR-Day and LWIR-Night is smaller than in VIS for class car, highlighting the reduced sensitivity of thermal imagery to illumination changes.

Across all scenarios, the car class consistently achieves a stable mAP, reflecting its stable visual and thermal signatures, which make it less sensitive to compression artifacts. The person class exhibits moderate performance, with noticeable differences between day and night conditions, particularly in the LWIR modality, where reduced illumination and compression jointly degrade fine-grained features. The bus class shows more variable behavior, which can be attributed to its lower number of instances within nighttime scenario.

4. CONCLUSION

This study provides a comprehensive evaluation of JPEG compression effects on road scene object detection using YOLO models from YOLOv5m to YOLOv12m across visible and LWIR imagery. The results demonstrate that recent YOLO architectures, particularly YOLOv12m and YOLOv8m, benefit from architectural and training improvements, achieving higher precision, recall, and mAP under both daytime and nighttime conditions. VIS detection performance is highly sensitive to illumination and compression, with daytime scenes outperforming nighttime, whereas LWIR offers more consistent detection across different lighting conditions. Compression impacts all models, with a gradual mAP decline for QF values above 20 and a steep drop below QF=20, emphasizing the need to maintain moderate image quality. The analysis also reveals modality-specific trends, VIS provides richer texture under sufficient light, while LWIR ensures robust detection at night. These findings underscore the importance of considering both compression level and imaging modality when deploying real time road scene object detection systems, and they provide practical guidelines for maintaining reliable performance in bandwidth limited scenarios. Future work may explore alternative compression schemes, additional detection architectures, and adaptive training strategies on compressed data to further improve detection performance.

Abstract: *The ongoing digital transformation of the mining industry has led to the increasing adoption of advanced geospatial technologies and autonomous robotic systems within the smart mining paradigm. This study examines the application and capabilities of autonomous 3D mobile mapping in underground mining environments, with particular emphasis on robotic platforms equipped with LiDAR and complementary sensor technologies. Conventional surveying methods in underground conditions are constrained by limited visibility, confined geometries, and elevated safety risks, often resulting in time-intensive data acquisition and incomplete spatial information. In contrast, autonomous mobile mapping systems enable rapid, high-resolution data collection in the form of dense point clouds, significantly enhancing both the accuracy and efficiency of spatial data acquisition. The study analyzes key enabling technologies, including terrestrial laser scanning (TLS), LiDAR-based systems, and autonomous robotic platforms, as well as their integration within geographic information systems (GIS) for advanced spatial analysis and visualization. Special consideration is given to the deployment of robotic systems in hazardous and inaccessible zones, where they minimize human exposure while enabling continuous and reliable monitoring. The findings demonstrate that the implementation of autonomous robotic mapping systems provides substantial improvements in data quality, operational efficiency, and safety. Furthermore, their integration supports the generation of 4D spatiotemporal models, facilitating improved decision-making and long-term planning in underground mining operations.*

Keywords: *LiDAR, terrestrial laser scanning.*

1. INTRODUCTION

The mining industry is undergoing an intensive digital transformation driven by the increasing demand for higher productivity, improved operational safety, sustainable resource management, and reduced production costs [1]. Within this context, the concept of Smart Mining has emerged as a comprehensive framework integrating advanced geospatial technologies, artificial intelligence, industrial communication networks, cloud computing, and autonomous robotic systems into a unified digital environment for mine management [2,3]. Underground mining represents one of the most demanding engineering environments due to confined spaces, poor visibility, dust, humidity, unstable geological conditions, and the absence of Global Positioning System (GPS) signals. These limitations significantly complicate conventional surveying operations and reduce the efficiency of spatial data acquisition. At the same time, underground environments expose personnel to numerous hazards, including rockfalls, toxic gases, ventilation problems, flooding, and mechanical risks associated with mining equipment [2,4].

Reliable spatial information is fundamental to virtually every stage of underground mining, including mine development, excavation control, deformation monitoring, ventilation planning, volume estimation, and long-term production management [5]. Traditionally, these tasks have relied on total stations, leveling networks, and conventional mine surveying techniques. Although these methods provide satisfactory accuracy, they require considerable time in the field and usually acquire only a limited number of discrete measurement points.

Recent advances in terrestrial laser scanning (TLS), LiDAR technology, simultaneous localization and mapping (SLAM), and autonomous robotic navigation have fundamentally changed the methodology of underground spatial data acquisition. Modern autonomous mobile mapping systems rapidly collect millions of three-dimensional points, producing dense point clouds that accurately represent the geometry of underground excavations while significantly reducing the need for direct human intervention in hazardous environments [3]. While TLS provides high-accuracy static data acquisition, autonomous mobile mapping extends these capabilities through continuous SLAM-based data collection.

Unlike conventional surveying, autonomous robotic mapping systems combine multiple sensors, including LiDAR scanners, inertial measurement units (IMUs), RGB cameras, thermal cameras, odometers, and environmental sensors, into a single integrated platform capable of autonomous navigation and real-time spatial data acquisition. The collected datasets are processed into

DOI: 10.5937/OTEH26061V

high-resolution three-dimensional models suitable for inspection, deformation analysis, infrastructure monitoring, volume calculations, and digital mine management.

Beyond underground mining, these technologies have attracted increasing attention in numerous safety-critical applications. Autonomous robotic mapping systems are now employed for the inspection of transportation tunnels, underground infrastructure, military facilities, emergency response operations, disaster assessment, border-security tunnels, and other environments where direct human access is difficult or dangerous. Their capability to rapidly generate accurate digital models while minimizing personnel exposure makes them particularly valuable for both civilian and defense-related engineering applications.

The objective of this paper is to present the principles, technological components, and practical applications of autonomous robotic systems for 3D mobile mapping in underground mining. Particular emphasis is placed on LiDAR-based mobile mapping technologies, robotic platforms, integration with Geographic Information Systems (GIS), and their contribution to improving operational efficiency, safety, and decision-making through the generation of high-resolution three-dimensional and four-dimensional spatial models.

2. CONVENTIONAL SURVEYING IN UNDERGROUND MINES

Accurate spatial information forms the basis for planning, construction, operation, and monitoring throughout the entire life cycle of an underground mine. Mine surveying supports exploration, excavation planning, construction of underground structures, deformation monitoring, production control, reserve estimation, and preparation of mine documentation [5]. Consequently, the quality of surveying data directly influences operational efficiency, production planning, and occupational safety.

Traditional underground surveying relies primarily on mine control networks established by polygon traverses and leveling systems connected to the surface reference network [5]. Depending on the mining stage and required accuracy, surveying activities include staking out underground excavations, monitoring shaft geometry, controlling excavation profiles, deformation measurements, determination of mined volumes, and preparation of mine plans.

Despite continuous improvements in surveying instruments, underground mining remains an extremely challenging working environment. Underground excavations are characterized by narrow passages, limited visibility, high humidity, dust, unstable rock masses, and the presence of hazardous gases. Furthermore, the absence of GNSS signals prevents the direct application of satellite-based positioning technologies, while magnetic disturbances may reduce the performance of certain navigation sensors [2,5].

Conventional surveying is predominantly performed using total stations, laser distance meters, leveling instruments, and prism-based measurements. These techniques provide high measurement accuracy but require extensive field operations, careful instrument setup, repeated occupation of survey stations, and direct access to the measured object. Consequently, spatial information is collected only at selected points or along predefined cross-sections, making the resulting representation only a partial description of complex underground geometries [5].

For example, excavation profiles are traditionally surveyed using direct measurements, arc intersection methods, or polar measurements performed with total stations. Although these procedures satisfy engineering requirements for many routine surveying tasks, they remain relatively slow and labor-intensive, especially when large underground areas must be documented [6].

Periodic inspection of underground structures represents another important surveying task. Monitoring mine shafts, haulage drifts, ventilation shafts, and transport galleries traditionally requires repeated measurements of predefined control points installed within concrete linings or surrounding rock masses.

Deformation monitoring is usually performed through convergence measurements and geodetic observations of permanently installed benchmarks (Figure 1), enabling the determination of displacement vectors and assessment of structural stability [7].

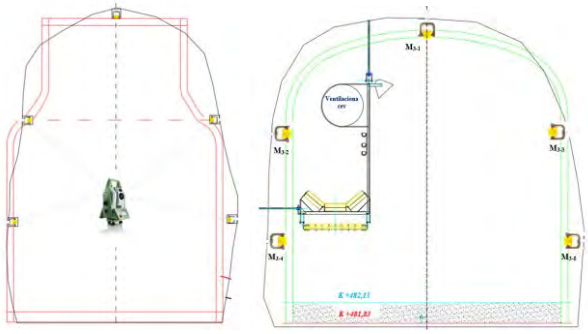

Figure 1. Conventional deformation monitoring using control benchmarks [7]

A particularly demanding surveying task is the inspection of vertical mine shafts. Conventional inspection procedures require surveyors to work inside confined vertical structures using suspended platforms or scaffolding while measuring only selected cross-sections (Figure 2). Such procedures are time-consuming, technically demanding, and expose personnel to considerable safety risks. Moreover, only limited geometric information can be obtained, making comprehensive structural assessment difficult [5].

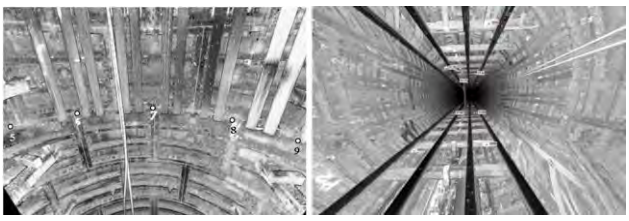

Figure 2. Conventional inspection of mine shafts [5].

Traditional methods are also employed for estimating excavated ore volumes. Volume calculations are generally based on measurements of excavation cross-sections or selected characteristic points acquired by total stations. Since only discrete points are measured, the generated two-dimensional models represent an approximation of the actual excavation geometry, often resulting in reduced accuracy of volume estimation and production assessment [5].

The principal limitations of conventional surveying methods include prolonged fieldwork, incomplete spatial coverage, dependence on direct human access, and relatively low efficiency when documenting large or geometrically complex underground environments. In hazardous locations, these limitations become even more pronounced, as the safety of surveying personnel must always take precedence over measurement efficiency.

These shortcomings have accelerated the adoption of autonomous mobile mapping technologies capable of rapidly acquiring complete three-dimensional spatial information while significantly reducing the need for human presence in hazardous underground areas.

3. AUTONOMOUS ROBOTIC SYSTEMS FOR 3D MOBILE MAPPING

The rapid development of digital technologies has fundamentally transformed spatial data acquisition in underground mining. Advances in robotics, laser scanning, artificial intelligence, computer vision, wireless communication, and geospatial information systems have enabled the transition from conventional surveying toward fully autonomous mobile mapping systems. These technologies represent one of the key components of the Smart Mining concept, providing continuous acquisition of high-resolution spatial information while significantly reducing human exposure to hazardous environments [2,3].

Unlike traditional surveying methods, autonomous robotic mapping systems continuously collect spatial information while moving through underground excavations. Instead of measuring selected points or cross-sections, they generate dense three-dimensional point clouds describing the complete geometry of underground structures with high spatial resolution. The resulting digital models enable detailed visualization, quantitative analysis, deformation monitoring, and long-term documentation of underground infrastructure.

A typical autonomous mapping platform integrates several complementary technologies, including LiDAR sensors, inertial measurement units (IMUs), simultaneous localization and mapping (SLAM) algorithms, digital cameras, odometry sensors, and onboard processing units. The combination of these technologies enables accurate localization even in environments where GPS positioning is unavailable, which is one of the principal challenges in underground applications.

The collected spatial information is commonly integrated into Geographic Information Systems (GIS), where it becomes available for visualization, spatial analysis, inspection planning, infrastructure management, and decision support. Continuous data acquisition at different time intervals also enables the creation of four-dimensional (4D) models that describe not only the geometry of underground excavations but also their temporal evolution, making it possible to monitor structural changes and deformation processes throughout the operational life of the mine [3].

3.1 LiDAR-Based Mobile Mapping

Light Detection and Ranging (LiDAR) technology has become one of the most important sensing techniques for autonomous underground mapping. LiDAR sensors determine object positions by measuring the travel time of emitted laser pulses reflected from surrounding surfaces, producing dense three-dimensional point clouds with high geometric accuracy.

Compared with conventional surveying techniques, LiDAR systems offer several important advantages. They rapidly collect millions of measurement points, operate independently of ambient lighting conditions, and accurately capture irregular geological structures, tunnel profiles, mining chambers, shafts, and excavation faces. Because measurements are performed continuously during platform movement, the entire underground environment can be documented much more efficiently than with traditional point-by-point surveying [3].

The resulting point clouds form the basis for numerous engineering analyses, including cross-sectional measurements (Figure 3), deformation assessment, excavation volume calculation, infrastructure inspection, geological mapping, and digital mine documentation.

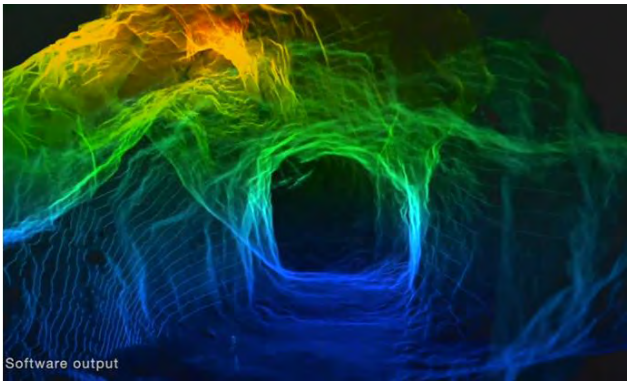

Figure 3. Mobile scanning of underground tunnels with LiDAR and point clouds software output [5]

3.2 SLAM-Based Navigation

Since satellite positioning systems cannot operate underground, autonomous mapping systems rely on Simultaneous Localization and Mapping (SLAM) algorithms. SLAM enables a robotic platform to determine its position while simultaneously constructing a map of an unknown environment using sensor observations.

LiDAR-based SLAM continuously matches newly acquired point clouds with previously recorded spatial information, allowing the robot to estimate its trajectory

with high accuracy even in long underground tunnels and complex mining areas (Figure 4). Modern SLAM algorithms combine laser measurements with data obtained from inertial sensors, wheel encoders, and visual cameras, improving positioning robustness under challenging operating conditions.

The application of SLAM significantly reduces cumulative positioning errors and enables autonomous navigation through extensive underground environments without requiring external positioning infrastructure [8,9].

Figure 4. LiDAR-based SLAM for mapping in high-risk mining areas [5]

Handheld mobile mapping systems represent another important category. These portable LiDAR devices enable rapid acquisition of spatial information while operators simply walk through underground excavations (Figure 5). Although handheld systems still require human presence, they dramatically reduce field time compared with conventional surveying techniques and generate considerably more comprehensive spatial datasets.

Figure 5. Handheld GeoSLAM LiDAR system for autonomous 3D mobile mapping [10]

3.3 Robotic Mobile Platforms

Recent years have witnessed the development of various robotic platforms specifically designed for underground mapping applications. Depending on operational requirements, autonomous systems may be classified as ground robotic vehicles (UGVs), aerial robotic platforms (UAVs), or hybrid systems combining multiple sensing technologies.

Ground robotic vehicles equipped with LiDAR scanners can autonomously inspect underground drifts, transport galleries, ventilation tunnels, shafts, and production areas while continuously collecting three-dimensional spatial information. Their ability to operate in hazardous or inaccessible locations substantially reduces the need for personnel exposure during routine inspection and surveying operations [10]. A scheme of an autonomous robotic mapping platform is given in Figure 6.

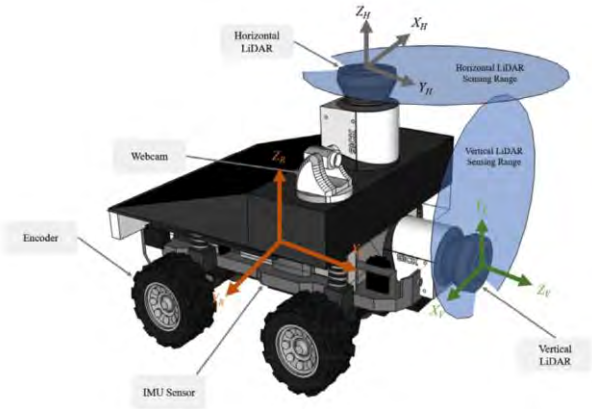

Figure 6. Conceptual configuration of an autonomous robotic mapping platform [11]

Unmanned aerial vehicles (UAVs) are increasingly being adopted for mapping large underground chambers, stopes, and vertical shafts where direct access is difficult or impossible. Equipped with lightweight LiDAR sensors or optical cameras, UAVs can safely inspect areas that would otherwise require complex and potentially hazardous surveying procedures [12].

Figure 7 presents the mobile mapping using a UAV equipped with LiDAR and the resulting point cloud.

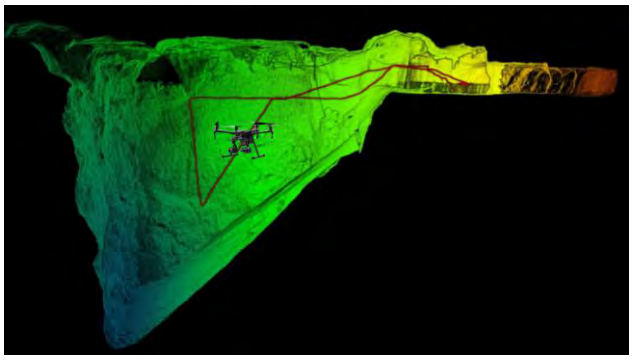

Figure 7. 3D models of the excavated space in the underground mine captured by a drone [13]

3.4 Advantages of Autonomous Robotic Mapping

The implementation of autonomous robotic mapping systems provides significant improvements compared with conventional surveying approaches. The most important advantages include:

- rapid acquisition of complete three-dimensional spatial information;
- generation of dense, high-resolution point clouds;
- reduced field survey time;

- improved operator safety through reduced exposure to hazardous environments;
- high repeatability of measurements suitable for long-term monitoring;
- direct integration with GIS and digital mine management systems;
- supports for the development of digital twins and four-dimensional (4D) spatiotemporal models;
- improved support for engineering analysis, production planning, and infrastructure maintenance.

These capabilities make autonomous robotic systems particularly suitable for continuous monitoring of underground infrastructure, where both measurement quality and personnel safety are of primary importance.

4. APPLICATIONS IN UNDERGROUND MINING AND SAFETY-CRITICAL INFRASTRUCTURE

Autonomous robotic mapping systems have become increasingly important in underground mining because they provide rapid and reliable spatial information while reducing personnel exposure to hazardous environments. Their application extends across the entire mining cycle, from mine development and infrastructure inspection to deformation monitoring and production control.

One of the most significant applications is the inspection of underground openings such as shafts, haulages, ventilation drifts, transport galleries, and mining chambers. Conventional inspection procedures require direct human access and often provide only partial geometric information. In contrast, autonomous mobile mapping systems acquire complete three-dimensional representations of underground structures, enabling detailed visualization and quantitative assessment of their condition [5].

Periodic scanning of underground excavations also enables deformation monitoring through comparison of point clouds acquired at different epochs. The generated datasets can be integrated within GIS environments to create four-dimensional (4D) models that describe both geometry and temporal changes, supporting stability assessment and long-term infrastructure management.

Another important application is the determination of excavated ore volumes. Dense point clouds generated by LiDAR-based mapping systems provide significantly more complete geometric information than conventional profile measurements, improving the accuracy of volume calculations and production analysis [14].

Because autonomous systems can operate in areas with limited accessibility, they are particularly valuable for inspection of hazardous zones affected by rock instability, poor ventilation, flooding, or other operational risks. The reduction of direct human exposure represents one of the principal advantages of robotic deployment in underground environments.

Although underground mining provides the primary application context considered in this study, the same technological principles are increasingly employed in other safety-critical environments characterized by confined geometry, limited visibility, and difficult access. Examples include transportation tunnels, underground utility corridors, storage caverns, emergency shelters, and critical infrastructure facilities.

Of particular relevance for defense and security applications is the use of autonomous robotic mapping systems for inspection and reconnaissance of underground structures where direct human entry may be undesirable or unsafe. Robotic platforms equipped with LiDAR and visual sensors can rapidly generate accurate three-dimensional models of tunnels, galleries, shelters, and other enclosed spaces while maintaining operator standoff distance. Such capabilities support situational awareness, route assessment, infrastructure inspection, and post-event damage evaluation.

Similarly, during emergency response and rescue operations, autonomous mapping systems can provide rapid spatial information in collapsed or unstable underground environments, helping responders identify accessible routes, obstacles, and areas requiring immediate attention.

The common denominator across mining, civil, and defense-related applications is the ability of autonomous robotic systems to acquire high-resolution spatial data in environments that are hazardous, inaccessible, or operationally constrained.

This combination of safety, speed, and geometric completeness is the main reason for the growing adoption of robotic mobile mapping technologies in modern underground operations.

5. DISCUSSION

The transition from conventional surveying toward autonomous robotic mapping represents a significant technological change in underground spatial data acquisition. Traditional surveying methods remain essential for establishing mine control networks and achieving high local accuracy; however, they are inherently limited by the need for direct human access and by the relatively sparse spatial information that can be collected during routine operations [5].

Autonomous mobile mapping systems address many of these limitations by acquiring dense three-dimensional datasets during continuous platform movement. The resulting point clouds provide a much more complete representation of underground geometry, enabling analyses that are difficult to achieve using discrete measurements alone. In addition, repeated scanning campaigns support temporal monitoring and the generation of 4D models, which are increasingly important for stability assessment and infrastructure management [3]. From an operational perspective, the most important benefit is the reduction of personnel exposure in hazardous underground environments.

Inspection of shafts, unstable excavations, flooded areas, or poorly ventilated zones can often be performed remotely by robotic platforms, improving safety while

maintaining the availability of high-quality spatial information.

The broader applicability of these systems is also noteworthy. The same combination of LiDAR sensing, SLAM-based navigation, robotic mobility, and GIS integration can be employed in mining, transportation tunnels, critical infrastructure inspection, emergency response, and defense-related underground operations. This technological convergence suggests that advances achieved in one domain can be transferred efficiently to other sectors with similar operational constraints [15,16].

6. CONCLUSIONS

This paper examined the application of autonomous robotic systems for 3D mobile mapping in underground mining environments. The analysis demonstrated that LiDAR-based mobile mapping, SLAM navigation, and, where appropriate, TLS implemented on handheld systems and autonomous robotic platforms, enable the rapid acquisition of dense three-dimensional spatial information even in environments where GNSS positioning is unavailable. Compared with conventional surveying methods, autonomous systems provide more complete geometric coverage, shorter field acquisition times, improved repeatability, and significantly enhanced operator safety. Their integration with GIS platforms enables advanced visualization, spatial analysis, deformation monitoring, and the generation of four-dimensional spatiotemporal models that support planning and decision-making throughout the mining life cycle.

The study also highlighted that the capabilities developed for underground mining are directly applicable to other safety-critical environments, including transportation tunnels, underground infrastructure, emergency-response scenarios, and defense-related underground facilities. The ability to obtain accurate spatial information while minimizing human exposure is the key factor driving the increasing adoption of autonomous robotic mapping technologies across multiple engineering and security domains.

Future developments are expected to focus on greater autonomy, improved multi-sensor fusion, real-time data processing, and tighter integration with digital-twin and intelligent decision-support systems, further strengthening the role of autonomous robotic mapping in underground operations [17].

Abstract: *Unmanned aerial systems (UAS) are increasingly present in modern operations, creating the need for efficient and reliable anti-drone detection systems. Artificial intelligence (AI), particularly real-time detection algorithms such as YOLO, provides fast and accurate analysis capabilities, improving situational awareness and response efficiency. This paper presents a hardware-oriented approach for detecting radio frequency (RF) communication between drones and their controllers. Since raw RF signals do not provide sufficient discriminative features, they are transformed into spectrogram representations, enabling feature extraction and subsequent classification [1]. The proposed system integrates RF signal acquisition, preprocessing, and YOLO-based detection, with the complete inference process deployed on an Edge AI platform. The solution was implemented and evaluated on the NVIDIA Jetson Orin device, demonstrating the feasibility of real-time drone communication detection in distributed C-UAS applications. Experimental results, including continuous execution and multi-process scenarios, confirmed stable operation with efficient resource utilization, while the integration of energy-based detection further improved computational efficiency by reducing unnecessary inference operations. These results highlight the potential of combining RF spectrogram analysis, deep learning, and Edge AI optimization for autonomous, low-latency, and energy-efficient C-UAS systems.*

Keywords: *Edge AI, C-UAS, RF detection, YOLO, spectrum analysis*

1. INTRODUCTION

This paper presents a hardware implementation of a convolutional neural network (CNN) based on the YOLOv8 algorithm, designed for counter-unmanned aerial systems (C-UAS) applications. The proposed approach focuses on the detection and classification of radio frequency (RF) communication between drones and their control stations. Since direct observation of RF signals does not provide sufficient discriminatory features for classification, the signals are transformed into spectrogram representations, enabling the extraction of relevant patterns for further analysis [2, 3].

Based on the acquired and preprocessed RF data, a dataset was constructed to train the YOLOv8 model. The network output corresponds to predefined classes, including scenarios with a single drone where the drone type can be identified as well as multi-drone scenarios, where only the number of detected drones is determined. YOLO-based classification has demonstrated strong potential in distinguishing UAV communication patterns from spectrogram data [4, 5].

The main contribution of this work is the implementation and evaluation of the proposed model on an Edge AI platform, specifically the NVIDIA Jetson Orin device. Given the time-sensitive requirements of C-UAS systems, the study emphasizes real-time processing capabilities and computational efficiency. In particular, the work investigates the feasibility of deploying deep learning models directly at the edge, reducing reliance on cloud infrastructure and minimizing latency in operational scenarios. Additionally, the analysis considers hardware constraints such as power consumption, memory usage, and processing throughput, which are critical for real-world deployment of embedded AI systems [6,7].

The model was evaluated through two processing approaches: simulation of a real-time execution on dedicated hardware and offline processing using a pre-collected dataset. This dual evaluation enables a direct comparison of performance and provides insight into the practical applicability of Edge AI solutions in operational environments.

Although the results demonstrate the feasibility of deploying such models on edge devices, the study is limited by the relatively small training dataset, which affects classification accuracy and generalization.

The paper is organized as follows: Section 2 presents the Edge AI implementation and describes the motivation for deploying deep learning-based classification algorithms on embedded hardware platforms. Section 3 describes the research methodology, including RF signal acquisition, spectrogram generation, dataset preparation, and the experimental setup used for evaluation. Section 4 presents the obtained results and provides an analysis of inference performance, hardware utilization, and the impact of energy-based detection on system efficiency. Finally, Section 5 summarizes the main findings and concludes the study, highlighting the potential of Edge AI-based solutions for C-UAS applications.

2. EDGE AI IMPLEMENTATION

The concept of Edge AI enables data processing directly at the source of generation on edge devices, reducing latency, enhancing response times, and minimizing the need for continuous data transmission to centralized servers. This capability is especially beneficial for time-sensitive applications, such as drone classification, where rapid decision-making is crucial. In the realm of security and defense, particularly in the context of drone classification, these advantages are essential. Real-time classification and decision-making are often necessary, and reliance on cloud infrastructure can lead to unacceptable delays or communication bottlenecks. Moreover, Edge AI enhances system resilience and operational autonomy by reducing dependence on persistent network connectivity, which is especially valuable in remote or contested environments where cloud access may be limited or unreliable. These features make Edge AI a compelling choice for implementing intelligent, distributed anti-drone defense systems. Given the time-sensitive nature of counter-drone operations the primary objective of this study was to explore the application of the NVIDIA Jetson Orin, a dedicated edge GPU computer, and to evaluate its processing efficiency in comparison to conventional approaches [6, 8].

3. METHODOLOGY

The research methodology is illustrated in segments, as shown in Figure 1. Each segment will be described in greater detail in the following sections.

The first segment involves the acquisition of raw RF communication signals from drones' communication, followed by their processing, with spectrograms generated as the output of this stage.

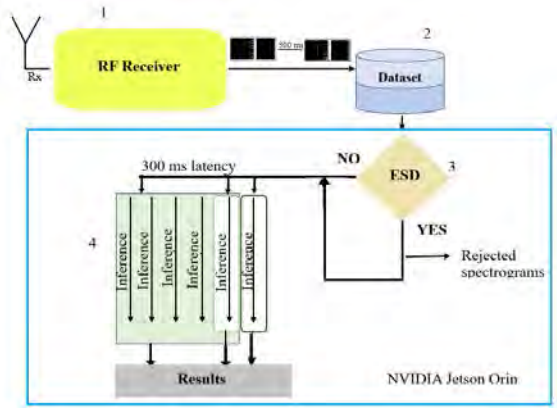

Figure 1. Methodology (1 – RF receiver, 2 – database for offline analysis and generating a dataset for model training, 3 – energy detection on spectrograms, 4 – Edge AI hardware Inference)

The RF receiver generates the spectrograms across four frequency bands: 400 MHz, 800 MHz, 2.4 GHz, and 5.8 GHz. Signal acquisition was conducted continuously, with the data captured in the form of *.txt files. Within each frequency band, three files were generated per second, each with dimensions of 2048×1000. The discrete Fourier transform length (N_DFT) was set to 2048, and the number of frames per file was 1000. Following signal acquisition, subsequent morphological operations were applied to the resulting spectrograms. These processed spectrograms were transferred into the black and white spectrograms. The total processing time, which includes both the acquisition and the computation phases is approximately 300 ms for 1000 frames. Representative examples of these generated spectrogram images are provided in Figure 2. [9, 10].

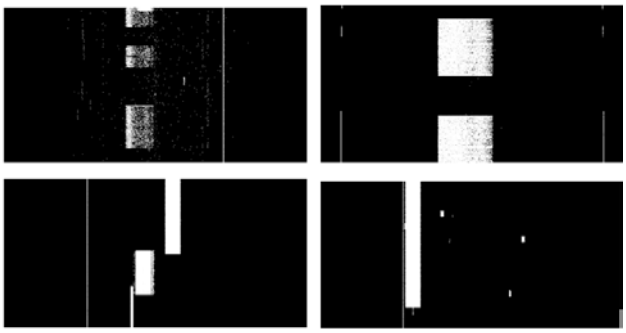

Figure 2. Generated black and white spectrograms

The second segment shown in the figure, represents a non-publicly available (VTI_RFDroneSET_USRP) database created using the outputs from the first segment. This database contains spectrograms intended for either the training or testing of existing or new models. The data stored within the database can subsequently be utilized in later stages of the processing pipeline. From the database, 1000 randomly selected spectrograms were used to train the model, while a separate set of spectrograms was reserved for the validation process. The dataset contains three classes (Lightbridge, OcuSync 20 and OcuSync 40) which are equally represented through the experimental phase. The model was trained to identify characteristic patterns of RF communication signals in the spectrograms

and to distinguish the communication signals associated with different drone types. An additional set of 5000 randomly selected spectrograms was used for inference testing.

The third segment involves applying the statistical analysis introduced in [11] to the existing emissions presented in the output spectrograms obtained in real time from the RF receiver. In this phase, spectrograms that do not contain meaningful information, typically associated with background or ambient noise, are discarded. The ESD threshold is determined empirically, and the threshold defined in [9] was adopted. In addition, an analysis of energy-based signal detection (ESD) was conducted within the Edge AI framework to further assess its role as a pre-filtering mechanism. Different operational scenarios were considered in order to evaluate the ratio between discarded and useful spectrograms, as well as its impact on processing time and overall system performance. The objective was to determine whether such filtering contributes to more efficient resource utilization on the edge platform by reducing unnecessary computations, or whether it introduces limitations that affect its applicability in real-time processing.

The fourth and final segment focuses on the evaluation of the developed YOLO-based solution implemented on the NVIDIA Jetson Orin NX 16GB Edge AI platform. The experiments were performed using the PyTorch-based implementation of the YOLO model. YOLO model was used in the PyTorch (.pt) format through the Ultralytics YOLO library. The model was executed directly within the PyTorch environment, without prior conversion to optimized inference formats such as ONNX or TensorRT.

The Jetson Orin is a powerful and compact AI computing module developed by NVIDIA, designed for Edge AI and robotics applications that offers strong performance for AI inferencing, suitable for real-time applications like computer vision, NLP, and sensor fusion. The device is equipped with 16 GB of 128-bit LPDDR5 memory with a peak bandwidth of up to 102 GB/s, an 8-core Arm Cortex-A78AE CPU and an NVIDIA Ampere GPU featuring 1024 CUDA cores and 32 Tensor Cores, with experiments conducted using Python 3.10.12, PyTorch 2.5, CUDA 12.4 and Ultralytics 8.3.91. The platform supports configurable power modes of 10 W, 15 W, and 25 W, enabling the computational resources to be adapted to the requirements of the deployed application [12].
The objective of this analysis was to assess the feasibility and efficiency of deploying the model in real-time C-UAS applications by evaluating inference performance, neural network output, and hardware resource utilization. This evaluation enables the identification of potential advantages and limitations of edge-based processing compared to traditional server-based or cloud approaches.

The performance of the YOLOv8 model executed through the Ultralytics framework was analyzed using inference and hardware-related metrics. The inference evaluation included model loading time, average processing time per image, processing speed expressed in frames per second (FPS), and total execution time. During the inference, a batch size of 1 was used, meaning that each spectrogram was loaded and processed individually. The confidence threshold was set to 0.5 based on the analysis of the trained model, which indicated that this threshold provides an appropriate balance between precision and recall. At a confidence threshold of 0.5, both precision and recall were approximately 0.995 across all classes, indicating that the model successfully detected the relevant samples while maintaining a minimal number of false-positive and false-negative predictions.

Additionally, hardware performance was assessed through GPU and CPU utilization, power consumption, and GPU temperature to evaluate workload distribution, energy efficiency, and thermal stability. All parameters were recorded during model execution and analyzed across different experimental scenarios, including cases with and without energy-based detection. The obtained results were used to determine whether energy-based filtering contributes to more efficient data processing and improved resource utilization on the Edge AI platform.

4. RESULTS

4.1 Practical evaluation

Practical evaluation was conducted according to the methodology defined in Section 3. The experiments were performed using a dataset of 2000 spectrograms containing ambient signals and 3000 spectrograms with drone communication samples. Two scenarios were analyzed: inference without energy-based filtering and inference with energy-based filtering. Each scenario was evaluated through three test configurations representing different operational conditions. The first configuration considered offline processing, where spectrograms were loaded sequentially from the dataset without additional timing constraints. The second configuration simulated the real-time operation of the RF acquisition system by introducing a 300 ms spectrogram generation interval, corresponding to the actual data flow from the receiver. The third and most demanding configuration involved five simultaneous inference processes, representing a multi-channel operational scenario in which the RF receiver generates spectrograms from five different frequency bands in parallel, which will be case in the future experiments (four different frequency bands are currently in use).

The collected results were stored in tabular form and used for further analysis. Each measurement was repeated ten times, and the presented values represent the corresponding average results, reducing the influence of random variations.

The Table 1 presents the inference results obtained without ESD, based on the parameters defined in the previous section.

Table1. Inference results obtained without ESD

Loading spectrograms scenario	Random	Real-time 300 ms	5 simultaneous processes
Number of spectrograms	5000	5000	5000 x5
Total detection number	5935	5935	5935 x5
Model loading and GPU transfer time	0.298 s	0.201 s	0.235 s
Average time per image	0.046 s	0.042 s	0.111s
Total inference time	225 s	215 s	550 s

The results presented in Table 1 confirm that the implemented YOLO-based classification system achieves real-time performance on the NVIDIA Jetson Orin Edge AI platform. The average inference time per spectrogram in the first test scenario was 46 ms, which enables continuous operation without processing delays. Considering that the current RF acquisition system, described in the Methodology section, generates a new spectrogram every approximately 300 ms, the obtained inference time is significantly shorter than the available processing interval. Therefore, the proposed Edge AI implementation can process incoming data without introducing additional latency.

In the multi-process scenario with five parallel inference streams, the average processing time increased to 111 ms per spectrogram due to higher computational demand. However, this value remains below the spectrogram generation interval, demonstrating that the Jetson Orin platform provides sufficient computational capability for real-time drone detection and classification applications.

The total number of detections differs from the total number of spectrograms because the detection process counts individual objects within each image. The RF communication of interest is generally not continuous within a single spectrogram (Figure 2) and may therefore be represented as two or even three separate objects. Consequently, in the first scenario, 5935 detections were obtained from 3000 useful spectrograms. The total number of detections is expected to be approximately comparable between the two scenarios, with possible differences arising from occasional errors in rejecting relevant spectrograms during the ESD filtering process. In the second scenario, 5920 detections were obtained, since the corresponding to the certain number of rejected spectrograms.

In the second scenario, ESD was introduced as a preprocessing step, while the inference procedure remained unchanged (Table 2). The YOLO inference time remained constant; however, the total processing time increased from 46 ms to 67 ms per spectrogram due to the additional ESD operation, indicating that the energy detection stage requires approximately 20 ms per input.

Although ESD introduces additional computational overhead, its main advantage is the reduction of unnecessary inference operations and more efficient utilization of available hardware resources. In the evaluated dataset, 1965 spectrograms without relevant RF activity were discarded before entering the detection model, thereby reducing unnecessary GPU utilization, memory access, and computational load.

Table 2. Inference results obtained with enabled ESD

Loading spectrograms scenario	Random	Real-time 300 ms	5 simultaneous processes
Number of spectrograms	5000	5000	5000 x5
Number of rejected spectrograms	1965	1965	1965
Total detection number	5920	5920	5920 x5
Model loading and GPU transfer time	0.288 s	0.195 s	0.222 s
Average time per image with ESD	0.067 s	0.065 s	0.105 s
Total inference time	203 s	197 s	319 s

This approach is particularly beneficial in scenarios with a significant amount of background data, where processing every input through the deep learning model would result in increased resource consumption without improving classification performance. For the current acquisition system, which generates spectrograms at approximately 300 ms intervals, the additional ESD processing time remains within acceptable limits. Therefore, energy-based filtering represents an effective optimization strategy for edge-based drone detection systems, enabling more efficient resource utilization while maintaining real-time operation.

4.2 Hardware Performance Analysis

During YOLO model inference on the NVIDIA Jetson Orin platform, real-time monitoring of hardware parameters was performed to evaluate system behavior and resource utilization. The analysis included GPU and CPU utilization, power consumption, operating frequencies, and component temperatures.

The collected measurements were used to assess workload distribution between processing units, energy efficiency, and thermal stability under different experimental scenarios. All parameters were recorded during model execution on spectrogram data, and the results represent averaged values obtained from repeated

measurements.

The hardware performance evaluation, including GPU and CPU utilization, power consumption, memory usage, and temperature variations, is presented in Table 3 for the two most computationally demanding scenarios. The analysis considers five parallel inference processes executed without ESD and with the additional ESD stage, enabling a direct comparison of the system behavior under maximum workload conditions.

Table 3. Hardware performance evaluation

Parameter	Without ESD	With ESD
Average RAM utilization (GB)	7.8	7.8
Maximum RAM utilization (GB)	8.0	7.9
Average GPU utilization (%)	25	30-35
Maximum GPU utilization (%)	98	99
GPU frequency (MHz)	305–407	305–611
Average CPU utilization (%)	28	13
Maximum CPU utilization (%)	89	90
Average power consumption (W)	8	8.4
Maximum power consumption (W)	9.6	9.1
CPU temperature (°C)	55–56	55–56.5
GPU temperature (°C)	51–53	52–53
Swap memory usage (MB)	2	0

Without ESD, the system maintained stable operation during continuous inference with five parallel processes. The average RAM utilization was approximately 7.8 GB, while GPU utilization varied depending on inference activity, reaching peaks close to 98%. The average power consumption remained around 8 W, with short peaks below 10 W. CPU and GPU temperatures remained stable, indicating that the workload was successfully executed within the thermal limits of the Jetson Orin platform.

Compared with the ESD scenario, the main difference is related to the distribution of the computational workload rather than to thermal behavior. The ESD approach reduces unnecessary inference operations by filtering spectrograms with no information before YOLOv8 inference. This reduces the number of redundant neural network executions, while introducing additional preprocessing operations and associated CPU workload. Therefore, the effect of ESD is expected to be reflected primarily in the utilization and distribution of computational resources rather than in a direct reduction of average power consumption.

Additional analysis of system parameters confirms that both approaches are suitable for deployment on the Jetson Orin platform. In the ESD scenario, average CPU utilization decreased from approximately 28% to 13%, while RAM utilization remained practically unchanged at approximately 7.8 GB. In contrast, average GPU utilization increased moderately from approximately 25% to 30–35%, while the maximum GPU utilization remained comparable, reaching approximately 99%. The GPU frequency also reached higher values in the ESD scenario, with a maximum of 611 MHz compared with 407 MHz without ESD. These results indicate that ESD changes the distribution of the computational workload rather than producing a uniform reduction in overall resource utilization. Regarding power consumption, the average value remained at a similar level, changing from approximately 8 W without ESD to 8.4 W with ESD. However, the maximum power consumption decreased from 9.6 W to 9.1 W. The thermal behavior remained stable in both configurations, with CPU and GPU temperatures remaining within comparable ranges. Although ESD introduces additional preprocessing time and computational overhead, it reduces redundant neural network executions and provides an additional mechanism for optimizing the processing pipeline during continuous operation. On the other hand, the scenario without ESD demonstrated that the system is capable of handling continuous inference of five parallel processes, with the average GPU utilization close to 35% and power consumption remaining within the platform limits. Therefore, both configurations satisfy the operational requirements, while the ESD approach provides additional optimization potential for long-term autonomous operation and energy-constrained applications.

5. CONCLUSION

This paper presented the implementation and evaluation of a YOLOv8 deep learning model for drone communication classification using RF spectrogram representations on an Edge AI platform. The proposed approach combines RF signal acquisition, spectrogram representation, deep learning inference, and hardware optimization, forming a complete processing chain for C-UAS applications. The experimental evaluation on the NVIDIA Jetson Orin platform demonstrated the feasibility of executing CNN-based drone detection directly on embedded hardware. The obtained results confirmed that the proposed solution meets the real-time processing requirements, with stable operation even in the most demanding scenario involving five parallel inference processes.

The analysis of hardware parameters showed that the system operates reliably within the constraints of an embedded AI platform, maintaining acceptable resource utilization, power consumption, and thermal behavior.

Furthermore, the integration of ESD as a preprocessing stage reduced the number of unnecessary neural network executions and significantly lowered the average CPU utilization, while maintaining a comparable average power consumption and stable thermal behavior. The results therefore demonstrate that ESD can optimize the processing pipeline without compromising the real-time operation of the system.

Overall, the results confirm that the combination of RF spectrogram analysis, deep learning inference, and Edge AI optimization represents a suitable approach for low latency and resource-efficient drone classification in C-UAS applications. Future work will focus on expanding the RF dataset, improving model generalization, and further optimizing the processing pipeline for more complex operational scenarios.

Abstract: *The standard engineering process for developing a multi-hole pressure probe included the use of 3D software during the design phase. At the same time, CFD (Computational Fluid Dynamics) was used to calculate the main characteristics of the probe. After the probe geometry was selected, the CFD results were verified by wind tunnel testing. This process ensured that the predicted probe characteristics were accurate under real flow conditions.*

However, numerical simulations and experimental testing required a significant amount of time and financial resources. For this reason, a machine learning model for predicting the characteristics of a multi-hole pressure probe was developed at the Military Technical Institute in Belgrade [1]. The selected model was a Random Forest Regressor because it achieved the lowest MAE (Mean Absolute Error).

The model was trained to predict probe characteristics for subsonic, transonic, and supersonic flow regimes and for two probe geometries: a sharp probe and a blunt probe. In the previous study, the Random Forest model achieved an MAE of 0,001681.

The aim of this research was to improve the performance of the existing model by using machine learning optimization methods. In addition, the effect of the dataset on model performance was analyzed. Grid Search with cross-validation was applied to find the best hyperparameter combination and improve the prediction accuracy of the model for different flow regimes.

Keywords: *multi-hole pressure probe, machine learning, Random Forest Regressor, hyperparameter optimization, flow regimes.*

1. INTRODUCTION

In previous research at the Military Technical Institute in Belgrade, a machine learning model based on the Random Forest Regressor was developed to predict the characteristics of a multi-hole pressure probe. The model was trained using experimental data from wind tunnel tests. The input data included flow parameters and probe geometry characteristics, while the output was ΔP/P0 (the normalized pressure difference) [1].

The previous model achieved a MAE of 0,001681. The Random Forest algorithm was selected as the best model after it was compared with other machine learning models [1]. Although the model showed high prediction accuracy, its performance could still be improved.

Since the performance of a machine learning model depended on the selected hyperparameters, this paper investigated different methods for improving the existing Random Forest model. The main focus was on hyperparameter optimization using Grid Search together with cross-validation to find the best combination of hyperparameters that gave the lowest prediction error.

In addition, the effect of dataset segmentation and dataset characteristics on model performance was analyzed. The analysis included different flow regimes (subsonic, transonic, and supersonic) and two different probe geometries. The results showed that model accuracy depended not only on the number of samples but also on the data distribution and homogeneity within each flow regime.

The aim of this paper was to improve the existing Random Forest model through hyperparameter optimization and analysis of the dataset structure.

2. DATASET DESCRIPTION

The dataset used in this study contained a total of 2095 samples collected for two probe geometries under different flow regimes. The samples were collected during wind tunnel tests in the T-35 and T-38 wind tunnels at the Military Technical Institute. The sharp probe is shown in Figure 1, while the blunt probe is shown in Figure 2. Each sample represented one measurement and included the following input parameters: static pressure (Pst), Mach number (M), flow temperature (T0), and effective angle of attack (θ_eff). The output variable was the normalized pressure difference (ΔP/P0).

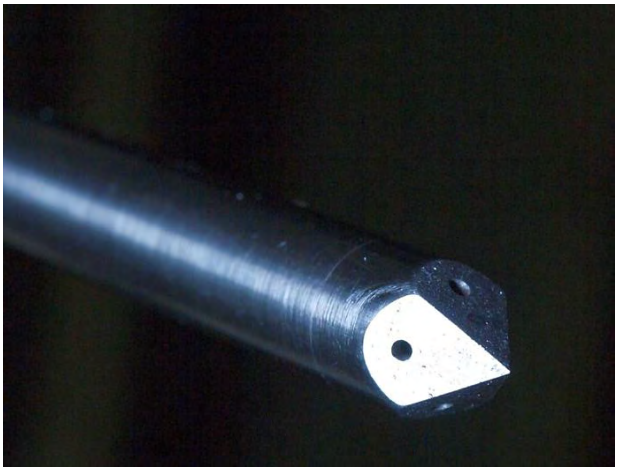

Figure 1. Four-hole pyramidal pressure probe, declared as *a sharp probe*; tested in the VTI T-38 wind tunnel in the Mach number range from 0.2 to 4

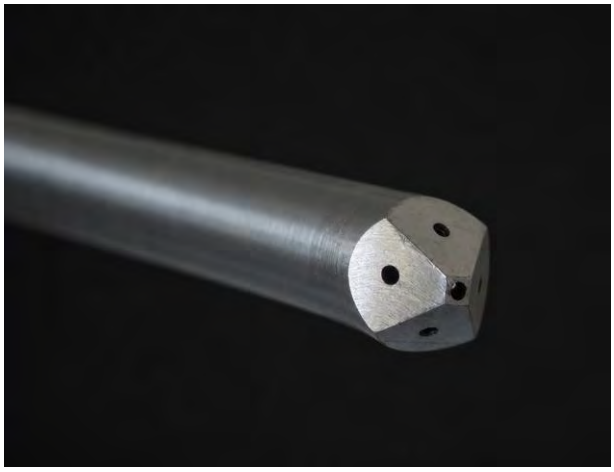

Figure 2. Five-hole pyramidal pressure probe designed for small UAV (unmanned aerial vehicle), declared as *a blunt probe*; single tested in the VTI T-38 wind tunnel

Data for the sharp probe were available for all three flow regimes (subsonic, transonic, and supersonic), while data for the blunt probe were available only for the subsonic flow regime. To better analyze the effect of the flow regime and probe geometry on model performance, the complete dataset was divided into four subsets. The number of samples in each subset is shown in Table 1.

The largest subset contained 1025 samples for the sharp probe in the supersonic flow regime, while the smallest subset contained 84 samples for the sharp probe in the transonic flow regime.

Table 1. Dataset structure

Dataset	Flow Regime	Geometry	Samples
sharp_subsonic	subsonic	sharp	672
sharp_transonic	transonic	sharp	84
sharp_supersonic	supersonic	sharp	1025
blunt_subsonic	subsonic	blunt	314

3. METHODOLOGY

3.1 Random Forest Regressor

In the previous study, the Random Forest Regressor was selected as the best model for predicting the characteristics of the pressure probe because it achieved the lowest MAE [1]. Based on these results, the same model was used in this study as the starting point for further optimization.

Random Forest is an ensemble machine learning method that consists of many decision trees. During training, each tree is built using a different subset of the training data. The final prediction is obtained by averaging the predictions of all trees. This approach reduces overfitting and improves the model's ability to make accurate predictions on new data [2].

To explain how the Random Forest algorithm works, Figure 3 shows one decision tree generated using the complete training dataset from this study. The maximum depth of the tree is limited to 3.

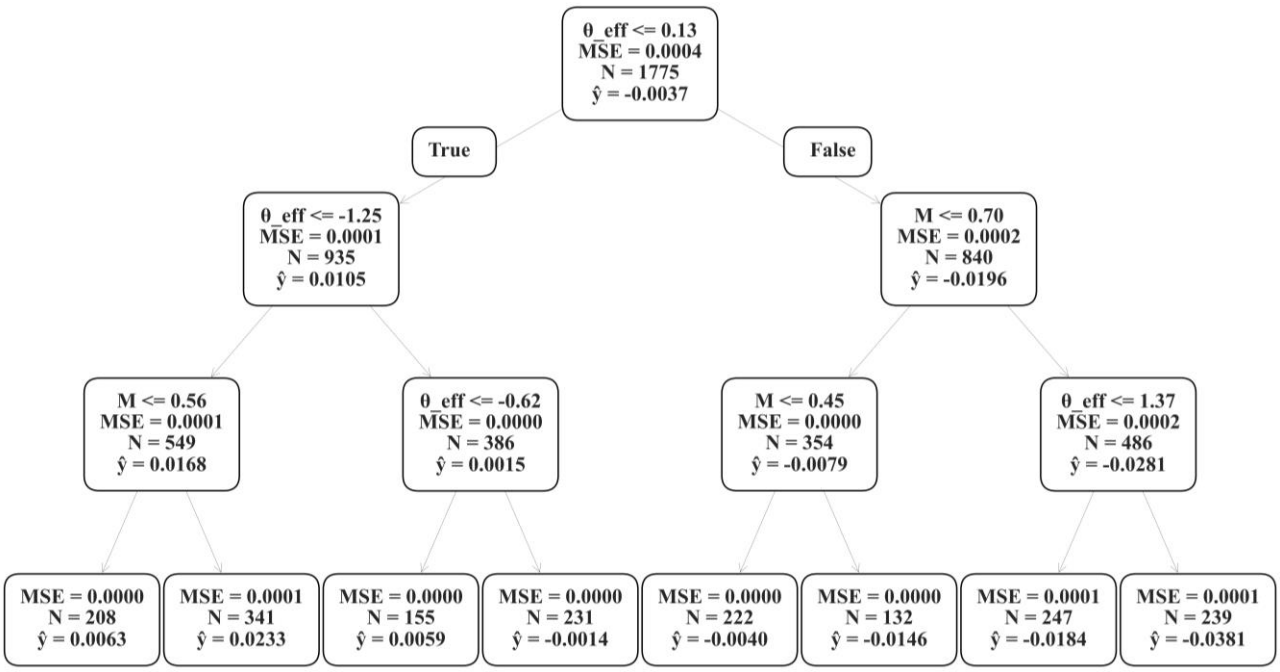

Figure 3. Example of a decision tree generated for the complete dataset

The root node represents the first data split. In this example, the algorithm selected the effective angle of attack, θ_eff, as the first splitting criterion. The threshold θ_eff ≤ 0.13° was automatically selected during training because it produced the largest reduction in the Mean Squared Error (MSE) among all possible splits of all input features. To find the best split, the algorithm checks different threshold values from the training data for each input feature. For every possible split, it calculates the MSE of the two new groups. The feature and threshold that give the lowest total MSE are selected.

All training samples are divided into two groups depending on whether θ_eff ≤ 0.13° or θ_eff > 0.13°. The root node contains all training samples used to train the model.

After the first split, the algorithm repeats the same process for each new group of data. At every node, it checks all input features and different threshold values again. The split that gives the largest reduction in MSE is selected. In this example, the next splitting criteria are again θ_eff and the Mach number (M), but with different threshold values. For example, on the right branch the next split is M ≤ 0.70, while on the left branch θ_eff is selected again with the threshold −1.25°. This shows that the algorithm chooses the best feature and threshold separately at each node.

Each node contains the Mean Squared Error (MSE), the number of training samples (N), and the predicted mean value of the target variable (ŷ). The parameter N represents the number of training samples contained in the node, while ŷ represents the average value of the target variable ΔP/P0 for those samples. The MSE shows how similar the target values are within a node. Lower MSE values indicate that the target values are more similar, meaning that the node is more homogeneous.

The splitting process ends at the leaf nodes. Each leaf contains training samples with similar input values. The prediction of a single decision tree is the value **ŷ**, which represents the average value of the target variable ΔP/P0 for all training samples contained in that leaf. The final prediction of the Random Forest Regressor is obtained by averaging the predictions of all decision trees in the forest.

3.2 Hyperparameter optimization

To improve the performance of the existing Random Forest model, hyperparameter optimization was performed using the Grid Search method. Grid Search tested all predefined combinations of hyperparameters to find the configuration that gave the lowest MAE [3].

In this study, the effect of three main hyperparameters of the Random Forest algorithm was analyzed: the number of trees in the forest (n_estimators), the maximum tree depth (max_depth), and the minimum number of samples required to split a node (min_samples_split). The tested hyperparameter values are shown in Table 2.

The selected hyperparameter values and different cross-validation configurations were combined in ten experiments to find the best model configuration. The cross-validation procedure used in this study is described in the next section.

Table 2. Tested hyperparameters

Parameter	Values
n_estimators	200, 300, 500, 700, 800, 1000
max_depth	10, 20, 30, 40, None
min_samples_split	2, 5, 7, 9, 10

3.3 Cross-validation

The performance of the model was evaluated using k-fold cross-validation. In this method, the dataset is divided into k subsets of approximately equal size. During the validation process, the model is trained using k−1 subsets, while the remaining subset is used for testing. This process is repeated k times, so that each subset is used once as the validation set [4].

In this study, cross-validation was used as part of the Grid Search procedure to select the best combination of hyperparameters for the Random Forest Regressor. In addition to hyperparameter optimization, the effect of the number of validation folds on model performance was also analyzed. For this purpose, ten experiments were performed using different values of the cv parameter (5, 10, 15, 40, 50, 60 and 75).

For each combination of hyperparameters, the average MAE was calculated over all validation iterations. The configuration with the lowest MAE was selected as the best model configuration.

3.4 Dataset segmentation

To study the effect of the dataset on the performance of the Random Forest regressor, the complete dataset was divided into four separate subsets. The division was based on the probe geometry and the flow regime. The four subsets were sharp subsonic, sharp transonic, sharp supersonic, and blunt subsonic.

The same Random Forest model was used for all four subsets. The model used the optimal hyperparameters found during the optimization process. The model was evaluated using k-fold cross-validation. This made it possible to compare the results under the same conditions.

The performance of each model was measured using the MAE. The Mach number distribution was analyzed for the sharp supersonic and blunt subsonic datasets because they had the highest and the lowest MAE. The distribution of the target variable ΔP/P0 was analyzed for all four dataset subsets using boxplot diagrams. The range and the standard deviation (Std) of the target variable were also calculated to measure the data variability.

The goal of this analysis was to find out whether the prediction accuracy depended only on the number of samples or also on the data distribution and variability.

4. RESULTS

4.1 Hyperparameter optimization results

The results of the hyperparameter optimization are shown in Table 3. Compared with the previously developed model [1], the optimized Random Forest Regressor achieved a lower MAE. The best result was obtained with the following hyperparameter values: n_estimators = 500, max_depth = 10, min_samples_split = 2, and cv = 50.

The obtained MAE was 0,001601, which represented an improvement of about 4.8% compared to the previous study, where the MAE was 0,001681. The results showed that hyperparameter optimization improved the prediction accuracy of the model, although the improvement was relatively small. This indicated that the original model already had high accuracy, while the optimization further improved its performance. All ten experiments were performed on the complete dataset.

Table 3. Comparison of MAE before and after hyperparameter optimization

Model	MAE
Random Forest (previous work)	0,001681
Random Forest (Grid Search optimized)	0,001601

4.2 Dataset segmentation results

The prediction results for the four dataset subsets are shown in Table 4. Each subset was analyzed separately using the Random Forest model with the same optimal hyperparameters (n_estimators = 500, max_depth = 10, and min_samples_split = 2). The model was evaluated using 50-fold cross-validation.

Table 4. Model performance for different dataset subsets

Dataset	Samples	MAE
sharp_subsonic	672	0,000804
sharp_transonic	84	0,001565
sharp_supersonic	1025	0,002799
blunt_subsonic	314	0,000405

The lowest MAE was obtained for the blunt subsonic dataset and was 0,000405. The highest MAE was obtained for the sharp supersonic dataset and was 0,002799. Although the sharp supersonic dataset contained the largest number of samples, it produced the highest prediction error. On the other hand, the sharp transonic dataset contained only 84 samples, but its MAE (0,001565) was much lower than the MAE of the sharp supersonic dataset. These results showed that a larger number of samples did not always lead to better prediction accuracy.

The distribution of the Mach number for the datasets with the highest and the lowest MAE is shown in Figure 4. It can be seen that the sharp supersonic dataset covered a much wider Mach number range than the blunt subsonic dataset. This indicated a larger variation of flow conditions in the sharp supersonic dataset.

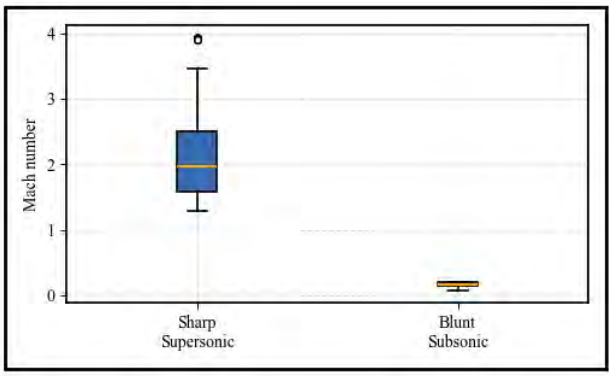

Figure 4. Distribution of Mach Number

Figure 5 shows the distribution of the target variable ΔP/P0 for all four dataset subsets. The differences between the distributions showed that the datasets had different levels of data variability.

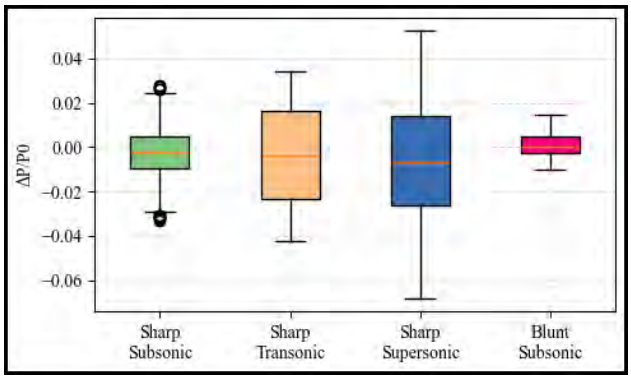

Figure 5. Distribution of ΔP/P0

For a more detailed analysis, the range, Std and MAE were calculated for each dataset subset. The results are shown in Table 5.

Table 5. Statistical characteristics of the dataset subsets

Dataset	Samples	Range	Std	MAE
sharp_subsonic	672	0,0614	0,0119	0,000804
sharp_transonic	84	0,0764	0,0225	0,001565
sharp_supersonic	1025	0,1203	0,0259	0,002799
blunt_subsonic	314	0,0249	0,0052	0,000405

The sharp supersonic dataset had the largest range (0,1203), the highest standard deviation (0,0259), and the highest MAE (0,002799). In contrast, the blunt subsonic dataset had the smallest range (0,0249), the lowest standard deviation (0,0052), and the lowest MAE (0,000405).

The results showed that the prediction accuracy of the Random Forest model did not depend only on the number of samples. Higher data variability and a wider data distribution made the learning process more difficult and increased the prediction error. On the other hand, more homogeneous datasets allowed the model to make more accurate predictions and achieve lower MAE values.

5. CONCLUSION

This paper analyzed different methods for improving the Random Forest Regressor developed for predicting the characteristics of a multi-hole pressure probe. By using Grid Search optimization and different cross-validation configurations, the MAE was reduced by about 4.8%. The best results were achieved with the following hyperparameter values: n_estimators = 500, max_depth = 10, min_samples_split = 2, and cv = 50.

In addition to hyperparameter optimization, the effect of dataset characteristics on model performance was also analyzed. The results showed that the sharp supersonic dataset, although it contained the largest number of samples, had the highest MAE and the highest variability of the target variable. In contrast, the blunt subsonic dataset had the lowest variability and the lowest MAE.

The results showed that, besides the number of samples, the data distribution and variability also had a significant effect on the accuracy of the Random Forest Regressor. They also showed that the structure of the dataset was an important factor that affected model performance. Therefore, future research will focus on a more detailed analysis of dataset characteristics and organization, as well as on developing methods for creating more representative training datasets.

Abstract: *Due to uncertainty in their mathematical models and external disturbances, which affect the quality of model-based control, the trajectory-tracking performance of serial robotic manipulators is always in question. There are many methods for compensating for undesired uncertainties and external disturbances, but for a system that operates repeatedly, such as a robot manipulator in an industrial setting, the Iterative Learning Control (ILC) strategy is particularly effective. Additional improvement is achieved by integrating fractional calculus into ILC, leading to a Fractional-order Iterative Learning Controller (FOILC). The FOILC controller iteratively compensates for the influence of parametric uncertainty on trajectory tracking. Optimal performance is achieved by tuning control parameters using the Particle Swarm Optimization (PSO) algorithm, which compares multiple objective functions to determine the most effective performance criterion. The efficiency of the proposed approach is validated through simulation on the RL15 6-DOF industrial serial robot. The results demonstrate the performance superiority of the tuned FOILC over its integer-order counterpart, while the comparative analysis of tuning criteria identifies the optimal objective function for achieving the best tracking accuracy.*

Keywords: *iterative learning control, fractional calculus, optimization, performance criteria, industrial robots.*

1. INTRODUCTION

Articulated robots have an open-loop kinematic chain structure, for which trajectory tracking is a fundamental requirement in applications such as welding, assembly, and sorting, and it poses a challenge for control design, given the system's coupled, nonlinear nature, unmodeled dynamics, external disturbances, and other uncertainties.

Today, PID controllers remain a primary feedback solution for most control problems, including robot manipulators [1], and a PD position controller combined with a nonlinear control strategy is particularly well-suited for articulated robots [2]. Rather than relying on a model-based feedback law such as inverse dynamics control, an Intelligent PID controller is adopted here as the feedback controller, preserving the model-free aspect of the overall control scheme while still providing a satisfactory response [3]. Articulated robot manipulators are generally used for repetitive tasks such as welding, assembly, or sorting. Iterative Learning Control (ILC), a memory-based learning control strategy [4], excels at improving the transient response of systems operating repetitively over a finite time interval [5], without relying on precise knowledge of the process model [6]. ILC can be easily incorporated into existing control systems [7].

Incorporation of fractional calculus theory (succinctly put, a generalization of integer-order calculus [8]) into ILC results in Fractional Order Iterative Learning Control (FOILC) [9]. The main advantage of fractional-order controllers is that they offer more degrees of freedom than their integer-order counterparts, thereby yielding better performance [10]. An increased number of control system parameters requires tuning for better system response, and the choice of performance criterion used in that tuning process, such as the Integral of Squared Error (ISE), Integral of Time-weighted Squared Error (ITSE), Integral of Absolute Error (IAE), or Integral of Time-weighted Absolute Error (ITAE), directly affects the resulting transient response. Although fractional-order PID tuning has been widely studied in the literature (e.g., [11], [12]), a proper tuning procedure that accounts for these performance criteria is still lacking for FOILC controllers. The research in [13] addresses the problem of tuning FOILC control parameters for a linearized robot with no uncertainty. Another research tackled tuning FOILC parameters for an articulated robot with model parameter uncertainty [14]. The main motivation for this research is to find an easy, computationally efficient, and performance-improving solution to tuning FOILC parameters by comparing the resulting closed-loop performance across several standard error-based criteria. The Particle Swarm Optimization (PSO) was chosen for FOILC parameter tuning, with the objective function formulated around the aforementioned performance criteria.

This paper focuses on applying FOILC to the legacy industrial robot LOLA15 (RL15) with an Intelligent PID position controller. This paper consists of the following sections: Section II provides a brief introduction to ILC and describes the controller design, divided into subsections on the Intelligent PID, the Fractional Order Iterative Learning Controller, and the tuning of FOILC control parameters using PSO with respect to different performance criteria (ISE, ITSE, IAE, ITAE); Section III presents the simulation results on the RL15 robot; and Section IV presents the concluding remarks.

2. CONTROL SYSTEM DESIGN

2.1. Intelligent PID

The intelligent PID (i-PID) control strategy is based on the combination of classical PID and dynamics estimation via ultra-local model [3]. The general form of the i-PID control law for SISO (Single Input Single Output) systems is:

$$u(t) = b^{-1}\left(r^{(v)}(t) - \hat{f}(t) + PID(e)\right), \qquad (1)$$

where $r^{(v)}(t)$ is v-th derivative of the desired output, $\hat{f}(t)$ is an estimate of nonlinear dynamics, model parameter uncertainties and external disturbances, PID(e) is general form of any PID controller structure (P, PI, PD, etc.), and b^{-1} is inverse of control parameter b. The detailed algorithm of obtaining the value of estimate $\hat{f}(t)$ can be found in [3].

Expanding from SISO to MIMO (Multiple Input Multiple Output) n-degree of freedom articulated robotic systems, the control law for i-PID can be written in the following form:

$$\mathbf{u}(t) = \mathbf{B}^{-1}\left(\mathbf{q}_d^{(v)}(t) - \hat{\mathbf{f}}(t) + \mathbf{PID}(\mathbf{e})\right), \qquad (2)$$

where $\mathbf{B}^{-1}$ is inverse matrix of $n \times n$ matrix $\mathbf{B}$, $\mathbf{q}_d^{(v)}(t)$ is a $n \times 1$ vector of v-th derivative of the desired output, $\hat{\mathbf{f}}(t)$ is a $n \times 1$ vector of an estimate of nonlinear dynamics, model parameter uncertainties and external disturbances, and $\mathbf{PID}(\mathbf{e})$ is a general form of any PID controller structure. For articulated robot matrix $\mathbf{B}$ can be obtained based on a robot's inertia matrix as explained in [15]. For this study proposed PID controller structure is adopted as PD and final form of the total control law is given as:

$$\mathbf{u}(t) = \mathbf{B}^{-1}\left(\mathbf{q}_\mathbf{d}^{(v)}(t) - \hat{\mathbf{f}}(t) + \mathbf{p}(t) + \mathbf{v}(t)\right), \qquad (3)$$

where $\mathbf{p}(t)$ is PD controller:

$$\mathbf{p}(t) = \mathbf{K_P}\mathbf{e}(t) + \mathbf{K_D}\dot{\mathbf{e}}(t), \qquad (4)$$

where, $\mathbf{e}_i = \mathbf{q_d} - \mathrm{q}_i$ is $n \times 1$ vector of position errors, $\dot{\mathbf{e}}_i = \dot{\mathbf{q}}_\mathbf{d} - \dot{\mathbf{q}}_i$ is the $n \times 1$ vector of velocity errors, $\mathbf{K_P}$, $\mathbf{K_D}$ are PD gains. Vector $\mathbf{v}(t)$ from (3) is the FOILC controller control law which will be explained in the following subsection.

2.2. Fractional order D^α-type ILC

Here, the FOILC D^α-type controller is considered to improve trajectory tracking and ensure system robustness to uncertainties compared to integer order. The FOILC control input vector $\mathbf{v}(t)$ is defined by the following equation:

$$\mathbf{v}_i = \mathbf{Q}\left(\mathbf{v}_{i-1} + \mathbf{L_P}\,\mathbf{p}_{i-1} + \mathbf{L_F}\,D_{GL}^{\alpha_j}(\mathbf{e}_{i-1})\right), \qquad (5)$$

where i is the iteration index, j is the joint index, $\mathbf{p}_{i-1}(t)$ is the vector of PD control signal, $\mathbf{L_P}$ and $\mathbf{L_F}$ are positive diagonal learning gain matrices, $D_{GL}^{\alpha_j}$ is the fractional derivative operator of the order α_j according to the Griunwald-Letnikov definition, and $\mathbf{Q}$ is positive diagonal robustness matrix. The overview of the proposed controller structure is displayed in Figure 1.

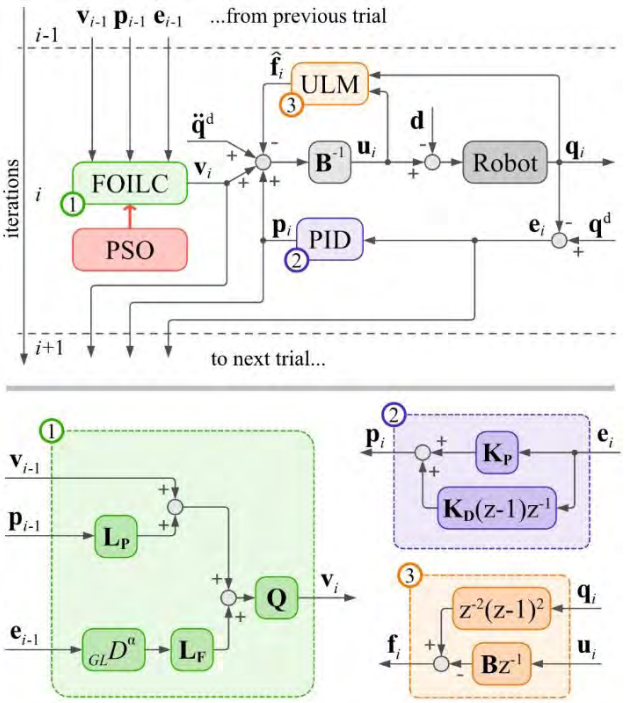

Figure 1. Control scheme of the proposed i-PD FOILC controller for robot LOLA15.

2.3. Tuning procedure using Particle Swarm Optimization

Introducing fractional derivative and integral operators into the control law increases the number of tunable degrees of freedom, which in turn leads to improved performance. Reference [16] demonstrates that raising the fractional order α of the derivative operator accelerates error convergence. This observation motivates treating α as a tunable parameter of the FOILC law. The same reasoning applies to the learning gain matrices $\mathbf{L_P}$ and $\mathbf{L_F}$ that appear in the FOILC control law (5), since both directly shape the system's output and are likewise subject to tuning. In contrast, the elements of the robustness filter matrix $\mathbf{Q}$ is held constant and excluded from the tuning procedure, leaving α, $\mathbf{L_P}$ and $\mathbf{L_F}$ as the only parameters to be optimized.

Unlike classical PID controllers, PID-type ILC laws such as (5) lack a widely accepted tuning methodology. For this reason, the Particle Swarm Optimizer (PSO) algorithm was selected as a straightforward approach to solving the FOILC parameter-tuning problem. PSO is a population-

based, nature-inspired optimization technique modeled on the collective behavior of social organisms such as flocking birds or schooling fish. Since its introduction in [17], the algorithm has become a widely used heuristic for tackling complex optimization tasks, and numerous variants and refinements have emerged over the years. This work adopts the PSO variant described in [18]; the corresponding algorithm parameters are listed in Table 1, most of which were determined empirically. Rather than re-tuning α, $\mathbf{L_P}$ and $\mathbf{L_F}$ after every single iteration as in [13,14], a fixed-horizon tuning approach is adopted: PSO is run once to find a single set of FOILC parameters, with the objective function evaluated over a fixed horizon of i_{max} ILC iterations rather than a single one. Per-iteration tuning was avoided because allowing the gains to vary from one iteration to the next undermines the contraction argument underlying ILC's convergence guarantees and reduces the search to a one-step-ahead optimization, which can drive the error toward divergence rather than zero.

To quantify tracking performance for tuning, standard error-based performance criteria like the Integral of Squared Error (ISE), the Integral of Time-weighted Squared Error (ITSE), the Integral of Absolute Error (IAE), and the Integral of Time-weighted Absolute Error (ITAE) are compared to evaluate which yields the best performance improvement for the proposed control system. The general form of the objective function minimized by PSO, evaluated over the fixed tuning horizon, is given as:

$$C = \sum_{k=1}^{i_{max}} J_k + P_b + P_{sat} + P_m, \tag{6}$$

where i_{max} denotes the duration of the tuning horizon, J_k represents the selected performance-criterion weighting corresponding respectively to ISE, ITSE, IAE, and ITAE:

$$ISE: J_k = \sum_{j=1}^{n} \int_0^T e_j^2(t)dt, \tag{7}$$

$$IAE: J_k = \sum_{j=1}^{n} \int_0^T |e_j(t)|dt, \tag{8}$$

$$ITSE: J_k = \sum_{j=1}^{n} \int_0^T te_j^2(t)dt, \tag{9}$$

$$ITAE: J_k = \sum_{j=1}^{n} \int_0^T t|e_j(t)|dt, \tag{10}$$

Term P_b from (6) is a bound violation penalty applied according to the following cases:

$$P_b = \begin{cases} 0, & L_{P_{jj}}, L_{F_{jj}}, \alpha_j > 0 \\ 1000, & \text{otherwise} \end{cases}. \tag{11}$$

Beyond penalizing particles for violations of tuned parameter bounds, the tuning procedure also enforces the manipulator's joint torque saturation limits as an explicit constraint:

$$P_{sat} = \begin{cases} 0, & |u_j| < [2130, 4500, 2118] \\ 1000, & \text{otherwise} \end{cases}. \tag{12}$$

Through this mechanism, P_{sat} effectively removes from the search process any particles that either destabilize the system or push its joint torques beyond their allowable limits by imposing an additional cost on them. Finally, penalty term P_m penalizes monotonicity violation across ILC iterations:

$$P_m = \begin{cases} 0, & \|\mathbf{e}_{k-1}\| < \|\mathbf{e}_k\| \\ 2 \cdot (\|\mathbf{e}_{k-1}\| - \|\mathbf{e}_k\|), & \text{otherwise} \end{cases}. \tag{13}$$

Table 1. Parameters for the PSO algorithm.

Variable	Value
Population number	30
Iteration number	10
Initial value of the individual-best acceleration factor	0.5
Final value of the individual-best acceleration factor	2.5
Initial value of the global-best acceleration factor	2.5
Final value of the global-best acceleration factor	0.5
Initial value of the inertia factor	0.9
Final value of the inertia factor	0.6

3. SIMULATION RESULTS

The proposed controller is tested through simulation using the LOLA15 industrial robot dynamics model with only the first three degrees of freedom considered. The masses of links 5 and 6 are added to the mass of link 4, since only a 3-DoF structure is considered. The experimental results are out of scope for this study since an experimental study requires additional torque safeguards to be implemented on the real controller. The LOLA15 robot's kinematics and dynamics parameters are listed in [19] and simulation is carried out in Simulink using the Robotics Systems Toolbox and Runge-Kutta solver (ode4) for ordinary differential equations with fixed-step T_s = 0.001s. The desired joint-space trajectories are obtained via inverse kinematics, converting end-effector desired path defined in the Cartesian space as a continuous circular path as illustrated in Figure 2.

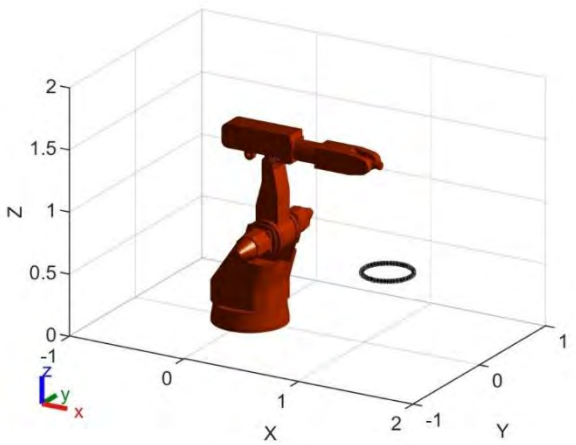

Figure 2. LOLA15 robot and desired path of the end-effector.

The gain matrices $\mathbf{K_P}$ and $\mathbf{K_D}$ of the PD controller are tuned empirically to a non-optimal solution in order to emphasize

the influence of FOILC on potentially under-tuned real systems. FOILC control parameters are tuned as described in subsection 2.3 of this paper and robustness matrix **Q** is set as diag([0.9 0.9 0.9]). The tuned control system parameters are given in Tables 2., 3., 4. and 5. This study measures the ILC controllers' performance quality in the iteration domain with the infinite norm of the error:

$$\|e_j\|_\infty = \max_k |e_j(t)|, \tag{14}$$

Table 2. Tuned parameters of the FOILC controller for ISE criterion.

$\mathbf{L_P}$	diag([0.09, 1.05, 1.32])
$\mathbf{L_F}$	diag([0.16, 1.33, 0.42])
α	[0.97, 1.89, 1.62]

The measure in (15), graphed for each iteration, shows how much the maximum absolute error of each joint is reduced (or increased if the learning process is unstable) after each iteration.

Based on the adopted quality measure in (15), Figure 3 shows that the FOILC controller improves the system's tracking performance, and for every joint and every criterion, the learning process is stable and convergent, meaning the maximum absolute error decreases over iterations for this setup.

Examining Figure 3 further, it can be seen that for the first joint, there is a minimal difference in performance among the selected criteria. On the other hand, there is a clear distinction between all selected criteria for the maximum absolute error for joint 2. ITSE criterion error reduction is the smallest relative to the other selected criteria, followed by ISE and IAE, and finally, the ITAE criterion shows best performance with the lowest converged maximum absolute error at the 10th iteration.

Maximum absolute error convergence for the joint 3 features situation, where performance is split into two groups: ITAE and ISE have similar error values compared to the IAE and ITSE group, which are almost identical but slower in convergence compared to the former.

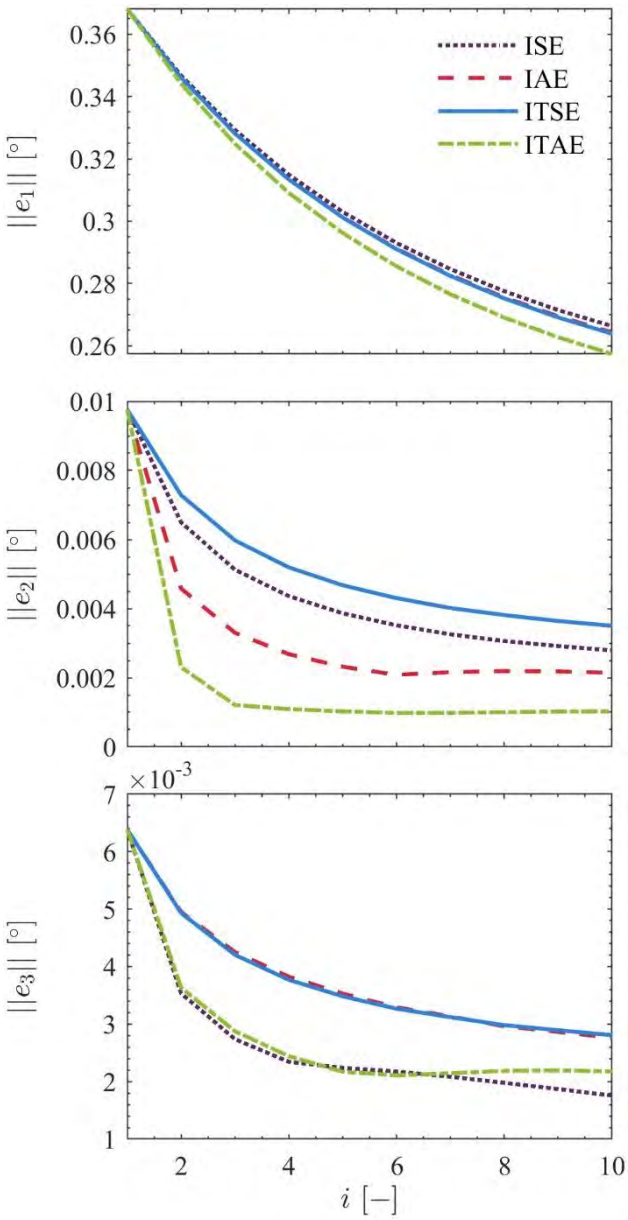

Figure 3. Infinite norm of the joint position error per joint comparison between ISE, IAE, ITSE and ITAE performance criteria.

Figure 4 shows joint position errors and indicate that FOILC enhances performance across iterations and illustrates differences between selected performance criteria in time domain. Figure 4 reflects results shown in Figure 3 in time domain at 10th iteration i.e. at the end of the learning process.

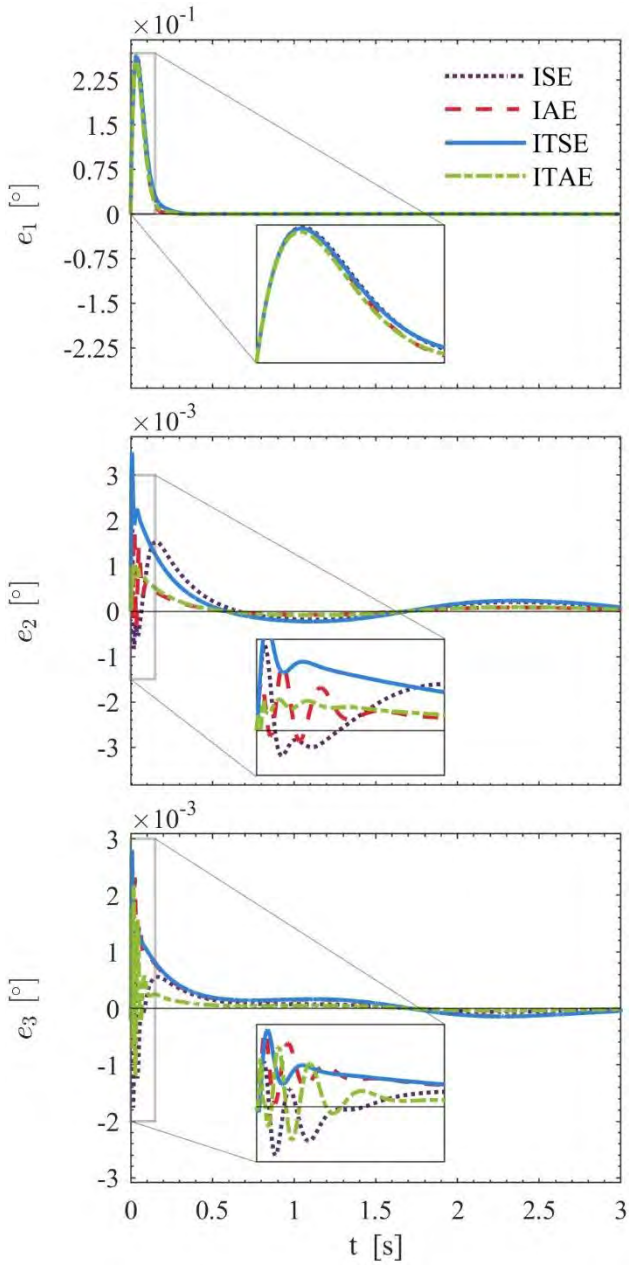

Figure 4. Joint position error at the 10-th iteration per joint comparison between ISE, IAE, ITSE and ITAE performance criteria.

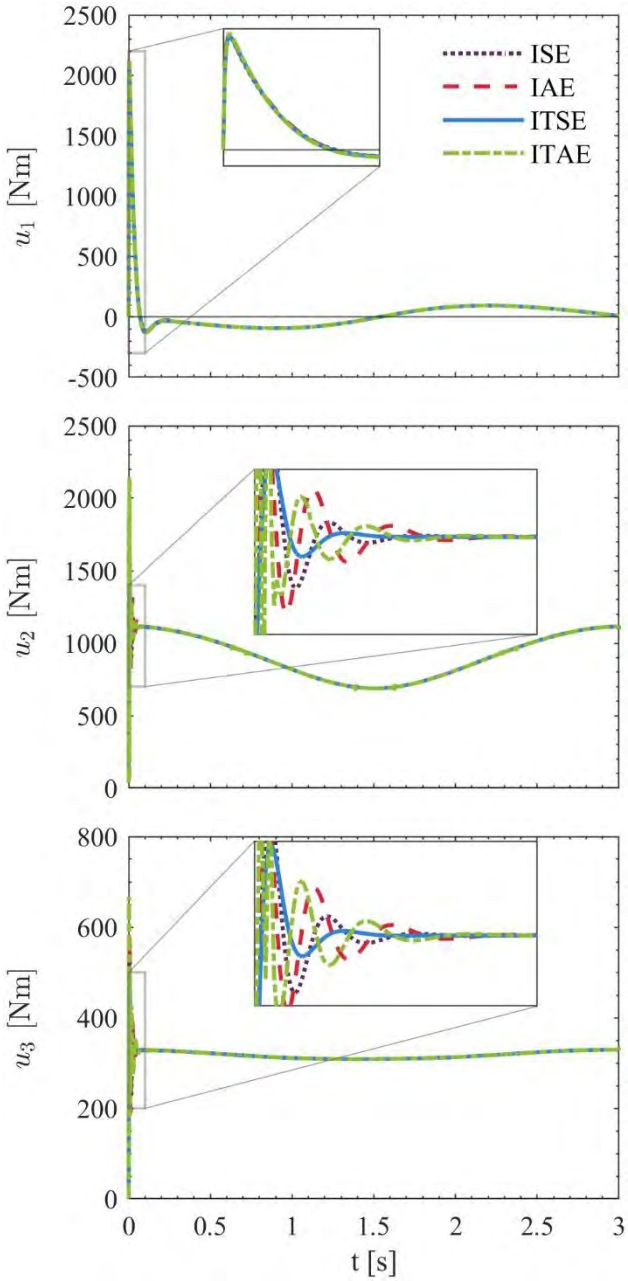

Figure 5. Joint control effort at the 10-th iteration per joint comparison between ISE, IAE, ITSE and ITAE performance criteria.

For joint 1, it is the same as in Figure 3: there are negligible differences among the selected criteria in performance. Joint 2 shows clearly that ITSE has the largest maximum absolute value among all selected criteria, and error tends to settle at zero for all criteria. Joint 3 error e3 again illustrates the same grouped distinction as in Figure 3.

Figure 5 shows joint control effort at the 10th iteration, and the most important conclusion is that none of the three joints enter torque saturation across all performance criteria.

4. CONCLUSION

This paper presented a control scheme combining Fractional-order Iterative Learning Control with a position PD controller for trajectory tracking of the LOLA15 6-DOF articulated robot. The central theme of this simulation study was the evaluation of performance across different criteria for PSO-based tuning of control parameters in the FOILC control law. Simulation results demonstrated that the proposed tuning procedure for the FOILC controller successfully improves tracking performance over successive iterations, and that, for FOILC parameter tuning of the robot LOLA15, the best criterion among the selected ones is ITAE, as it shows stable convergence and the best overall performance. The results show that the choice of optimization criterion affects both convergence behavior

and final tracking accuracy, and that this should be considered in PSO-based FOILC tuning. Future work will include experimental validation of the physical manipulator further to confirm the effectiveness of the proposed control approach.

METHOD AND SYSTEM FOR THROUGH-THE-WALL RADAR IMAGING

MLADEN ŽIVKOVIĆ
Military Academy, Belgrade, Serbia, zm215039p@student.etf.bg.ac.rs

Abstract: *Through-the-wall radar imaging is a challenging problem in integrated sensor systems due to strong reflections from walls that obscure weak target responses. This paper presents a method and system for through-the-wall imaging based on the processing of numerically generated scattering data, without requiring prior knowledge of wall characteristics or reference measurements. The proposed approach focuses on enhancing target visibility and improving image quality in complex and obstructed environments. The proposed method and system are intended for integration into advanced sensor and robotic platforms requiring reliable situational awareness. Numerical results demonstrate effective suppression of unwanted reflections and improved target localization performance. The approach is evaluated in comparison with conventional imaging techniques, showing competitive or improved results in terms of robustness and detection capability. Reliable detection of targets behind walls is achieved, with potential applications in surveillance, search and rescue, and autonomous sensing systems.*

Keywords: *Through-the-wall radar imaging, wall clutter suppression, target detection, integrated sensor systems, robotic sensing.*

1. INTRODUCTION

Through-the-wall radar imaging (TWRI) represents an important sensing technology for the detection and localization of targets in visually obscured environments. In many practical scenarios, such as surveillance, search and rescue operations, disaster response, and autonomous robotic inspection, optical sensors and conventional imaging systems are ineffective because the region of interest is hidden behind walls or other obstacles [1]-[2]. Radar systems, due to their ability to penetrate dielectric materials and operate under poor visibility conditions, provide a promising solution for obtaining situational awareness in such environments.

Despite its potential, through-the-wall imaging remains a highly challenging problem. The electromagnetic wave transmitted by the radar is strongly affected by the wall, resulting in reflections, attenuation, phase distortion, multipath propagation, and clutter. In many cases, the wall response is significantly stronger than the response of the target behind it. As a consequence, weak target signatures can be masked by dominant wall reflections, which reduces the quality of the reconstructed image and degrades target localization accuracy. This problem becomes even more difficult when the wall parameters are unknown or when reference measurements of the empty scene are not available.

A common approach for wall clutter mitigation is background subtraction, where a reference measurement containing only the wall response is subtracted from the measurement containing the target [3]-[4]. However, such an approach requires access to a target-free scene, which is often unrealistic in real applications. In addition, small changes in the environment, antenna position, or wall properties can reduce the effectiveness of reference-based methods. Therefore, there is a need for imaging techniques that can suppress unwanted wall reflections directly from measured radar data, without requiring prior knowledge of the wall structure or reference measurements.

Recent research in radar sensing has also shown the importance of robust signal processing when radar systems are used in complex and obstructed environments. For example, radar mounted on unmanned aerial vehicles has been investigated for detecting and monitoring people in collapsed buildings, where strong reflections from static objects and platform motion must be compensated before weak human-related signals can be extracted [5]. Such systems demonstrate that reliable detection in difficult environments depends not only on the radar hardware, but also on advanced processing methods capable of suppressing unwanted responses and enhancing the desired target information.

In this paper, a method and system for through-the-wall radar imaging are proposed based on the processing of numerically generated scattering data. The main objective is to improve target visibility and localization performance in the presence of strong wall reflections and clutter. Unlike conventional approaches that rely on reference measurements or known wall parameters, the proposed method operates directly on the available measured data. By applying data-driven processing, the dominant unwanted components are reduced, while the weaker target-related responses are enhanced.

The proposed approach is intended for integration into advanced sensor and robotic platforms that require reliable situational awareness in obstructed environments. Such platforms may include mobile robots, unmanned ground vehicles, or aerial systems used in surveillance, emergency response, and search and rescue missions.

The performance of the proposed method is evaluated

DOI: 10.5937/OTEH26065Z

using numerical data. The obtained results are compared with conventional imaging techniques in order to assess target localization accuracy, robustness, and clutter suppression capability. The results demonstrate that the proposed method can effectively suppress dominant wall reflections and improve the visibility of targets behind walls.

2. THROUGH-THE-WALL RADAR IMAGING SYSTEM AND METHOD

The proposed through-the-wall radar imaging system consists of a stationary linear antenna array, a measurement unit for acquiring complex scattering parameters, and a signal-processing module for wall-clutter suppression and image reconstruction (Figure 1).

A linear array containing M antenna elements is positioned in front of the wall, as illustrated in Figure 2. Each antenna element is successively used for signal transmission and reception. Consequently, the complete set of transmit–receive measurements forms the complex scattering matrix:

$$\mathbf{S} \in \mathrm{C}^{M\times M}. \tag{1}$$

The measured scattering matrix can be represented as

$$\mathbf{S} = \mathbf{S}_{\text{wall}} + \mathbf{S}_{\text{target}} + \mathbf{N}, \tag{2}$$

where $\mathbf{S}_{\text{wall}}$ represents the dominant wall reflection, $\mathbf{S}_{\text{target}}$ contains the target responses, and $\mathbf{N}$ denotes measurement noise and other unwanted components.

2.1. Signal Preprocessing

The wall reflection is generally considerably stronger than the field scattered from a target. Therefore, direct image reconstruction from the original scattering matrix may result in strong wall-related artifacts.

As the first preprocessing step, the measured matrix is centered column-wise. The mean column vector is calculated as

$$\bar{\mathbf{s}} = \frac{1}{M}\sum_{m=1}^{M} \mathbf{s}_m, \tag{3}$$

where $\mathbf{s}_m$ denotes the mth column of $\mathbf{S}$. The centered scattering matrix is then obtained as

$$\mathbf{S}_c = \mathbf{S} - \bar{\mathbf{s}}\mathbf{1}^T, \tag{4}$$

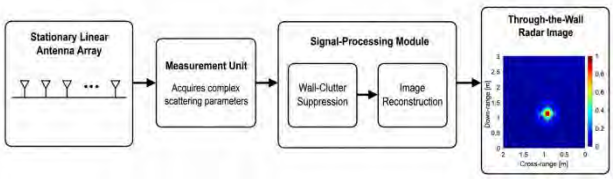

Figure 1. Proposed through-the-wall radar imaging system

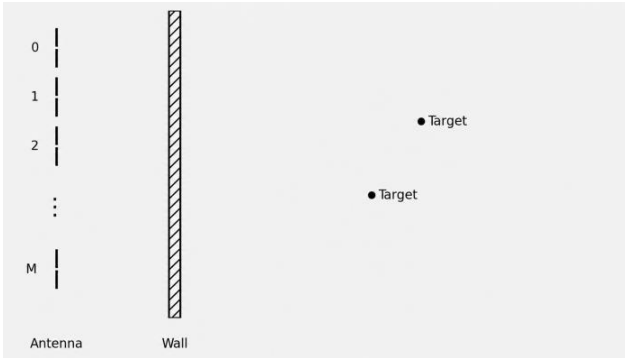

Figure 2. Geometry of the considered through-the-wall radar imaging system

where **1** is an all-ones vector of length M . This operation reduces the common-mode component present in the measured signals.

2.2. SVD-Based Wall-Clutter Suppression

Singular value decomposition is applied to the centered scattering matrix:

$$\mathbf{S}_c = \boldsymbol{U\Sigma V}^H, \tag{5}$$

where **U** and **V** contain the left and right singular vectors, respectively, while

$$\boldsymbol{\Sigma} = \operatorname{diag}(\sigma_1, \sigma_2, \dots, \sigma_M). \tag{6}$$

contains the singular values arranged in descending order,

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_M \geq 0. \tag{7}$$

The dominant wall reflection is assumed to occupy a low-rank subspace associated with the largest singular values. To determine the wall-subspace dimension, the singular values are first normalized:

$$\sigma_{norm,k} = \frac{\sigma_k}{\max\limits_i(\sigma_i)}. \tag{8}$$

The rank estimate is obtained by applying Otsu's threshold γ_{Otsu} to the normalized singular-value spectrum:

$$r = max\{k: \sigma_{norm,k} \geq \gamma_{Otsu}\}. \tag{9}$$

The low-rank wall component is reconstructed according to:

$$\mathbf{S}_{\text{wall}} = \mathbf{U}_{(:,1:r)}\boldsymbol{\Sigma}_{(1:r,1:r)}\mathbf{V}^H_{(:,1:r)}. \tag{10}$$

The sparse residual containing the target response is obtained by subtracting the estimated wall component:

$$\mathbf{S}_{\text{sparse}} = \mathbf{S}_c - \mathbf{S}_{\text{wall}}. \tag{11}$$

2.3. Regularized Image Reconstruction

The sparse scattering matrix is decomposed again using SVD:

$$\mathbf{S}_{\text{sparse}} = \mathbf{U}_t\boldsymbol{\Sigma}_t\mathbf{V}_t^H. \tag{12}$$

For every point $\mathbf{p} = (x_i, y_j)$ within the region of interest, the steering vector is calculated as

$$\mathbf{a}(\mathbf{p}) = \begin{bmatrix} \exp\left(-j\frac{2\pi f}{c}d_1(\mathbf{p})\right) \\ \exp\left(-j\frac{2\pi f}{c}d_2(\mathbf{p})\right) \\ \vdots \\ \exp\left(-j\frac{2\pi f}{c}d_M(\mathbf{p})\right) \end{bmatrix}, \quad (13)$$

where

$$d_m(\mathbf{p}) = \sqrt{\{(x_i - x_m)^2 + y_j^2\}} \quad (14)$$

is the distance between the mth antenna element and the considered image point, while c is the speed of light. The regularization parameter is determined from the singular values and the statistics of the wall-suppressed residual (sparse) matrix:

$$\alpha = \kappa \frac{\max(\boldsymbol{\sigma}_t)}{1 + \operatorname{std}(\mathbf{S}_{\text{sparse}})} \quad (15)$$

where

$$\kappa = 0.01 \frac{\operatorname{std}(\boldsymbol{\sigma}_t)}{\operatorname{mean}(\boldsymbol{\sigma}_t)} \quad (16)$$

For each sampling point $\mathbf{p}$, the regularized solution vector is calculated using a truncated Tikhonov filter:

$$\mathbf{f}(\mathbf{p}) = \sum_{k=1}^{r} \frac{\sigma_{t,k}}{\sigma_{t,k}^2 + \alpha^2} \left(\mathbf{u}_{t,k}^H \mathbf{a}(\mathbf{p})\right) \mathbf{v}_{t,k}. \quad (17)$$

Finally, the image intensity is defined as

$$L(\mathbf{p}) = \frac{1}{\|\mathbf{f}(\mathbf{p})\|_2^2} \quad (18)$$

3. NUMERICAL RESULTS AND METHOD COMPARISON

The performance of the proposed through-the-wall radar imaging system was evaluated using scattering parameters numerically generated in WIPL-D Pro, a full-wave three-dimensional electromagnetic solver based on the Method of Moments [7]. The objective was to determine whether the proposed processing method can suppress the dominant wall response and preserve the weaker fields scattered from targets located behind the wall.

The proposed method was compared with the Multiple Signal Classification (MUSIC) method [3] and the Linear Sampling Method (LSM) [6]. All methods were evaluated using the same antenna geometry, wall configuration, region of interest, and spatial discretization.

3.1. Imaging Scenario

The considered TWRI configuration consists of a uniform linear antenna array placed at a distance of 0.3 m from the front surface of the wall. The antenna array consists of M = 21 dipoles operating at a frequency of f = 1 GHz. The region of interest (ROI) is discretized into a rectangular grid spanning x ∈ [0, 2] meters in the cross-range and down-range directions y ∈ [0, 3] meters, with 100 × 100 pixel resolution.

The wall is placed in front of the array, while the targets are positioned behind it, as illustrated in Figure 2. The wall dimensions are 2×2×0.2 m, where 0.2 m represents the wall thickness. The wall is modeled as a homogeneous dielectric medium with a relative permittivity of $\varepsilon_r = 6$.

The targets are modeled as perfectly electrically conducting (PEC) objects with the shape of small human figures. Two target configurations are considered. In the single-target scenario, the target is located at (0.75, 1, 0) m. In the multi-target scenario, three targets are positioned at (1, 1.5, 0) m, (1.75, 2.5, 0) m, and (2, 2 ,0) m, respectively. These configurations allow the localization performance and robustness of the proposed method to be evaluated under different scene complexities.

For MUSIC and LSM, the background-subtracted scattering matrix is calculated as

$$\mathbf{S}_\Delta = \mathbf{S}_{target} - \mathbf{S}_{bg}, \quad (19)$$

where $\mathbf{S}_{target}$ denotes the scattering matrix measured with the targets present and $\mathbf{S}_{bg}$ represents the corresponding background measurement without targets.

In contrast, the proposed method operates directly on the measured matrix $\mathbf{S}$, without requiring a background measurement or prior knowledge of the electromagnetic properties of the wall.

3.2. Reference Imaging Methods

The LSM reconstructs an indicator function by solving a regularized inverse problem for each sampling point within the imaging region. The method uses the background-subtracted matrix $\mathbf{S}_\Delta$ as the operator kernel [6].

The norm of the regularized solution is used to define the imaging indicator. High indicator values correspond to positions at which a target is likely to be present.

The MUSIC method estimates target positions by projecting the steering vector onto the noise subspace. For each point $\mathbf{p}$ within the region of interest, the MUSIC pseudo-spectrum is calculated as

$$P_{\text{MUSIC}}(\mathbf{p}) = \frac{1}{\mathbf{a}^H(\mathbf{p})\mathbf{E}n\mathbf{E}_n^H\mathbf{a}(\mathbf{p})}, \quad (20)$$

where $\mathbf{E}n$ contains the eigenvectors associated with the noise subspace. Large values of $P_{\text{MUSIC}}(\mathbf{p})$ indicate possible target locations [3].

3.3. Single-Target Results

Figure 3 compares the reconstructed images obtained using LSM, MUSIC, and the proposed method for the single-target scenario. The actual positions and dimensions of the targets are indicated by black squares.

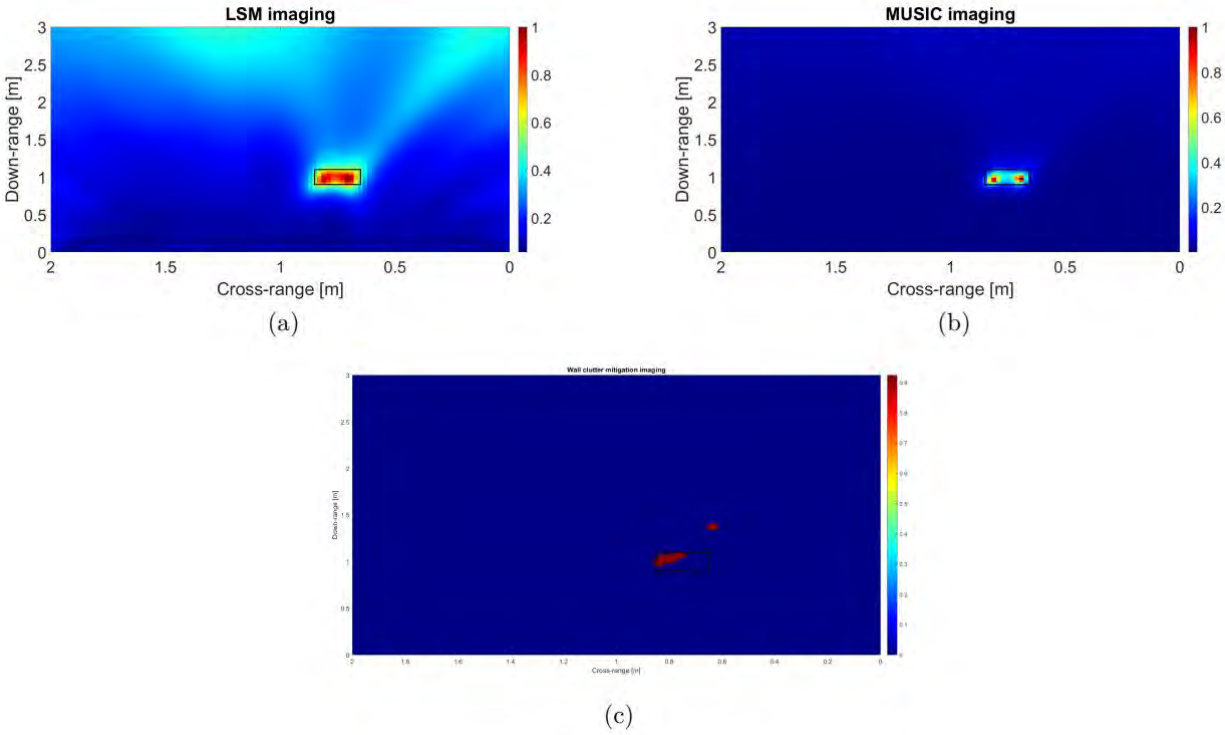

Figure 3. Comparison of reconstructed images for the single-target scenario: (a) LSM, (b) MUSIC, and (c) proposed method.

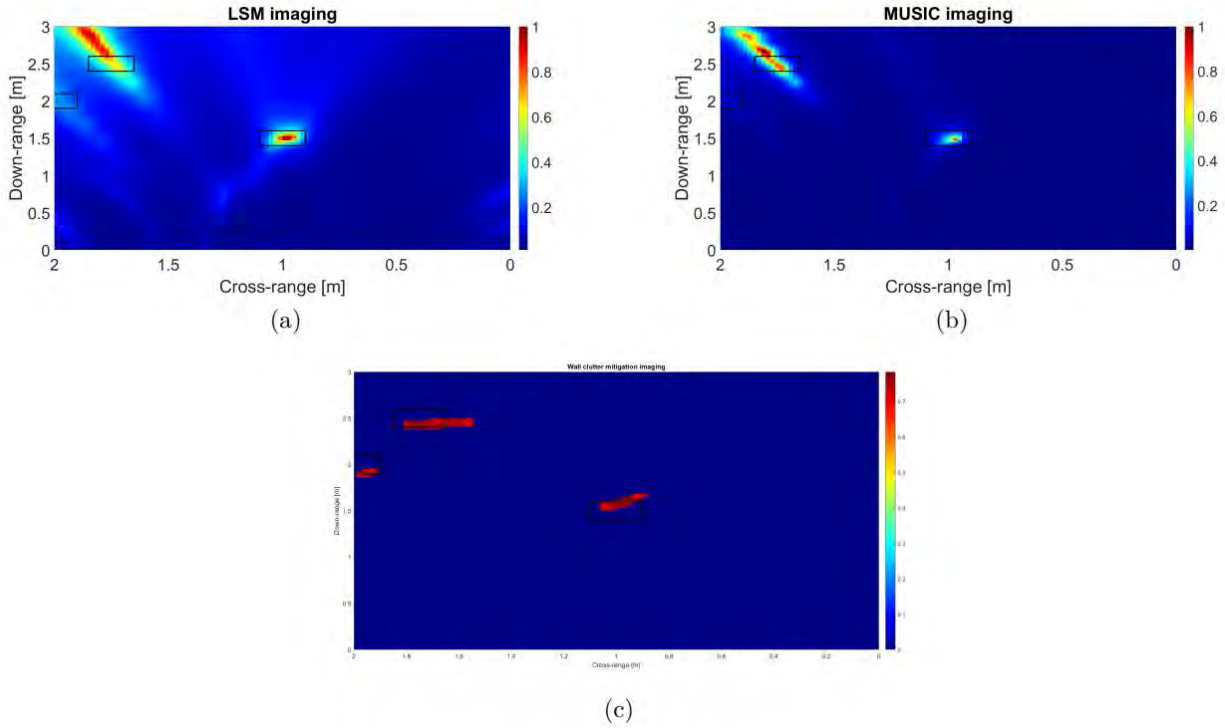

Figure 4. Comparison of reconstructed images for the multi-target scenario: (a) LSM, (b) MUSIC, and (c) proposed method.

The LSM reconstruction indicates the approximate target position, but the target response is broadened and accompanied by an elevated background level. These effects reduce image contrast and may make precise target localization difficult.

The MUSIC method produces a more compact response and a lower background level. However, the reconstructed target region contains a split peak, indicating that the target response is distributed between two closely spaced image maxima.

The proposed method significantly attenuates the dominant wall reflection and produces a clearly visible response in the vicinity of the actual target position. Minor isolated artifacts may remain outside the main target region, but their intensity is considerably lower than the dominant target response. The results demonstrate that the wall clutter can be suppressed without using a reference measurement.

3.4. Multi-Target Results

Figure 4 presents the reconstructed images for the scenario containing three targets behind the wall.

The LSM reconstruction contains broadened target responses, wall-related artifacts, and sidelobe-like structures. Although the regions associated with the three targets can still be observed, the elevated background level and spatial spreading make their separation and precise localization more difficult.

MUSIC provides more compact responses and a cleaner background, allowing the three target regions to be distinguished more clearly. Nevertheless, residual energy and weak leakage remain around the dominant responses.

The proposed method reveals scattering regions associated with all three targets while substantially suppressing the direct wall response. However, compared with the single-target case, additional spurious responses and spatial smearing are present. These effects reduce the separability of closely spaced targets and may introduce localization errors.

The reduced robustness in the three-target scenario indicates that decomposition of the measured matrix into a low-rank wall component and a sparse target component becomes more challenging as the number of scatterers increases. Interactions between target responses, residual wall components, and multipath effects can further complicate the reconstruction process.

4. CONCLUSION

This paper presented a through-the-wall radar imaging method based on SVD-based wall-clutter suppression. The proposed approach operates directly on the available scattering matrix and does not require a background measurement or prior knowledge of the wall parameters.

Numerical results obtained from scattering parameters generated in WIPL-D demonstrated that the method substantially reduces the dominant wall response while preserving target-related scattering information. In the single-target scenario, the proposed method produced a focused target response with a low background level and performance comparable to MUSIC and LSM, although both reference methods relied on background-subtracted data.

In the three-target scenario, the proposed method continued to indicate the target regions, but residual artifacts and spatial smearing reduced target separability and localization accuracy. This result shows that the low-rank wall and sparse target decomposition becomes more challenging as the number of scatterers and scene complexity increase.

Future work will focus on improving multi-target robustness through multifrequency processing, adaptive wall-subspace rank selection, enhanced sparse regularization, and more accurate propagation models that account for wall refraction, dispersion, and multipath effects.

Abstract: *Automatic image captioning is a fundamental artificial intelligence task at the intersection of computer vision and natural language processing. This paper presents a generative encoder-decoder model for automatic caption generation from images of military exercises. The model employs an ImageNet-pre-trained 152-layer Residual Network (ResNet-152) encoder to extract visual representations and a long short-term memory (LSTM) decoder to generate corresponding textual descriptions. The original model was trained on the Microsoft Common Objects in Context (MS COCO) dataset and subsequently fine-tuned on a domain-specific collection of military-exercise images. Five pseudo-reference captions per image were generated automatically using Florence-2 and used to supervise domain adaptation.*

Experimental evaluation was performed on a held-out military-domain test set containing 25 images. The fine-tuned model achieved Bilingual Evaluation Understudy scores of 70.87, 49.67, 33.61, and 21.94 for BLEU-1, BLEU-2, BLEU-3, and BLEU-4, respectively, together with a Recall-Oriented Understudy for Gisting Evaluation based on the longest common subsequence (ROUGE-L) score of 45.52. On the same military test set, the original MS COCO checkpoint achieved 52.00, 33.10, 23.00, 15.80, and 37.05, respectively. These results indicate that domain-specific fine-tuning improves agreement with the available military-domain reference captions.

However, because the test set is small and its reference captions were generated automatically rather than independently written by domain experts, the reported results should be interpreted as preliminary evidence rather than a definitive estimate of performance on the broader military-image domain. The proposed architecture may provide a basis for future investigation of onboard semantic reporting and bandwidth-efficient communication on unmanned platforms, while its practical contribution can be further experimentally validated through the evaluation of execution speed, energy consumption, and communication savings on a real unmanned aerial vehicle.

Keywords: *image captioning, LSTM, ResNet, encoder-decoder, domain-specific dataset, military-exercise*

1. INTRODUCTION

Automatic image captioning addresses one of the central challenges in machine learning: converting visual perception into structured natural language. Unlike image classification or object detection, where the output is usually a fixed label or a set of localized categories, caption generation requires a model to identify objects, infer their attributes and relations, and express the resulting scene understanding as a grammatically coherent sentence. This makes image captioning a representative vision-language problem at the intersection of computer vision and natural language processing.

The practical relevance of automatic image captioning is particularly strong in scenarios where large volumes of visual data must be interpreted and communicated efficiently. In surveillance, reconnaissance, digital archiving, assistive technologies, and autonomous robotic systems, raw image and video streams can contain substantially more data than can be transmitted, stored, or inspected in real time. A compact textual description may provide a semantic summary of a scene and support filtering, indexing, prioritization, and operator decision-making. For distributed systems, including unmanned platforms, onboard caption generation could potentially reduce the amount of visual data that must be transmitted to a central station. Nevertheless, the present study evaluates only captioning accuracy on an offline image dataset. It does not experimentally evaluate onboard inference, real-time processing, energy consumption, communication latency, or operation on an actual unmanned platform.

In this paper, we study automatic caption generation for images of military exercises. This domain introduces a meaningful distribution shift with respect to general-purpose image-captioning datasets because the scenes may contain specialized equipment, formations, activities, uniforms, vehicles, and operational contexts that are underrepresented in broad collections of everyday

Corresponding author: A. Denić;
E-mail: andja.denic@elfak.ni.ac.rs
DOI: 10.5937/OTEH26066D

imagery. The original model was trained on the Microsoft Common Objects in Context (MS COCO) dataset, which provides useful general visual and linguistic regularities but does not adequately represent all concepts found in military-training environments. Domain adaptation is therefore investigated as a means of improving the relevance of generated descriptions for the target imagery.

The proposed approach follows an encoder-decoder paradigm. A 152-layer Residual Network (ResNet-152) acts as the visual encoder and transforms an input image into a fixed-dimensional representation. A long short-term memory (LSTM) network then generates the caption sequentially, one word at a time. The model is first trained on MS COCO and subsequently fine-tuned on automatically annotated military-exercise images. The principal contribution is an end-to-end domain-adaptation pipeline that connects target-domain data collection, automatic annotation, deterministic image preprocessing, image-level dataset partitioning, parameter-efficient fine-tuning, and comparative evaluation of the original and adapted checkpoints.

This architecture offers a favorable balance between modeling capacity and deployment practicality. While large vision-language foundation models have recently achieved impressive performance, compact encoder-decoder systems remain attractive for edge scenarios where computational resources, latency, power consumption, and communication bandwidth are constrained. In such settings, a ResNet-LSTM model can provide interpretable and efficient caption generation without requiring continuous transmission of high-resolution visual streams.

The main contribution of this work is an end-to-end captioning pipeline adapted to military-exercise imagery. The paper demonstrates how a general image-captioning model can be transferred from MS COCO to a specialized operational domain, evaluates the impact of fine-tuning using standard captioning metrics, and discusses the suitability of the resulting system for distributed surveillance and drone-based deployment. Experimental results indicate that domain-specific fine-tuning improves the quality and relevance of generated captions compared with the base model trained only on generic data.

2. THEORETICAL BACKGROUND AND RELATED WORK

The present study extends the encoder-decoder framework examined in the preceding work. A central instance of this framework is the neural image-caption generator introduced by Vinyals et al. [1], in which a convolutional neural network (CNN) encodes an image and a recurrent neural network (RNN) estimates the probability of a caption conditioned on the resulting visual representation.

Let I denote an input image and Y its caption of length T. The model factorizes the conditional probability of the complete caption autoregressively as

$$P_\theta(Y \mid I) = \prod_{t=1}^{T} P_\theta(y_t \mid I, y_1, y_2, \dots, y_{t-1}) \qquad (1)$$

where θ contains the trainable parameters of the visual encoder, word-embedding layer, recurrent decoder, and output classifier. Learning is performed by maximizing the conditional likelihood of the reference captions, or equivalently by minimizing token-level cross-entropy. This probabilistic formulation provides a direct connection between visual representation learning and sequence modeling and is the theoretical basis of both the original model and its domain-specific adaptation considered here.

The visual encoder used in this work is based on ResNet-152. Residual networks introduce identity shortcuts that allow a stack of nonlinear layers to learn a residual mapping rather than an unconstrained direct mapping, thereby facilitating the optimization of very deep convolutional architectures [2]. In the adopted implementation, the classification layer of a ResNet-152 model pre-trained on ImageNet is removed. Global image features produced by the convolutional backbone are transformed by an additional linear layer and batch-normalization layer into a fixed-dimensional context vector. Transfer learning is particularly important in the present setting because a comparatively small collection of military-exercise images is insufficient for learning a deep visual representation from random initialization.

The decoder is a long short-term memory network. LSTM units were designed to model long-range dependencies through a recurrent cell state regulated by input, forget, and output gates [3]. For image captioning, the encoded image is supplied to the recurrent model before the textual sequence, after which the decoder predicts one word at a time. The probability distribution over the vocabulary at time step t depends on the current LSTM hidden state, which summarizes the image representation and the previously observed or generated words. During training, reference tokens are provided as preceding inputs, whereas inference is autoregressive and uses the model's own previous predictions.

MS COCO dataset provides a broad source domain for learning general visual and linguistic regularities because it contains complex everyday scenes paired with multiple human-written captions [4]. Nevertheless, its content distribution differs from that of military-training imagery. Uniforms, formations, specialized vehicles, aircraft, vessels, weapons, field exercises, and operational activities may occur rarely or under different contextual priors in a general-purpose dataset. As a result, a model trained only on MS COCO can produce grammatically plausible captions while omitting domain-relevant details or selecting vocabulary that is semantically inappropriate for the target environment. The problem addressed in this paper is therefore one of domain adaptation: knowledge acquired from a large generic dataset is retained, while the trainable components are updated using target-domain image-caption pairs.

The broader development of vision-language modeling has introduced attention mechanisms, Transformer architectures, and large prompt-conditioned foundation models. Visual attention allows a decoder to select spatially relevant image regions while generating

individual words [5], whereas Transformer-based models replace recurrence with attention-based sequence processing [6]. Florence-2 represents a more recent unified approach: it treats captioning, detection, grounding, and related tasks as prompt-conditioned sequence generation within a single vision-language model [7]. In the present pipeline, Florence-2 is not the final deployed captioning model and its parameters are not fine-tuned. Instead, the pre-trained Florence-2 model is used as an automatic annotation system that generates pseudo-reference captions for the military-exercise images. These annotations subsequently supervise the fine-tuning of the more compact ResNet-LSTM model.

Domain-specific captioning has also been investigated for remote-sensing imagery, where the distribution of viewpoints, spatial structures, and semantic categories differs substantially from ordinary ground-level photography [8]. This line of work illustrates the general principle relevant to defence-oriented data: a captioning architecture may be transferable, but its vocabulary and conditional output distribution must be adapted to the target domain. For surveillance and drone-based platforms, compact encoder-decoder systems remain attractive because they can convert high-bandwidth visual observations into short semantic reports locally. Such use does not eliminate the need for human verification, particularly in safety-critical or operational contexts, but it can support filtering, indexing, prioritization, and bandwidth-efficient communication.

3. METHODOLOGY AND DATA

3.1. Dataset

The target-domain dataset was constructed from publicly available photographs of military exercises published on the official website of the Ministry of Defence of the Republic of Serbia. The images depict military personnel, formations, training procedures, helicopters, boats, ground vehicles, equipment, and outdoor exercise environments that are not adequately represented in general-purpose captioning datasets. The complete collection contains 167 distinct images. Of these, 142 images are used for training and validation, while 25 images form a held-out military-domain test set.

Because manually producing several independent descriptions for every image is time-consuming, the images were automatically annotated using the open-source Florence-2 model, specifically microsoft/Florence-2-base-ft. Annotation was performed using a graphics processing unit (GPU), and five pseudo-reference captions were generated for each image. These captions provide scalable supervision for fine-tuning the smaller ResNet-LSTM model, but they should not be treated as equivalent to independently written expert annotations.

The quality of the automatically generated captions directly affects both model training and evaluation. Florence-2 may omit relevant objects or actions, use overly general terminology, repeat similar sentence structures, or occasionally introduce an object that is not present in the image. Such errors act as label noise during fine-tuning and can encourage the adapted model to reproduce the same omissions, biases, or hallucinations. Moreover, because the evaluation references were generated by the same automatic annotation procedure, BLEU and ROUGE-L primarily measure agreement with Florence-2 wording and may not fully reflect factual correctness or agreement with a military-domain expert. Five captions produced by one model are also likely to be linguistically correlated and therefore do not provide the same diversity as five descriptions written independently by human annotators.

The training-validation split is performed at the image level rather than at the image-caption-pair level. Unique image identifiers are sorted, shuffled using a fixed pseudorandom seed, and partitioned using a validation ratio of 0.15. This produces 121 training images with 605 captions and 21 validation images with 105 captions. Because all captions belonging to one image remain in the same subset, direct image leakage between training and validation data is prevented. The independent test collection contains 25 images and 125 automatically generated reference captions and is used to compare the original and fine-tuned checkpoints.

The limited size of the target dataset is an important limitation of the study. In particular, results calculated on only 25 test images can be sensitive to the presence or absence of a small number of scenes, objects, and environmental conditions. Consequently, the reported metric improvements may not generalize to the full diversity of military imagery, including different exercises, equipment categories, seasons, weather conditions, illumination levels, viewpoints, sensors, and geographic environments. The current evaluation should therefore be regarded as an initial controlled comparison on the available test collection. A larger independently collected test set, preferably with captions reviewed or written by domain experts, is required for a more reliable estimate of generalization.

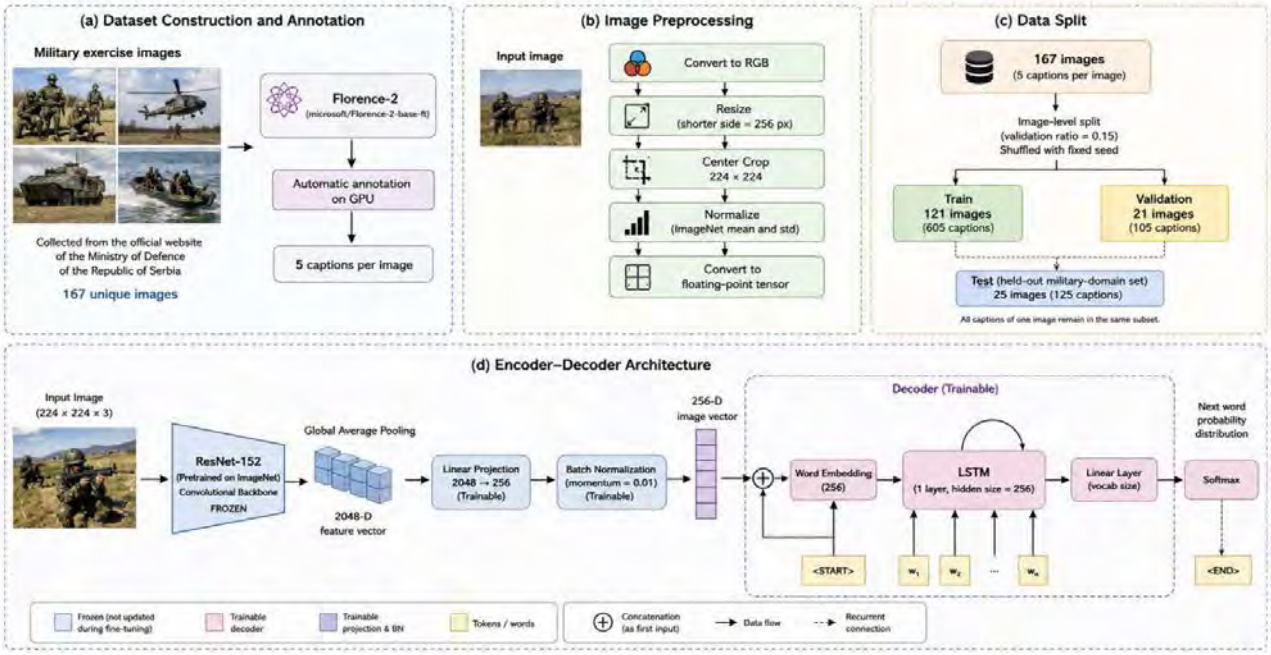

Figure 1. Overview of the methodology: (a) dataset construction and automatic annotation with Florence-2; (b) image preprocessing pipeline; (c) train/validation/test split performed at the image level; (d) encoder-decoder architecture with a frozen ResNet-152 encoder and trainable LSTM decoder

Figure 1 presents an overview of the complete methodology used in this study, from dataset construction and preprocessing to model training and inference. Before being passed to the ResNet encoder, each image is opened with the Python Imaging Library, converted to RGB, resized so that the shorter side equals 256 pixels, center-cropped to 224×224 pixels, and converted to a floating-point tensor. Channel-wise normalization uses the ImageNet statistics $\mu=(0.485, 0.456, 0.406)$ and $\sigma=(0.229, 0.224, 0.225)$, which is consistent with the pre-training of the ResNet backbone. The same deterministic transformation is used during fine-tuning and evaluation.

Because manually producing several independent captions for every image is costly, the images were automatically annotated using the open-source Florence-2 model (microsoft/Florence-2-base-ft). Annotation is performed on the GPU. Five captions have been collected for an image.

Fine-tuning performed the training-validation split at the image level rather than at the image-caption-pair level. Unique image identifiers are sorted, shuffled using a fixed pseudorandom seed, and partitioned using a validation ratio of 0.15. This yields 121 training images and 21 validation images. Because all captions associated with one image remain in the same subset, the split prevents direct image leakage between training and validation data. The held-out military-domain test collection is reserved for the comparison between the original and fine-tuned models.

3.2. Encoder-Decoder Architecture

The target model retains the architecture developed in the preceding study [1]. Its encoder is an ImageNet-pre-trained ResNet-152 with the original classification layer removed. After global average pooling, the convolutional backbone produces a 2,048-dimensional vector. A trainable linear projection maps this vector to a 256-dimensional joint representation, followed by batch normalization with momentum 0.01. All parameters in the ResNet convolutional backbone are frozen, whereas the projection and batch-normalization parameters remain trainable.

The decoder contains a word-embedding layer of dimension 256, a single-layer LSTM with a hidden-state dimension of 256, and a linear output layer whose dimension equals the vocabulary size. The image vector and word embeddings consequently occupy the same dimensional space. Following the Show and Tell formulation [1], the encoded image is inserted as the first input to the LSTM, before the <START> token and caption words. The final linear layer transforms each LSTM hidden state into unnormalized vocabulary scores, and a softmax interpretation yields the conditional probability of the next token.

Captions are converted to lowercase and punctuation is removed. The sequence is tokenized by whitespace, mapped to indices from the vocabulary inherited from the MS COCO model, and surrounded by <START> and <END> markers. Variable-length sequences are sorted within each mini-batch, padded, and packed for efficient recurrent processing. Tokens absent from the inherited vocabulary are excluded by the current preprocessing implementation rather than being used as explicit <UNK> targets. This choice preserves compatibility with the pre-trained decoder checkpoint but may remove specialized domain terminology; extending the vocabulary is therefore an important direction for subsequent work.

3.3. Training on MS COCO

The base model parameters are those obtained through training on MS COCO 2017. The source-domain training set contains more than 118,000 images, and the validation set contains 5,000 images, with approximately five human-written captions per image. The model uses a 256-dimensional image and word representation, a 256-dimensional LSTM state, and one recurrent layer. Training is conducted for 10 epochs with mini-batches of 64 examples and the Adam optimizer with a learning rate of 10^{-3}.

For a mini-batch, the encoder first produces image feature vectors, and the decoder generates vocabulary scores under teacher forcing.

The trainable parameters, denoted as θ, are the solutions to an optimization problem that maximizes the conditional likelihood of the reference captions given the input images.

The optimizer updates the complete decoder together with the encoder's linear projection and batch-normalization layer; the ResNet-152 convolutional backbone remains fixed. At the end of each epoch, the average validation loss is computed without gradient tracking. The encoder and decoder checkpoints associated with the lowest validation loss are retained for inference and evaluation. At inference time, the model uses greedy decoding: the most probable word is selected at each step until the <END> token is produced or a maximum caption length of 20 tokens is reached.

3.4. Domain-Specific Fine-Tuning

Fine-tuning starts from the saved encoder and decoder checkpoints of the MS COCO model; no component is reinitialized. The same Encoder CNN and Decoder RNN classes, vocabulary, image transformation, loss definition, and optimizer family are used to ensure architectural compatibility with the source model. The target-domain training and validation loaders use a batch size of 64.

The domain-adaptation stage is run for five epochs with Adam and a learning rate of 10^{-3}. Consequently, the frozen ResNet backbone preserves general ImageNet visual features, while the projection and language decoder adapt the joint image-text representation and conditional word distribution to the military-exercise domain. This parameter-efficient strategy reduces the computational cost and the risk of overfitting relative to updating all ResNet-152 layers on the limited target dataset.

Each epoch consists of a training phase and a validation phase. Whenever the validation loss improves, the fine-tuned state dictionaries overwrite the previous encoder and decoder checkpoints.

4. EXPERIMENTAL RESULTS

The experiments were conducted using an NVIDIA Quadro RTX 4000 graphics processing unit (GPU) with 8 GB of video memory, an eight-core central processing unit (CPU) supporting 16 processing threads, and 64 GB of random-access memory (RAM). The implementation was developed in Python using PyTorch. Torchvision provides the pre-trained ResNet-152 architecture and image transformations, while Florence-2 annotations are generated through the Hugging Face Transformers interface.

Caption quality is evaluated using the Bilingual Evaluation Understudy (BLEU) metric from BLEU-1 through BLEU-4 and the Recall-Oriented Understudy for Gisting Evaluation based on the longest common subsequence (ROUGE-L). BLEU measures modified n-gram precision with a brevity penalty [9], with larger n placing progressively greater emphasis on multiword correspondence. ROUGE-L measures sequence-level overlap using the longest common subsequence and therefore considers both shared content and word order [10]. All values in Table 1 are reported as percentages.

Table 1. Captioning performance on the base and military-domain evaluation sets (%)

Model / evaluation domain	BLEU-1	BLEU-2	BLEU-3	BLEU-4	ROUGE-L
Base model / MS COCO	68.36	50.35	35.70	25.23	49.51
Original model / military test set	52.00	33.10	23.00	15.80	37.05
Fine-tuned model / military test set	**70.87**	**49.67**	**33.61**	**21.94**	**45.52**

When the original MS COCO checkpoint is applied directly to the military test set, all metrics decrease relative to its source-domain performance, confirming the presence of a distribution shift. Fine-tuning improves BLEU-1, BLEU-2, BLEU-3, BLEU-4, and ROUGE-L on the same military test set by 18.87, 16.57, 10.61, 6.14, and 8.47 percentage points, respectively. Because both checkpoints are evaluated using the same images and reference captions, this comparison provides evidence that adaptation improves agreement with the available target-domain annotations.

Nevertheless, the military test set contains only 25 images. Metric values calculated from such a small collection may have high sampling variability and can be disproportionately influenced by a few easy or difficult examples. No confidence intervals or repeated evaluations on independently sampled military test sets are available. The observed improvements are therefore valid for the evaluated collection but should not be interpreted as a precise estimate of performance across the broader military-image domain.

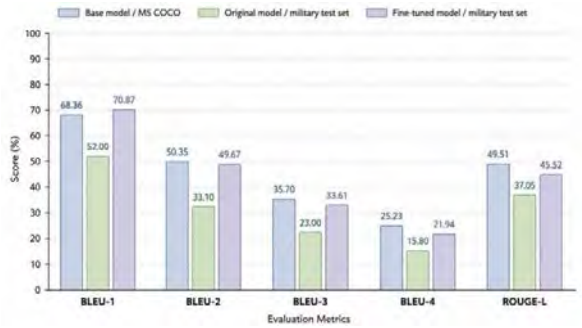

Figure 2. Captioning performance on the base (MS COCO) and military-domain evaluation sets. The fine-tuned model outperforms the original model on all metrics of the military test set

Figure 2 provides a visual comparison of the captioning performance achieved by the base and fine-tuned models on the MS COCO and military-domain evaluation datasets using the BLEU and ROUGE-L metrics. The scores obtained by the base model on MS COCO are included to document its source-domain performance, but they should not be interpreted as a controlled comparison with the military-domain scores because the reference captions and image distributions differ. The relevant evidence for the effectiveness of fine-tuning is the comparison of the two checkpoints on the same military test set.

Figure 3. Comparison of captions generated by the original model and the fine-tuned model for the first representative image from the military test set

Original model: “a man is sitting on a chair with a laptop”
Fine-tuned model: “two soldiers are sitting inside of a military vehicle”

Figure 4. Comparison of captions generated by the original model and the fine-tuned model for the second representative image from the military test set

Original model: “a group of people standing around a field of grass”

Fine-tuned model: “a group of soldiers in military uniforms are standing in a line”

Figure 5. Comparison of captions generated by the original model and the fine-tuned model for the second representative image from the military test set

Original model: “a group of people standing near a fire”

Fine-tuned model: “a group of soldiers walking through a forest”

Figure 6. Comparison of captions generated by the original model and the fine-tuned model for the second representative image from the military test set

Original model: “people standing beside a yellow truck”

Fine-tuned model: “a group of soldiers standing next to a tank”

Figures 3–6 illustrate both the benefits and the remaining limitations of domain-specific fine-tuning. In Figure 3, the original model focuses on familiar indoor objects and produces the caption “a man is sitting on a chair with a laptop,” whereas the fine-tuned model identifies the military context and describes two soldiers inside a military vehicle. Similarly, in Figure 4, the original model generates the overly general description “a group of people standing around a field of grass,” while the fine-tuned model more accurately identifies soldiers in military uniforms standing in a line.

The examples also reveal several characteristic errors. For the low-light firefighting scene in Figure 5, the caption “a group of people standing near a fire” is broadly related to the image but incomplete: it does not identify the people as military firefighters, does not describe their protective

equipment, and omits the active response to a forest fire.

Figure 6 demonstrates that domain adaptation can improve one part of a caption while introducing a different error. The original model describes the scene as “people standing beside a yellow truck,” which recognizes the presence of people and a large yellow vehicle but does not identify either the military personnel or the tracked construction machine. The fine-tuned model generates “a group of soldiers standing next to a tank.” This caption correctly introduces the military personnel but incorrectly classifies the tracked bulldozer as a tank. The error suggests that the adapted model may over-apply military-domain priors when a visually similar but non-combat vehicle appears in a military setting.

The observed qualitative errors can therefore be grouped into three categories: overly general captions that omit domain-relevant information, incomplete captions that identify the main scene but omit important objects or actions, and incorrect object classifications caused by visual similarity or target-domain bias. These examples also show why improvements in BLEU and ROUGE-L should be complemented by human evaluation of factual correctness. Since the qualitative analysis contains only a small number of selected images, it illustrates possible failure modes but does not establish their frequency in the broader target domain.

5. CONCLUSION

This paper extends a ResNet-152-LSTM image-captioning model trained on MS COCO to a specialized collection of military-exercise imagery. The principal contribution is an end-to-end domain-adaptation pipeline that combines automatic target-domain annotation with parameter-efficient fine-tuning. A pre-trained Florence-2 model generates five pseudo-reference captions per image, after which the original encoder-decoder checkpoint is adapted by updating the complete LSTM decoder and the encoder's projection and batch-normalization layers while keeping the convolutional ResNet backbone fixed.

Evaluation on military-domain images demonstrates a clear advantage over direct application of the source model. Fine-tuning improves BLEU-1, BLEU-2, BLEU-3, BLEU-4, and ROUGE-L by 18.87, 16.57, 10.61, 6.14, and 8.47 percentage points, respectively.

Beyond improving the quality of the generated captions, the results of this study also indicate the significant potential of such models for applications in modern defence technologies. During reconnaissance missions using unmanned platforms, video streams are typically transmitted continuously from the onboard camera to the ground control station. For example, transmitting a Full HD video stream (1920 × 1080 pixels, 30 fps) compressed using the H.264 codec at a bitrate of 5 Mb/s requires the transmission of approximately 625 kB of data per second. In contrast, a textual description of a single image generated by the proposed model occupies approximately 150 bytes. When processing 30 images per second, this corresponds to a data rate of only about 4.5 kB/s. These results open up the possibility of significantly reducing the amount of data transmitted over the communication link during the communication between the unmanned aerial vehicle and the ground control station, which may be particularly important under conditions of limited bandwidth.

Additional reductions in the required communication bandwidth can be achieved by applying an event-driven information transmission strategy. In this case, the system would continuously analyse images directly on the unmanned platform, while textual descriptions would be transmitted only if the generated caption contains predefined objects or activities of interest, such as military personnel, combat vehicles, helicopters, vessels, or other assets. This approach avoids transmitting a large number of irrelevant scenes, further reducing the communication load and improving the overall efficiency of the system.

Although this study focuses on automatic image captioning, the proposed approach also opens the possibility for the development of semantic communication systems, in which only information with operational significance is transmitted instead of the complete video stream. Such a concept could represent an important direction for the development of future intelligent reconnaissance systems, particularly in scenarios with limited communication bandwidth and the need for timely decision-making.

Several extensions should be considered in future work. First, the dataset should be expanded across a broader range of exercises, seasons, weather conditions, viewpoints, platforms, and equipment categories, with strict source-level partitioning to reduce correlations between training and test scenes. Second, a subset of automatically generated captions should be independently reviewed or rewritten by domain experts, and inter-annotator agreement should be reported. Finally, because defence-oriented captioning is safety-relevant, future work should quantify uncertainty, identify hallucinated objects or activities, and define a human-in-the-loop protocol under which generated descriptions support rather than replace operator judgment.

Abstract: *Swarm intelligence describes collective problem solving that emerges from interactions among multiple agents. This paper compares biological and artificial swarm principles and evaluates a stylized close-range defense scenario using two explicitly parameterized stochastic models. For each model, 10,000 Monte Carlo runs were performed with ten defenders and one intruder under identical initial conditions. The biological model represents fast local detection and recruitment, whereas the artificial model includes sensor-processing and communication delays. Under the stated assumptions, the biological swarm achieved a mean elimination time of 5.17 s versus 12.17 s for the artificial swarm and a lower mean defender-loss rate (1.13% versus 4.76%). These values are scenario-specific simulation outputs rather than physical measurements. The comparison illustrates the trade-off between rapid decentralized reaction and richer digitally mediated coordination.*

Keywords: *swarm intelligence, biological swarm, artificial swarm, multi-agent systems, Monte Carlo simulation.*

1. INTRODUCTION

Swarm intelligence refers to collective behavior that emerges from interactions among multiple relatively simple units without requiring continuous centralized control. In biological systems, such behavior is visible in social insects, fish schools, and other animal collectives, where local rules can produce robust group-level organization [1], [8], [12]. In this paper, an agent denotes an autonomous decision-making unit that perceives information from its environment or peers, selects actions, and contributes to a shared task [10], [11].

Bio-inspired computational methods such as Ant Colony Optimization (ACO) and Particle Swarm Optimization (PSO) translated these principles into engineering and optimization algorithms [1]-[3]. Contemporary swarm robotics extends this idea to groups of physical or simulated robots that coordinate through local interaction, communication, and distributed decision-making [8], [9].

Biological and artificial swarms share principles of emergence, redundancy, and collective coordination, but they differ in communication bandwidth, memory, learning mechanisms, and access to global information. Artificial systems can additionally use machine learning, shared digital state, edge or cloud computation, and higher-level coordination mechanisms [10], [11]. These capabilities create new opportunities but also introduce latency, communication dependence, security risks, and possible single points of failure [13], [14].

The contribution of this paper is twofold. First, it provides a structured comparison of biological and artificial swarm principles using consistent terminology. Second, it evaluates a reproducible stochastic close-range defense model with explicitly stated assumptions, algorithms, and parameters. The simulation is intended as a comparative computational experiment rather than as a validated model of a particular biological species or robotic platform.

2. BIOLOGICAL PRINCIPLES OF SWARM INTELLIGENCE

Biological swarm intelligence emerges from local interactions among individuals and between individuals and the environment. No single individual normally maintains a complete representation of the global state; coordinated behavior instead arises through self-organization, feedback, and repeated local responses [1], [12].

DOI: 10.5937/OTEH26067J

Decentralization is a defining property of many biological swarms. Individuals react to chemical, visual, acoustic, tactile, or motion-related cues. Ant foraging is a classical example of stigmergy, in which pheromone deposition modifies the environment and influences the subsequent behavior of other agents. The environment therefore acts as a distributed and continuously updated memory [1].

Redundancy and local interaction contribute to robustness and scalability. The loss of an individual agent usually does not terminate collective behavior, and coordination can continue without a dedicated central controller. Recent reviews of animal collective behavior and swarm robotics emphasize self-organization, resilience, adaptability, and locality as important principles transferred from biology to engineered swarms [8], [12].

These advantages coexist with limitations. Biological communication has restricted bandwidth, information propagation is local, and long-term adaptation is primarily evolutionary or behavioral rather than based on persistent digital memory. Accordingly, the biological model used later in this paper should be understood as a stylized model of rapid local collective response, not as a simulation of a specific animal species.

The distinction between biological principles and artificial implementation is therefore important: bio-inspired algorithms reproduce selected coordination mechanisms, whereas living swarms operate under biological sensing, communication, and energy constraints that cannot be transferred directly to engineered systems [8], [9].

3. ARTIFICIAL SWARM INTELLIGENCE AND ARTIFICIAL INTELLIGENCE-BASED COORDINATION

Artificial swarm intelligence refers to computational or robotic systems in which multiple autonomous agents cooperate to achieve a collective objective. Early approaches were strongly bio-inspired, including ACO and PSO, while modern swarm robotics combines distributed control, sensing, communication, and computation [2], [3], [8], [9].

Artificial agents can exchange digital messages directly and can access shared state through networked infrastructure. This allows faster dissemination of precise information than in many biological mechanisms and can provide partial or full knowledge of the system state. However, the achievable benefit depends on communication latency, bandwidth, synchronization, and fault tolerance [9], [14].

Machine learning further extends artificial swarm capabilities. Reinforcement learning and multi-agent reinforcement learning (MARL) allow agents to adapt policies from interaction data, while centralized training, decentralized execution, learned communication, and shared experience can support increasingly complex cooperative behavior [10], [11].

Higher-level coordination can also be introduced without removing local autonomy. An edge, cloud, or command component may aggregate observations, estimate global conditions, optimize task allocation, and periodically update agent policies. In a hybrid architecture, local agents still execute immediate actions while the higher-level component supports system-wide learning and planning [10], [14].

Persistent digital memory is another major difference from biological stigmergy. Artificial systems can store historical observations, compare alternative strategies, use predictive models, and redistribute learned policies. These functions are especially relevant to distributed sensing, vehicle coordination, multi-robot task allocation, and other applications that require information beyond the immediate local neighborhood [9], [11].

Artificial swarms may also support dynamic role assignment. Individual agents can be assigned to sensing, communication, pursuit, transport, or support roles according to mission state and available resources. Such explicit task decomposition can improve efficiency but increases algorithmic and communication complexity [11].

The same infrastructure that enables global information and learning can introduce vulnerabilities. Communication outages, compromised agents, malicious messages, or failure of shared infrastructure can disrupt collective behavior. Security of swarm communication and resilience to faults are therefore essential design considerations [13], [14].

For consistency, the term artificial swarm is used throughout the remainder of this paper. It covers decentralized, centralized-support, and hybrid implementations and avoids introducing a second label for the same class of engineered multi-agent systems.

4. KEY DIFFERENCES: BIOLOGICAL VS ARTIFICIAL SWARMS

Although artificial swarm intelligence is inspired by natural collective behavior, the two classes of systems should not be treated as equivalent. The most important differences concern the origin of coordination, communication mechanisms, memory, learning, system-level knowledge, and dependence on infrastructure [8], [9], [12].

Control and coordination provide the first distinction. Biological swarms are predominantly decentralized and rely on local interaction. Artificial swarms can also be decentralized, but they may additionally employ centralized-support or hybrid architectures in which global information is used for planning or learning while execution remains distributed [10], [14].

Communication is similarly different. Biological systems rely on local signals such as pheromones, movement, sound, or direct contact, whereas artificial agents may exchange structured digital messages at high speed. Digital communication can improve synchronization and task allocation, but it also creates dependence on networks and communication security [13].

Learning and memory provide another distinction. Biological adaptation is constrained by physiology,

behavior, and evolution, while artificial agents may use persistent databases, online learning, predictive models, and policy updates. These capabilities can increase flexibility but also create non-stationarity and coordination challenges in multi-agent learning [10], [11].

From a reliability perspective, the comparison is therefore a trade-off rather than a general ranking. Biological swarms emphasize locality, redundancy, and graceful degradation; artificial swarms can achieve richer planning and information sharing but must explicitly manage communication failures, cyber-security threats, and architectural bottlenecks [13], [14].

Table 1. Key Characteristics of Biological and Artificial Swarm Intelligence

Feature	Biological swarm	Artificial swarm
Control structure	Fully decentralized	Decentralized or hybrid (centralized support possible)
Agent complexity	Very limited individual intelligence	Programmable agents with learning capabilities
Communication	Indirect, low bandwidth (pheromones, movement, sound)	Direct, high-speed digital communication
Global knowledge	None	Partial or full global state awareness possible
Adaptation	Evolutionary, slow	Real-time learning and adaptation
Robustness	Very high	Moderate to high (architecture-dependent)
Scalability	Natural and implicit	Requires careful system design
Memory	Environmental (stigmergy-based)	Persistent digital memory
Optimization capability	Emergent and approximate	Explicit and goal-oriented

Table 1 summarizes these differences. The characteristics shown are general design tendencies rather than universal properties; a particular artificial swarm may deliberately reproduce fully decentralized biological principles or combine them with centralized support.

5. SIMULATION METHODOLOGY AND SWARM MODELS

The study uses two custom discrete-time stochastic multi-agent swarm models under the same close-range defense task: a biological-response model and an artificial-response model. One hostile intruder enters a defended local zone. The objective is to eliminate the intruder while recording response time and defender losses. The model is deliberately non-spatial: continuous coordinates, trajectories, and geometric collision dynamics are not simulated. Spatial effects are represented indirectly through detection, mobilization, and recruitment delays.

Each swarm contains $N = 10$ autonomous defender agents; the hostile intruder is an external entity and is not counted as a swarm agent. Each model was evaluated in 10,000 independent Monte Carlo runs (20,000 runs in total). Every run started with one intruder and the ten defender agents, used a discrete time step $\Delta t = 0.05$ s, and terminated when the intruder was eliminated or when the 120 s maximum duration was reached. A master random seed of 20260702 was used for reproducibility.

The simulation was implemented in Python using NumPy random-number generators. At the start of each run, detection time and mobilization delay were sampled from gamma distributions. When their combined delay elapsed, an initial subset of defenders became active. Each remaining inactive defender was then recruited independently in every time step with probability $P_R = 1 - \exp(-\rho\Delta t)$, where ρ is the model-specific recruitment rate.

Once defenders were active, the same event logic was used for both models. First, additional defenders could be recruited; second, intruder elimination was sampled using the aggregate elimination probability in (1); and third, if the intruder remained active, defender losses were sampled from a binomial distribution using the per-defender loss probability in (2). The number n of active defenders was updated after every recruitment or loss event.

Both swarms are represented by the same custom discrete-time stochastic multi-agent model evaluated by Monte Carlo simulation; they are not implementations of ACO or PSO. The biological-response model contains $N = 10$ defender agents and represents faster local detection, shorter mobilization, faster recruitment, and stronger local coordination. The artificial-response model likewise contains $N = 10$ defender agents but represents sensor-processing, communication, threat-classification, and task-allocation delays. Thus, the simulation algorithm and the number of swarm agents are identical, while the parameter sets differ as reported in Table 2.

For each run, the recorded outputs were intruder-elimination time, number of defenders lost, defender-loss percentage, and elimination success or failure. Across all runs, the mean, median, standard deviation, 90th and 95th percentiles of elimination time, mean defender loss, probability of losing at least one defender, and success rate were calculated.

The probability that the active defenders eliminate the intruder during an individual simulation interval was calculated as

$$P_E = 1 - e^{-\lambda c n \Delta t}, \quad (1)$$

where P_E is the probability of eliminating the intruder during the observed interval, λ is the basic elimination effectiveness of an individual defender, c is the coordination factor, n is the current number of active defenders, and Δt is the simulation time step.

The probability of an individual active defender being lost during a simulation interval was calculated as

$$P_L = 1 - e^{-\mu \Delta t}, \quad (2)$$

where P_L is the probability of losing an individual active defender during the interval and μ is the defender-loss rate.

Table 2 lists all parameter values used in the two models. Gamma distributions are parameterized by shape k and scale θ; their expected delay is $k\theta$. Parameters were selected as explicit scenario assumptions for a controlled comparison and were not fitted to measurements from a particular biological colony or physical robotic swarm.

Table 2. Parameters of the stochastic simulation models.

Parameter	Biological	Artificial
Defenders (N)	10	10
Time step Δt (s)	0.05	0.05
Max. time T_{max} (s)	120	120
Detection $\Gamma(k, \theta)$	(4, 0.38)	(4, 0.85)
Mobilization $\Gamma(k, \theta)$	(3, 0.15)	(3, 0.40)
Initial active (n_0)	3	2
Recruitment ρ (s^{-1})	1.80	0.80
Elimination λ (s^{-1})	0.027	0.016
Coordination (c)	1.30	1.00
Loss μ (s^{-1})	0.0038	0.0075

The biological-response model starts with $n_0 = 3$ active defenders after detection and mobilization, recruits nearby defenders at a higher rate ρ, and uses a coordination factor $c > 1$ to represent efficient local collective action. The artificial-response model starts with $n_0 = 2$ active defenders and uses longer sensing and mobilization delays, slower recruitment, and a lower effective elimination rate λ.

The simulation does not encode a specific ant, bee, hornet, drone, or robot platform. Instead, it isolates the consequences of two contrasting coordination assumptions under a single local-defense task. Consequently, the numerical results must be interpreted only within the stated model and parameter ranges.

This explicit parameterization is important because the same qualitative labels, such as faster detection or stronger coordination, can produce different outcomes when assigned different numerical values. Reproducibility therefore depends on reporting both the stochastic algorithm and the complete parameter set.

The comparative design intentionally holds the initial threat, defender population, time step, stopping rule, and output metrics constant. This allows observed differences to be attributed to the stated model parameters rather than to different initial conditions.

6. RESULTS AND DISCUSSION

Both models eliminated the intruder in all 10,000 runs. The biological model achieved a mean elimination time of 5.17 s, compared with 12.17 s for the artificial model. This corresponds to a 57.5% lower mean elimination time under the stated parameterization.

The median elimination times were 4.40 s and 10.30 s, while the standard deviations were 3.11 s and 7.40 s for the biological and artificial models, respectively. Figure 1 presents the cumulative distribution of elimination time across all simulation runs.

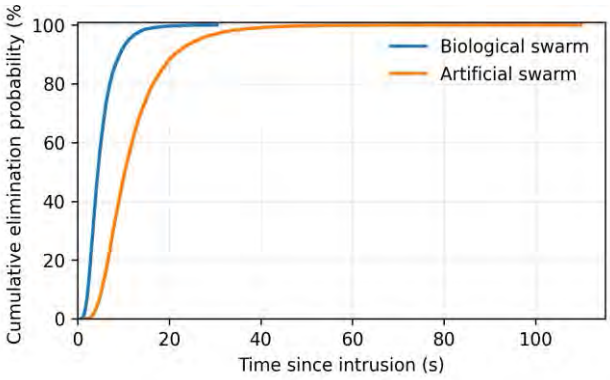

Figure 1. Cumulative probability of intruder elimination for the biological and artificial swarm models.

The biological curve rises earlier because the model combines shorter detection and mobilization delays with faster recruitment. Ninety percent of biological-model runs completed elimination within 9.20 s, whereas the artificial model required 21.20 s. At the 95th percentile, the corresponding values were 11.20 s and 26.45 s.

The wider artificial-model distribution reflects the additional variability introduced by longer sensing, processing, communication, and mobilization delays. This finding should not be interpreted as a universal property of artificial swarms; it follows directly from the close-range scenario and the parameter values reported in Table 2.

Figure 2 compares the mean elimination times with one-standard-deviation error bars. The mean difference was 7.00 s. In this scenario, the intruder therefore remained active for more than twice as long on average in the artificial model.

The result is consistent with the model design: immediate local information is sufficient for the task, so the biological parameterization gains little from global state while avoiding the additional stages assigned to artificial coordination. This is a task-specific advantage of the modeled response chain rather than evidence that biological swarms are generally more capable.

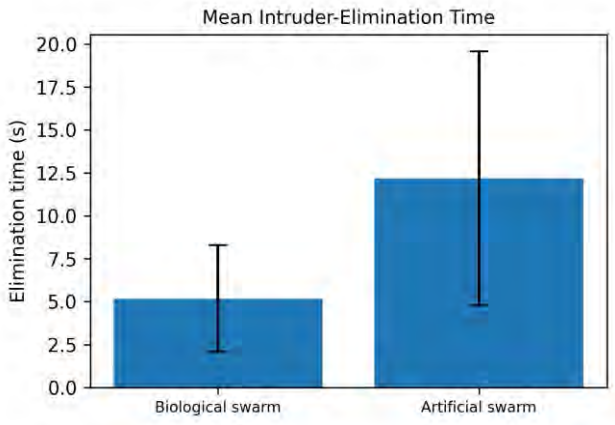

Figure 2. Mean intruder-elimination time for the biological and artificial swarm models; error bars show one standard deviation.

Defender losses show the same scenario-specific tendency. The biological model lost an average of 0.113 defenders per intrusion, or 1.131% of the initial population. The artificial model lost 0.476 defenders, or 4.759%. Figure 3 summarizes the mean loss rates.

The relative reduction in mean defender losses was 76.2%. The probability of losing at least one defender was 9.81% for the biological model and 31.99% for the artificial model, making such a loss approximately 3.26 times more frequent in the artificial-model runs.

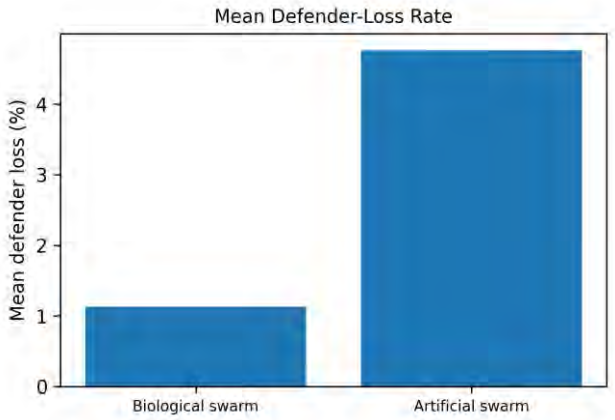

Figure 3. Mean defender-loss rate for a nest initially containing ten defenders.

These simulated losses arise because longer engagements expose active defenders to the per-interval loss process for more time. The loss difference is therefore linked to both the elimination dynamics and the model-specific loss-rate parameter; it is not an independently measured property of biological or robotic systems.

The simulation directly supports only conclusions about the modeled close-range defense task: under the parameters in Table 2, faster local detection, recruitment, and coordination produce shorter engagements and fewer losses. It does not test tasks that require global mapping, long-distance coordination, prediction, persistent memory, or dynamic allocation across multiple geographically separated threats.

Advantages commonly associated with artificial swarms in those broader tasks are therefore literature-based design capabilities rather than outputs of the present simulation. Recent work on MARL and multi-robot systems shows how learned policies, shared information, and centralized-training/decentralized-execution architectures can support complex coordination [10], [11], while resilience research emphasizes the need to preserve local autonomy when communication or shared infrastructure fails [14].

The main limitation of the present experiment is the use of synthetic scenario parameters rather than empirical calibration. The model is also non-spatial and does not simulate radio propagation, packet loss, physical trajectories, heterogeneous agents, or multiple simultaneous intruders. These simplifications make the experiment reproducible and interpretable but limit external validity.

Accordingly, the results should be interpreted as a controlled comparison of two coordination assumptions. They demonstrate how local-response and communication-mediated delays can affect a stochastic defense model, not that one class of swarm is universally superior to the other.

For immediate local defense, decentralized reaction can be advantageous when local information is sufficient and communication infrastructure is unnecessary. In contrast, artificial swarms may be preferable when the task depends on persistent memory, remote information, adaptive task allocation, or coordinated action over larger spatial scales [9]-[11].

This distinction reconciles the simulation results with the broader comparison in Table 1: the present experiment evaluates one operating regime, while the general strengths and weaknesses of biological and artificial swarms depend on mission requirements and system architecture.

7. CONCLUSION AND FUTURE RESEARCH

This paper compared biological and artificial swarm intelligence at both conceptual and simulation levels. Biological swarms emphasize local interaction, self-organization, and redundancy, whereas artificial swarms can add digital communication, persistent memory, machine learning, and higher-level coordination. These additional capabilities expand the range of possible tasks but introduce communication, security, and architectural dependencies.

In the explicitly parameterized close-range defense model, the biological swarm achieved a mean elimination time of 5.17 s compared with 12.17 s for the artificial swarm, while the mean defender-loss rates were 1.13% and 4.76%, respectively. Because the parameters are synthetic and the model is non-spatial, these results are evidence about the stated computational scenario only.

The central conclusion is therefore conditional: rapid decentralized reaction is advantageous when a threat is local and immediate, whereas richer artificial coordination can become advantageous when tasks

require information aggregation, learning, prediction, or system-wide resource allocation. Neither architecture is universally superior.

Future work should calibrate the model against empirical observations or physical multi-robot experiments, introduce explicit spatial motion and communication-network models, and evaluate multiple simultaneous threats. Additional experiments should compare decentralized and hybrid artificial architectures under packet loss, latency, agent failure, and adversarial communication conditions [13], [14].

A further research direction is to replace fixed artificial-swarm parameters with learned policies based on MARL and to test whether adaptive task allocation can compensate for communication and processing delays in close-range scenarios [10], [11]. Such extensions would provide a stronger basis for determining when biological principles should be preserved directly and when artificial-intelligence-based coordination provides measurable benefit.

Abstract: *This paper presents the application of the Bartlett method for estimating the angle of arrival of targets using an FMCW radar system. After organizing the samples and forming the radar data cube, a 2D FFT algorithm is first applied to obtain the Range–Doppler matrix. Subsequently, an IFFT is performed on the samples corresponding to the same target range, and the Bartlett method is then applied to estimate the angle of arrival. The algorithm is repeated for all range resolution cells. Range–Angle map obtained using both the Angle-DFT method and the Bartlett method are presented, and their results are comparatively analyzed. The simulation is conducted for multiple targets with different parameters and varying SNR levels, while experimental validation is performed using an FMCW TDM MIMO radar system.*

Keywords: *Bartlett method, Angle estimation, FMCW TDM MIMO Radar, Angle DFT, Range-Angle map.*

1. INTRODUCTION

The need for accurate estimation of fundamental target parameters, such as range, velocity, and angle of arrival, has led to the widespread adoption of Frequency-Modulated Continuous-Wave (FMCW) radar systems in modern applications. FMCW radars are used in the mode of precise target tracking, especially in military applications such as guidance radars for missile control and ballistic radars [1]. Also, this type of radar has found extensive use in medical applications, including biosignal monitoring [2] and tumor detection [3], in the detection of unmanned aerial vehicles (UAVs) with a low radar cross-section [4], and, most notably, in the automotive industry, particularly in autonomous driving systems [5]. Owing to their high time-bandwidth (tB) product, FMCW radars provide highly accurate and precise range and velocity estimation, whereas angle estimation and angular resolution are directly determined by the antenna aperture and the number of receiving antennas [6].

In practical scenarios, however, the implementation of a large number of receiving antennas is often impractical due to space constraints, cost considerations, and the need to optimize hardware resources. When conventional angle estimation techniques, such as the Angle Discrete Fourier Transform (Angle DFT), are employed, even Multiple-Input Multiple-Output (MIMO) radar systems, which utilize multiple transmitting antennas and virtual array formation techniques, fail to achieve satisfactory angle estimation performance.

Therefore, the use of more advanced angle-of-arrival (AoA) estimation algorithms is essential. At the same time, there is a strong demand for computationally efficient algorithms that do not require excessive processing power, thereby enabling their practical implementation in real-time radar systems.

The Bartlett method is a conventional beamforming technique for estimating the direction of arrival (DoA) of signals impinging on an antenna array, and it is most widely used in direction-finding applications. Moreover, the method can also be applied when two antenna arrays need to be precisely aligned toward each other, ensuring accurate orientation and minimizing signal attenuation. However, with appropriate modifications, it can also be applied to radar systems. The method is based on beamforming, electronically steering the array toward a desired direction, and calculating the received signal power. Its main advantages include straightforward implementation, low computational complexity, fast execution, and robust performance in the presence of noise.

The paper is organized as follows. The first section introduces the research problem, discusses the motivation for the study, and provides a brief overview of the Bartlett method for target angle-of-arrival estimation. The second section presents the signal and system models used throughout the study. The third section describes the

DOI: 10.5937/OTEH26068D

mathematical formulations of the Angle Discrete Fourier Transform (Angle DFT) algorithm and the Bartlett method for target angle estimation in radar systems. The fourth section presents simulation results evaluating the performance of the proposed algorithms in terms of angle estimation accuracy for multiple targets, the ability to resolve closely spaced targets in the angular domain, and robustness to noise. The fifth section provides an experimental validation of the algorithms using an FMCW MIMO radar platform, followed by the conclusions of the study..

2. RADAR SYSTEMS AND SIGNAL MODEL

2.1. Radar System Model

Fig. 1 illustrates the architecture of the Time Division Multiplexing (TDM) Multiple-Input Multiple-Output (MIMO) Frequency-Modulated Continuous-Wave (FMCW) radar system employed in this study..

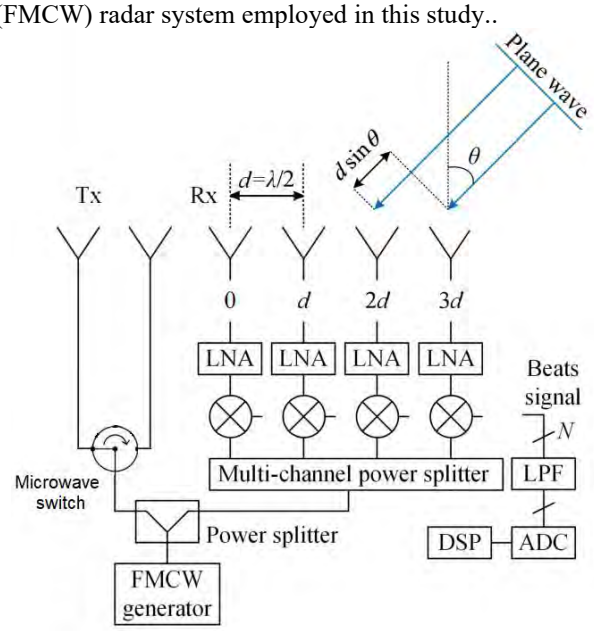

Figure 1. Radar System Model

The radar system consists of two transmitting antennas and four receiving antennas. The FMCW signal is routed to the transmitting antennas through a microwave switch, which controls the transmission sequence in the time domain. Specifically, the signal is transmitted alternately from the first and the second transmitting antenna. After being reflected by the target, the echo signal is received by a linear antenna array. Since the target is assumed to be located in the far field, the reflected wavefront can be approximated as a plane wave at the receiving array.

The received signal is first amplified by a low-noise amplifier (LNA) and then fed into an I/Q demodulator. Subsequently, it passes through a low-pass filter, producing the intermediate-frequency (IF) signal. After analog-to-digital conversion, the I/Q samples are processed digitally. The acquired samples are arranged into a three-dimensional data structure, commonly referred to as the radar data cube. One dimension contains the samples acquired within a single chirp, the second dimension contains samples from multiple chirps, and the third dimension contains samples collected by multiple receiving antennas.

Two radar data cubes are formed, each corresponding to one transmitting antenna. By concatenating the received signals, a virtual antenna array is created, exhibiting the characteristics of a system with a single transmitting antenna and eight receiving antennas. This enables the construction of a unified radar data cube. Since the chirp duration is very short, typically on the order of a few milliseconds, the target can be assumed to remain within the same range resolution cell during the acquisition interval, making Doppler phase compensation unnecessary.

The target range is estimated from the beat frequency of the IF signal, which depends on the target position, whereas the target angle is determined from the phase delay of the received signal across the antenna array [7].

2.2. Radar Signal Model

To construct the Range–Angle map at a given time instant, the signal samples corresponding to a single chirp and multiple receiving antennas are considered. These signal samples can be analytically represented as a two-dimensional complex exponential signal [8]:

$$Y(m,n) = \sum_{l=1}^{L} \alpha_l e^{j\varphi_l} e^{j2\pi \frac{2R_l B}{cT_c} m T_S} e^{j\frac{2\pi}{\lambda} d n \sin\theta_l} + n_n(m,n), \quad (1)$$

where $\alpha_l e^{j\varphi_l}$ denote the complex amplitude and phase, R_l range, Θ_l angle of the l-th target out of a total L targets, B bandwith of FMCW signal, c the propagation velocity of the electromagnetic (EM) wave, which can be assumed to be equal to the speed of light in air, Tc chirp duration, T_S sampling period, λ wavelength of the transmitted signal, inter-element spacing between the receiving antennas $d = \lambda/2$, $n_n(n,m)$ noise , $n = 0...N_{R_x}-1$, where N_{R_x} is number of receiving antennas, $m = 0... N_o-1$, where N_o is number of samples in a chirp, which is given by $N_o = T_c/T_S$. The sample matrix Y has dimensions $[N_o \, x \, N_{R_x}]$.

3. ANGLE ESTIMATION METHODS

3.1. Angle DFT Algorithm

The Angle DFT algorithm is typically applied after the Range DFT processing stage, once the beat frequency and target range have been estimated using the Discrete Fourier Transform (DFT). The Angle DFT algorithm is based on the application of the Discrete Fourier Transform to estimate the phase shift between signals received at different antenna elements. This phase shift arises due to the time delay associated with the additional propagation path length when the target is located at a non-zero angle of arrival.

The angle of the target is given by [7]:

$$\Theta_u = sin^{-1}(u\frac{\lambda}{Nd}), \quad (2)$$

where is $-\frac{N}{2} \leq u < \frac{N}{2}$, where N denotes the number of DFT coefficients. The angular measurement range and angular resolution are given by:

$$-sin^{-1}(\frac{\lambda}{2d}) \leq \theta < sin^{-1}(\frac{\lambda}{2d}), \quad (3)$$

$$\theta_{\text{res}} = 2 \cdot sin^{-1}(\frac{\lambda}{2N_{R_x} d\, cos(\tilde{\theta})}), \quad (4)$$

where $\tilde{\theta}$ is the central angle under which the target is observed. The angular resolution does not depend on the number of DFT coefficients, but solely on the number of receiving antennas.

3.2. Bartlett Method

If the Bartlett method were applied directly to the radar data cube, the resulting output would consist of the angles of arrival corresponding to all targets, and the estimated angles could not be associated with specific targets. Therefore, before applying the Bartlett method, it is necessary to perform target selection in the range domain. Subsequently, the method is applied to all range resolution cells corresponding to the same range bin.

Let Z be a three-dimensional radar data cube of dimensions [m x p x n], such that:

$$Z(:,:,k) = Y_k,\ k = 1, 2, \ldots, p, \quad (5)$$

where Y_k represents the matrix Y corresponding to the k - th chirp within a frame. In order to perform target selection in the range domain, it is first necessary to apply the Range DFT and Doppler DFT algorithms [9] across all antennas, yielding the range–Doppler matrices RD_n of dimensions [m x p]:

$$RD_n = fft2\ (Z\ (:, :, n), \quad (6)$$

where is $n = 0...N_{R_x}-1$, and *fft2* represents the two-dimensional Fast Fourier Transform (2D FFT) algorithm. In order to obtain signal samples corresponding to a single range resolution cell m, it is necessary to apply the inverse Fourier transform only to the selected samples. Accordingly, a vector $R_{n,m}$, of dimensions [1 x p] is obtained, which is given by:

$$R_{n,m} = ifft(\ RD_n(m,:)), \quad (7)$$

where *ifft* represents the inverse Fast Fourier Transform algorithm. When the matrices $R_{n,m}$ corresponding to a single range resolution cell are computed for all antennas in the antenna array, a matrix x_m of dimensions [n x p], can be obtained, which is given by:

$$x_m = [R_{1,m}; R_{2,m}; \ldots; R_{n,m}]^T. \quad (8)$$

The Bartlett method is based on the principle of maximizing the average output power of a conventional delay-and-sum beamformer as a function of the signal's direction of arrival. Accordingly, the Bartlett criterion function for target angle estimation within a single range resolution cell is given by [10]:

$$P_m\ (\theta,\varphi) = v^H\ (\theta,\varphi) X_m\ v\ (\theta,\varphi), \quad (9)$$

where X_m the estimated covariance matrix of the antenna array signal for a single range resolution cell is given by:

$$X_m = \frac{1}{p} x_m x_m^H, \quad (10)$$

where x_m^H is the Hermitian transpose of the matrix x_m. The vector $v(\theta,\varphi)$ is the steering vector corresponding to a given direction and is given by::

$$v(\theta,\varphi) = e^{-j2\pi\ a\ P/\lambda_0}, \quad (11)$$

where a represents the vector that determines the target direction of arrival:

$$a = -[sin(\varphi)cos(\theta),\ cos(\theta)cos(\varphi),\ sin(\theta)], \quad (12)$$

the vector P has dimensions [3 x N_{R_x}] and defines the positions of the receiving antennas in a Cartesian coordinate:

$$P = \begin{bmatrix} x_1 & \cdots & x_{N_{Rx}} \\ y_1 & \cdots & y_{N_{Rx}} \\ z_1 & \cdots & z_{N_{Rx}} \end{bmatrix}, \quad (13)$$

and λ_0 wavelength at the radar operating frequency. Vector $v^H(\theta,\varphi)$, denotes the Hermitian transpose of the steering vector $v(\theta,\varphi)$.

The Bartlett criterion function is evaluated over the set of search angles, and after applying it to all range resolution cells, a unified Range–Angle map is obtained.

4. SIMULATION

For simulation purposes, a radar data cube was generated according to Equation (1) and (5) of the radar signal model. The radar parameters used in both simulation and experimental validation are as follows: operating frequency f_c = 24 GHz; signal bandwidth B =1 GHz; chirp duration T_c = 0,5 ms; sampling frequency f_s = 64 KHz; number of samples per chirp N_o = 32, and number of antennas in the virtual antenna array N_{R_x} = 8. The number of chirps per frame is Nc = 128. These parameters provide an unambiguous radar range of up to 4.8 m and enable angle estimation over the range of -90º do 90º.

The simulation results are presented in the form of Range–Angle maps obtained using both methods. For the Bartlett method, a range step of 0.15 m and an angular step of 0,5º were used, resulting in a Range–Angle map of dimensions [32 x 361]. For a fair comparison, the DFT coefficients in the Angle DFT method were computed using the same number of points.

Table 1 presents the target parameters used in the simulation.. The parameter A denotes the normalized amplitude of the received target echo signal, which can be associated with the radar cross section (RCS) of the target. The parameter r represents the target range, while v denotes the radial velocity of the target, which can take both positive and negative values depending on whether

the target is moving toward or away from the radar. The parameter Θ represents the target angle, which can also be positive or negative depending on whether the target is located to the left or right of the radar boresight.

In these applications, target velocity is not of primary importance, as Range–Doppler maps are not considered. The targets are generated with different amplitudes. Furthermore, targets 2 and 3, as well as 4 and 5, are arranged in pairs such that the angular separation within each pair is identical, while the central observation angles differ, in order to investigate the effect on angular resolution performance. The targets are generated without the presence of noise.

Table 1. Target Parameters

R. br	*A* [V]	*r* [m]	*v* [m/s]	Θ [º]
1.	1	4	-5	50
2.	0.9	3	3	-20
3.	0.8	3	2	-40
4.	0.7	1	-2	45
5.	0.6	1	-1.5	65

Fig. 2 shows a three-dimensional representation of the Range–Angle matrix obtained using the Angle DFT method. The matrix is normalized with respect to its maximum value, and the target angles can be estimated by identifying local peaks. An estimation error in the angle is clearly observable, particularly for targets located at larger angles.

It can also be observed that targets 4 and 5 are not successfully resolved, even though their angular separation is the same as that of targets 2 and 3. This indicates that, as the central observation angle increases, the effective angular resolution cell also increases, which in turn degrades the ability to resolve closely spaced targets.

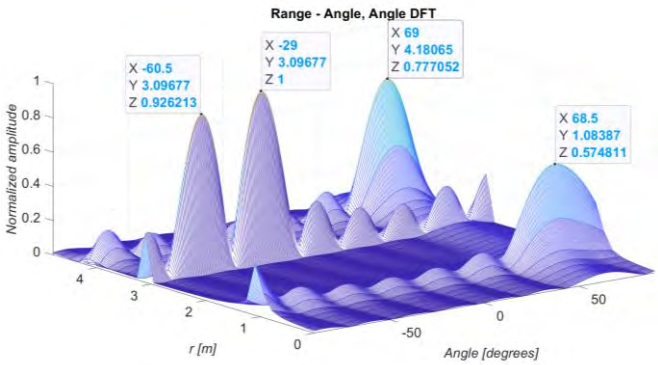

Figure 2. Range–Angle Matrix – Angle DFT Algorithm

Fig. 3 shows a three-dimensional representation of the Range–Angle matrix obtained using the Bartlett method. In contrast to the Angle DFT method, the Bartlett method exhibits significantly higher accuracy in target angle estimation. However, it can be observed that targets 4 and 5 are still not successfully resolved in this case as well, leading to the conclusion that the Bartlett method does not improve angular resolution.

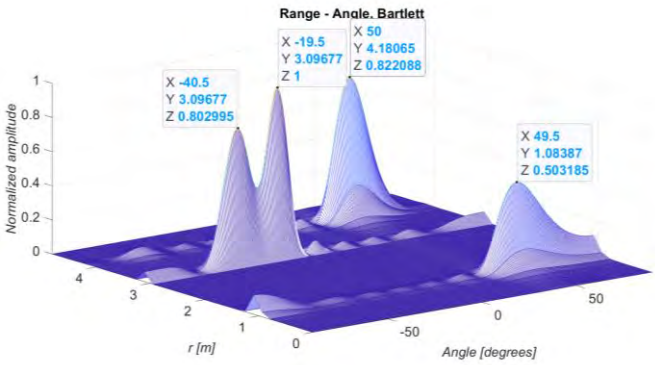

Figure 3. Range–Angle Matrix – Bartlett Method

Table 2 presents the absolute angle estimation errors obtained using the considered methods. It can be observed that the Bartlett method, compared to the Angle DFT algorithm, provides significantly more accurate target angle estimates. For targets that are successfully resolved, the estimation error is on the order of the angular step size used in the angle estimation procedure.

Table 2. Absolute angle estimation error

Cilj	1.	2.	3.	4.	5.
Angle DFT	19º	-9º	-20.5º	23.5º	3.5º
Bartlett	0º	0.5º	-0.5º	4.5º	-15.5º

FMCW radars enable signal detection even at low signal-to-noise ratios (SNR) [11]. Fig. 4 shows Range–Angle heatmaps for the targets listed in Table 1 under additive noise conditions applied to the radar data cube, with signal-to-noise ratio (SNR) levels of 10 dB, 0 dB, and −10 dB. The targets in the heatmaps are marked with red circles.

It can be concluded that the Bartlett method exhibits significantly higher robustness to noise, as targets can still be reliably detected even at low SNR values, whereas this is not the case for the Angle DFT algorithm.

.

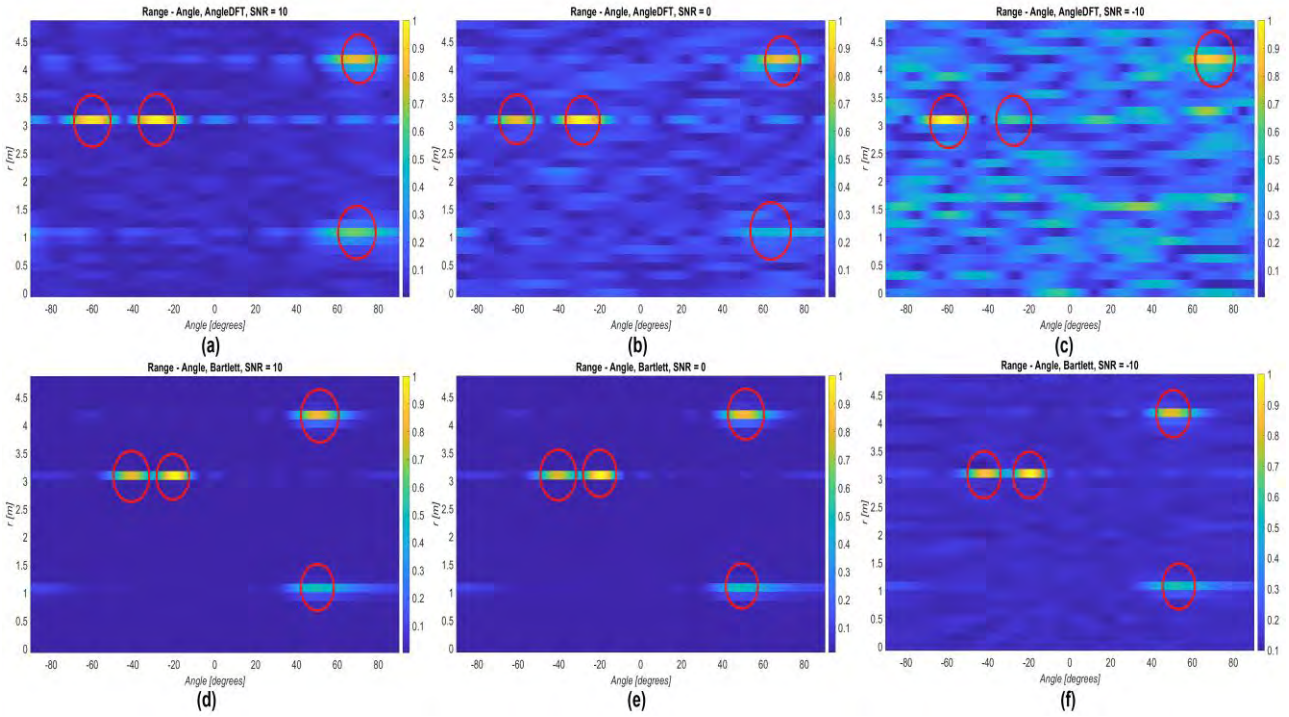

Figure 4. Range–Angle Maps (a) Angle DFT, SNR = 10 dB; (b) Angle DFT, SNR = 0 dB; (c) Angle DFT, SNR = −10 dB; (d) Bartlett method, SNR = 10 dB; (e) Bartlett method, SNR = 0 dB; (f) Bartlett method, SNR = −10 dB

5. EXPERIMENTAL VALIDATION

For the experimental validation, a MIMO radar platform PUP_DUAL24P_T2R4 manufactured by Luswave Technology was used (Fig. 5).

Figure 5. FMCW MIMO Radar platform

The platform operates in the K frequency band and consists of two transmitting and four receiving antennas. It generates an FMCW waveform and enables the adjustment of parameters such as chirp duration, number of samples per chirp, operating frequency, and signal bandwidth, as well as the capability to record I/Q samples for subsequent signal processing [12].

The radar target in the experiment was a person moving toward the radar from its right-hand side at an angle of approximately 30°. Fig. 6 shows the Range–Angle map obtained using the Angle DFT algorithm, while Fig. 7 presents the results obtained using the Bartlett method. The experimental results demonstrate that, in addition to providing more accurate angle estimation, the Bartlett method exhibits significantly higher robustness to noise.

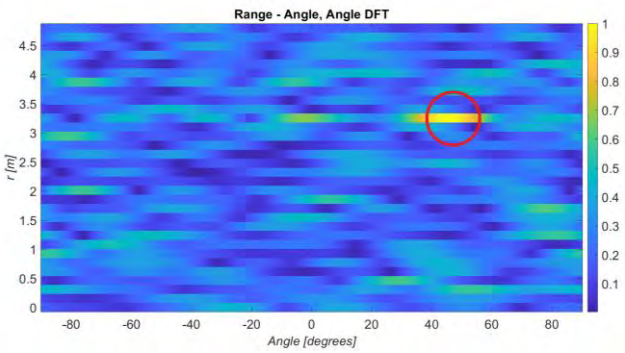

Figure 6. Range-Angle map, Experimental validation - Angle DFT

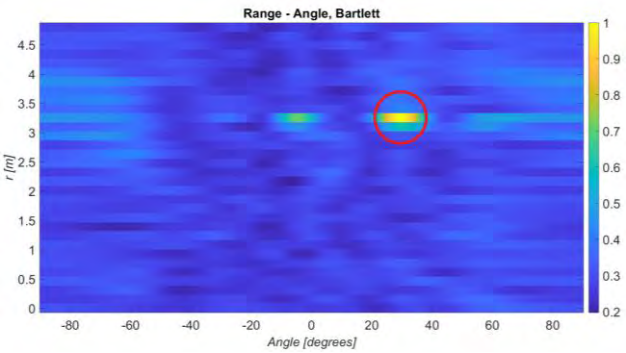

Figure 7. Range-Angle map, Experimental Validation – Bartlett Method

6. CONCLUSION

In this paper, the efficiency of the Bartlett method in target angle estimation and Range–Angle map generation using FMCW radar has been demonstrated through both simulation and experimental validation. It is confirmed that, compared to the Angle DFT algorithm, the Bartlett method introduces a negligible error in angle estimation, on the order of the angular search step size. It is also shown to be significantly more robust to noise and capable of producing satisfactory results at low signal-to-noise ratio (SNR) levels.

Furthermore, it is established that the use of the Bartlett method does not improve angular resolution, as it is fundamentally determined by the number of antennas in the antenna array. It is also observed that the separation of closely spaced targets in angle is somewhat more challenging, which requires tuning of the optimal detection threshold for angle estimation and opens possibilities for further research.

Overall, the Bartlett method represents a significantly more efficient approach for Range–Angle map generation compared to the Angle DFT algorithm. Its importance is further supported by its low computational complexity, as, in addition to FFT and IFFT operations, all other mathematical operations are trivial, making it suitable for implementation in compact systems.

Acknowledgment

In this paper, part of the results derived from the project CPME/P1/26-28, supported by the Ministry of Defence and the Serbian Armed Forces, have been used.

Abstract: *Object detection represents one of the key areas of visual data processing and has significant applications in the analysis of satellite and aerial imagery, intelligent transportation systems, surveillance, and autonomous systems. In modern applications, visual data are often compressed using lossy compression techniques to reduce storage and transmission requirements. However, compression leads to image quality degradation, which may negatively affect the performance of object detection algorithms. In this paper, a comparative analysis of the performance of YOLO models on images compressed using different methods and compression levels is conducted. The experimental analysis is performed on a set of 90 selected images from the DOTA v1.0 dataset. The images are compressed using JPEG, BPG, and VVC methods, with 11 representative compression factor values applied for each method. Object detection was carried out using YOLOv5 and YOLOv7–YOLOv12 models. Detection performance is evaluated using standard metrics, including precision, recall,* mAP_{50}*–*mAP_{95}*, and overall mAP. Particular emphasis is placed on analyzing the impact of compression type and compression level on the robustness of different YOLO models. The proposed experimental framework enables a systematic comparison of performance under degraded image quality conditions and the identification of models that exhibit greater resilience to compression-induced degradation. The results of this study are expected to contribute to a better understanding of the trade-off between compression efficiency and object detection reliability, which is of particular importance in systems with limited storage and transmission resources.*

Keywords: *YOLO, object detection, image compression, DOTA, remote sensing.*

1. INTRODUCTION

Determining the exact position and class of objects in remote sensing imagery is a fundamental task in the domain of computer vision (CV). This process plays an important role in real-world applications in defense and security and can also be used for autonomous driving, environmental monitoring, updating geographic information systems (GIS), and emergency management. The application of object detection and classification algorithms to remote sensing imagery requires the use of large amounts of video content and images that need to be archived, while storage resources are limited, and transmission capacity is particularly constrained. Consequently, compression of visual signals is necessary in most cases. Lossy compression can provide several-fold savings in storage space, but its consequence is degradation of the visual quality of the image, which is unacceptable in some fields (e.g., medicine) [1], [2]. On the other hand, there are fields in which a certain degree of degradation is acceptable if it saves resources without substantially affecting object detection and recognition in the image.

Deep learning methods applied to target detection and classification in remote sensing images can generally be divided into two-stage and one-stage approaches. Two-stage detectors typically provide high detection accuracy but have higher computational requirements, which may limit real-time applications. In contrast, one-stage detectors perform object localization and classification within a unified processing framework, providing a favorable trade-off between detection accuracy and speed. The YOLO (You Only Look Once) family represents one of the most widely used groups of single-stage detectors and is known for fast and efficient real-time object detection in various application domains, including remote sensing [3]–[11].

The compression techniques analyzed in this paper

DOI: 10.5937/OTEH26069B

include JPEG, which is still widely used for image compression [12], [13]. However, with the development of newer techniques such as BPG (Better Portable Graphics) [14], and especially VVC (Versatile Video Coding) [15], which represents the latest generation of video compression, the question arises as to what extent these modern approaches can improve compression efficiency in specific domains such as remote sensing. New formats introduce advanced prediction, transformation, and quantization algorithms, resulting in greater compression capability but also higher computational complexity.

Algorithm performance is evaluated using standard quantitative metrics: precision, recall, mAP, and mAP_{50}–mAP_{95} for detection and classification [16], and PSNR [17] alongside bits per pixel (bpp) for compression efficiency. Section 2 describes the image dataset, compression techniques, YOLO models and evaluation metrics. Section 3 presents and discusses the experimental results, while Section 4 summarizes the main conclusions and outlines directions for future research.

2. DESCRIPTION OF THE IMAGE DATASET, COMPRESSION TECHNIQUES, DETECTION AND CLASSIFICATION ALGORITHMS AND APPLIED MEASURES

2.1. Image dataset

The DOTA v1.0 image dataset [18] was used in this paper. The dataset contains 2,806 images with resolutions ranging from 800 to 4,000 pixels, originating from Google Earth and the GF-2 and JL-1 satellites. Most images are in color (RGB), while grayscale images were not considered. The dataset is divided into training (1/2), validation (1/6), and testing (1/3) subsets. The original images were split into 1024 × 1024 pixel images, resulting in 15,749 images divided into the same three subsets. Previously trained YOLO models from [19] were used, with 7,874 images in the training subset. From the newly formed test subset containing 5,356 images, 90 images with an average bpp value of 12.88 were selected for comparison of compression methods and detection models. The DOTA v1.0 dataset contains 15 object classes, of which 14 are represented in the selected set and were considered in the analysis. Compression-induced degradation may reduce the overlap between predicted and reference bounding boxes, leading to lower detection accuracy. The 90 images were selected to represent the test set in terms of image complexity. Spatial Information (SI_{mean}) indicates the amount of detail in an image [20], while colorfulness (CF) indicates the richness of colors [21].

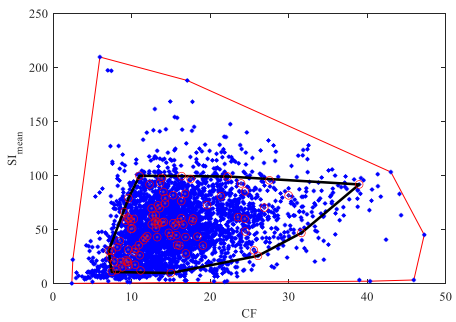

Figure 1 Relationship between colorfulness and spatial information for the DOTA v1.0 test-image subset and the selected image set for compression.

Fig. 1 shows the relationship between CF and SI_{mean} for the DOTA v1.0 test-image subset and the selected set of 90 images. In this representation, each point corresponds to one test image. Blue symbols (*) correspond to the DOTA v1.0 test-image subset (excluding grayscale images), while the quantitative indicators for the 90 selected images are shown in red. The red contour encloses all values for the original subset, whereas the black contour encloses all values for the images selected for compression. It can be observed that the black contour covers a large percentage of the area of the test-image subset, confirming that the 90 selected images are representative for further analysis of compression standards.

2.2. Compression techniques

Three compression techniques were considered in this paper: JPEG, BPG, and VVC. JPEG is a lossy image compression technique based on the discrete cosine transform [12]. Its compression strength is determined by the quality factor QF (Quality Factor), which ranges from 1 to 100, with lower QF values corresponding to lower image quality. In the experiments, QF values of 10, 15, 20, 25, 30, 35, 40, 45, 50, 75, and 95 were used. JPEG

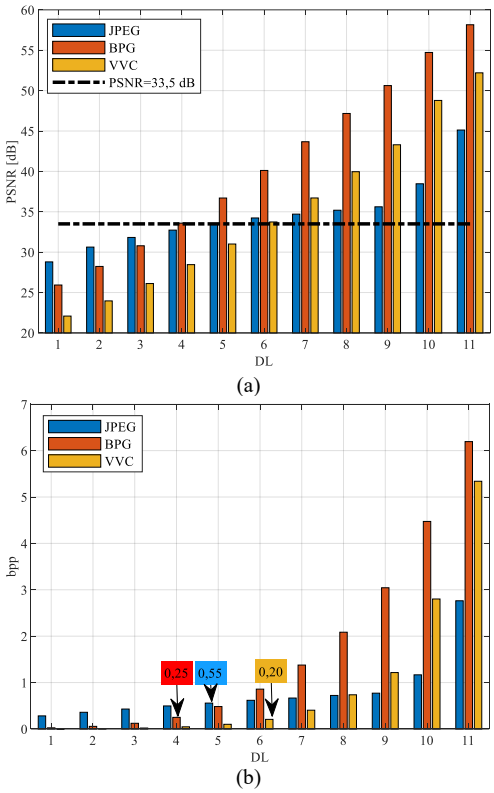

Figure 2 Objective indicators of compression techniques:
(a) PSNR and (b) bpp.

compression was performed in MATLAB using the built-in imwrite function.

Unlike JPEG, BPG is an image format based on HEVC (High Efficiency Video Coding) intra coding, developed by the JCT-VC (Joint Collaborative Team on Video Coding) [22]. The degree of compression is controlled by the parameter Q, whose values range from 0 to 51; increasing Q results in greater image degradation. The analyzed images were encoded using Q values of 0, 5, 10, 15, 20, 25, 30, 35, 40, 45, and 50. Compression was carried out using the BPGconv application [23] with compression level 9 (slow), chroma format 4:4:4, YCbCr color space, 8-bit depth, and the JCTVC HEVC encoder.

VVC, also known as H.266, represents the latest video-compression standard and succeeds HEVC [15]. It was primarily developed for efficient transmission of UHD video and advanced media formats such as 360° video. In VVC, compression is governed by the quantization parameter QP, which ranges from 0 to 63, with higher QP values leading to lower reconstructed-image quality. The selected QP values were 0, 10, 20, 25, 30, 35, 40, 45, 50, 55, and 60. VVC-compressed images were generated using the VVC Test Model VTM-23.11 [24] with a 4:4:4 chroma format.

2.3. Detection and classification algorithms

Seven models from the YOLO family were considered in this paper: YOLOv5, YOLOv7, YOLOv8, YOLOv9, YOLOv10, YOLOv11, and YOLOv12. YOLOv5 [5], introduced in 2020, was developed within the Ultralytics platform and is characterized by a good trade-off between detection speed and accuracy. YOLOv7 [6] introduces the trainable bag-of-freebies approach to improve performance without a significant increase in inference cost. YOLOv8 [7], introduced in 2023, uses an anchor-free detection approach and an improved architecture. YOLOv9 [8] introduces Programmable Gradient Information (PGI) and the GELAN architecture for more efficient training and preservation of important information. YOLOv10 [9] uses an end-to-end approach that enables detection without the need for the standard NMS procedure during inference. YOLOv11 [10] represents the next generation of Ultralytics models, with improved computational efficiency and feature extraction. YOLOv12 [11] integrates attention mechanisms more extensively while preserving the efficiency required for real-time detection.

Figure 3 (a) original image, (b) JPEG (QF=30), (c) BPG (Q=35) and (d) VVC (QP=35).

2.4. Applied measures

For successful comparison of different YOLO models depending on the compression techniques used, appropriate measures are required. The performance of object detection and classification algorithms was evaluated using precision (P), recall (R), mean Average Precision (mAP) calculated over IoU thresholds ranging from 0.50 to 0.95 (mAP_{50}–mAP_{95}), and mean Average Precision at an IoU threshold of 0.50 (mAP_{50}) [16]. The quality of the compressed images was evaluated using the traditional Peak Signal-to-Noise Ratio (PSNR), which is based on the mean squared error [17], while compression efficiency was expressed by the number of bits per pixel (bpp), which represents the number of bits used to represent one image pixel. It is calculated as the ratio of image size in bits to the number of pixels in the image.

3. RESULTS AND DISCUSSION

The comparison of YOLO models for object detection in compressed remote sensing images was performed in two ways. In the first approach, the objective quality measure of the compressed images, PSNR, was equalized for all three compression techniques, after which the YOLO models were compared using the previously described parameters for evaluating the performance of object detection and classification algorithms; the efficiency of the compression techniques was also presented. In the second approach, the robustness of different YOLO models to the applied compression techniques was analyzed by monitoring the mAP and mAP_{50} parameters.

3.1. Analysis for equalized PSNR values

The values shown in Fig. 2 were obtained by averaging the PSNR and bpp values over all 90 images for each of the three compression techniques and eleven representative distortion levels. The results are presented as a function of the distortion level (DL), which corresponds to the previously defined QF, Q, and QP parameter values for JPEG, BPG, and VVC, respectively. Lower DL values correspond to a higher degree of image degradation, while higher DL values represent a lower level of distortion.

It can be observed that the PSNR level for the different compression techniques is approximately the same and equals 33.5 dB for the following DL values. For JPEG compression, DL=5 (QF=30); for BPG compression, DL=4 (Q=35); and for VVC compression, DL=6 (QP=35). Fig. 2(b) shows the bpp values corresponding to the PSNR values in Fig. 2(a). For the selected PSNR level of approximately 33.5 dB, the bpp values are 0.55 for JPEG, 0.25 for BPG, and 0.20 for VVC. Consequently, at a matched objective visual quality of 33.5dB, BPG and VVC reduce the bits per pixel requirements by factors of approximately 2.2 times and 2.75 times relative to JPEG, respectively.

Fig. 3 shows an original image from the newly formed dataset (image No. 64) and the lower-right regions of its compressed versions whose values were analyzed in the previous paragraph. Degradation of the source signal can be observed in the region containing soccer fields and the surrounding grass surfaces. The blocking effect is dominant in the JPEG-compressed image, Fig. 3(b), while blurring is the dominant effect in the BPG- and VVC-compressed images, Figs. 3(c) and 3(d). In addition, it can be observed that details of the soccer-field lines are lost when BPG and VVC compression are applied.

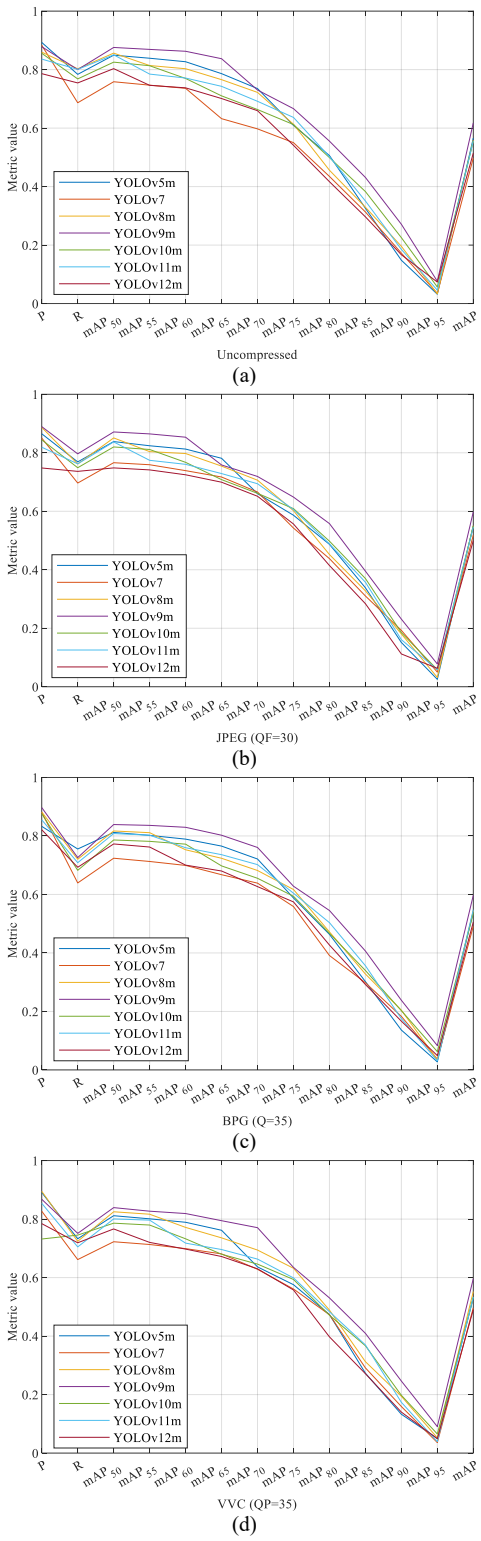

Figure 4. Characteristics of YOLO models: (a) uncompressed images, and compressed images (b) JPEG (QF=30), (c) BPG (Q=35) and (d) VVC (QP=35).

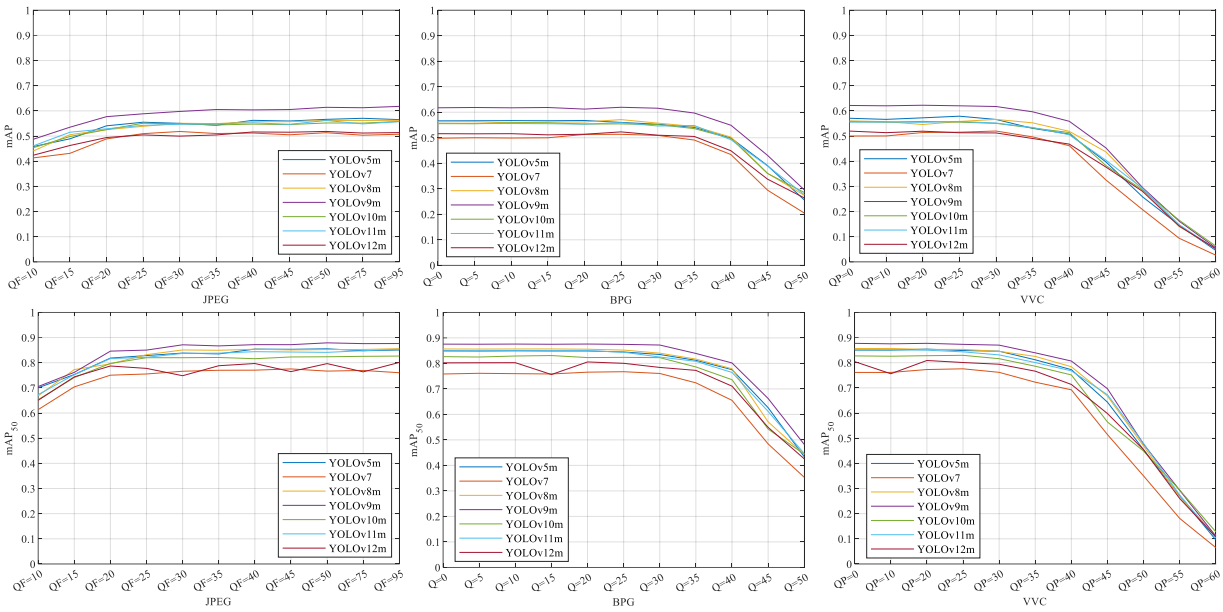

(a) (b) (c)

Figure 5 Values of the mAP and mAP_{50} parameters of YOLO models with respect to the compression techniques used: (a) JPEG, (b) BPG and (c) VVC.

Fig. 4 compares the characteristics of all seven YOLO models used on uncompressed images and on images compressed using JPEG (QF = 30), BPG (Q = 35), and VVC (QP = 35), through precision, recall, $mAP_{50\text{-}95}$ and overall mAP. For all models, mAP decreases as the IoU threshold increases, which is expected because a higher threshold requires greater precision. Fig. 4(a) shows that YOLOv9 has the highest values of the presented parameters among all applied models on uncompressed images, with an advantage of 0.01 in favor of YOLOv5 for P and mAP_{70}. The mean Average Precision (mAP) is 62%, and the mean Average Precision at an overlap threshold of 0.5 (mAP_{50}) is 88%. Fig. 4(b) shows that YOLOv9 maintains top-tier detection performance across all models on images compressed using JPEG with QF = 30, with an advantage of 0.01 in favor of YOLOv5 for mAP_{65}. The mAP is 60%, and mAP_{50} is 87%. Fig. 4(c) shows that YOLOv9 consistently dominates among all models using BPG with Q = 35, with an advantage of 0.03 in favor of YOLOv5 for R. The mAP is 60%, and mAP_{50} is 84%. Fig. 4(d) also shows that YOLOv9 achieves the highest overall accuracy on images compressed using VVC with QP = 35, with an advantage of 0.02 in favor of YOLOv5 and YOLOv8 for P. The mAP is 60%, and mAP_{50} is 84%.

3.2. Robustness analysis of YOLO models

Fig. 5 shows the mAP and mAP_{50} values of the analyzed YOLO models for JPEG, BPG, and VVC compression. At the lowest compression levels (JPEG QF = 95, BPG Q = 0, and VVC QP = 0), the obtained mAP and mAP_{50} values are approximately equal to those for uncompressed images. Among the analyzed models, YOLOv9 achieves the highest baseline values, with mAP = 0.62 and mAP_{50} = 0.88.

Fig. 5(a) shows the dependence of mAP and mAP_{50} for the YOLO models on the compression coefficient for the JPEG technique. For all YOLO models, the mAP values remain relatively stable as the compression level increases down to QF = 20, with only small fluctuations, and the reduction for individual models does not exceed 0.04. With a further decrease in QF, a more pronounced decrease in mAP is observed. Likewise, for JPEG compression, the mAP_{50} values remain relatively stable down to QF = 20 for all applied YOLO models except YOLOv12. The reduction does not exceed 0.03 for most models, while for YOLOv8 it reaches 0.06. The mAP_{50} curve for YOLOv12 exhibits somewhat different behavior, with more pronounced fluctuations at QF values of 75, 45, and 30.

Fig. 5(b) shows the dependence of mAP and mAP_{50} for the YOLO models on the compression coefficient for the BPG technique. Across all YOLO architectures, mAP metrics remain consistently stable up to quantization level Q = 30, exhibiting only minor fluctuations. For Q values above 30, a more pronounced decrease in mAP is observed for all YOLO models. Relative to the uncompressed images, mAP degradation is negligible for YOLOv7 through YOLOv9, equals 0.01 for YOLOv10–YOLOv12, and equals 0.02 for YOLOv5. Similarly, the mAP_{50} values remain resilient up to Q = 30, with overall degradation bounded within 0.03 across most models. However, the mAP50 curve for YOLOv12 localized instability, characterized by a sharp fluctuation at Q = 15.

Fig. 5(c) shows the dependence of mAP and mAP_{50} for the YOLO models on the compression coefficient for the VVC technique. For all YOLO models, the mAP values remain relatively stable for QP values up to 30, with only minimal variance. With a further increase in QP, a more pronounced decrease in mAP is observed for all YOLO models. Compared with uncompressed images, the reduction in mAP is absent for YOLOv5 and YOLOv7–YOLOv9, while it equals 0.01 for YOLOv10–YOLOv12. Similarly, the mAP_{50} values remain relatively stable as compression increases up to QP = 30, with only small fluctuations, and the reduction for individual models does not exceed 0.02. The mAP_{50} curve for YOLOv12 exhibits

somewhat different behavior due to a more pronounced fluctuation at QP = 10. At QP values of 55 and 60, corresponding to the highest VVC compression levels, YOLOv10 achieves higher mAP and mAP_{50} values than YOLOv9, whereas YOLOv9 achieves the highest values of these parameters in all other cases.

4. CONCLUSION

This work evaluated the impact of image compression standards (JPEG, BPG, and VVC) on deep learning-based object detection in remote sensing imagery using the YOLO framework. The experimental results demonstrate that modern coding standards, particularly BPG and VVC, can significantly reduce the amount of data while causing only a minimal decrease in YOLO model performance. YOLOv9 consistently achieved the highest absolute mAP and mAP50 values in most of the analyzed cases.

Future research may focus on the analysis of a larger number of images and other datasets, as well as on determining the optimal trade-off between compression level, image quality, and detection accuracy for different object classes.

Abstract: *This study extends previous research on DC motor-driven servo mechanisms for missile fin control by incorporating finite element method (FEM) analysis of the moving components. The maximum aerodynamic moment acting on the missile fin was adopted as the primary operational load for the structural assessment. A detailed three-dimensional model of the servo mechanism was developed, and a static structural analysis was performed to identify critical sections and evaluate the mechanical integrity of key components. Stress, strain, and deformation distributions were quantified under operational loading conditions, revealing potential failure zones and the most critical regions of the mechanism. The highest stress concentrations were identified at the actuator arm and transmission linkage, while maximum deformation occurred in the output lever assembly. The obtained FEM results provide a basis for future design modifications and structural optimization aimed at improving reliability and stiffness while maintaining functional performance.*

Keywords: *FEM analysis, servo mechanism, brushed DC motor, missile fin control surfaces.*

1. INTRODUCTION

Missile control systems require compact, lightweight, and highly reliable actuation mechanisms capable of generating sufficient torque for accurate positioning of aerodynamic control surfaces under demanding flight conditions. During high-speed manoeuvres, aerodynamic hinge moments acting on missile fins produce significant mechanical loads that are transmitted through the actuator mechanism. Consequently, structural stiffness, strength, and reliability of the mechanical transmission system are essential requirements for ensuring accurate fin positioning and safe operation throughout the missile flight envelope.

Electromechanical actuators (EMAs) are increasingly employed in modern aerospace applications owing to their compact architecture, high efficiency, reduced maintenance requirements, and improved reliability compared with conventional hydraulic actuation systems [1]. Recent research has focused on the design and development of aerospace electromechanical actuators through improved numerical modelling, virtual verification techniques, and optimization strategies aimed at enhancing actuator performance and supporting engineering design [2–5]. In particular, recent studies have investigated numerical modelling approaches for aerospace electromechanical actuators [2], virtual ground testing methodologies for actuator performance evaluation [3], modelling and identification of electromechanical actuators for rocket applications [4], and optimization of missile actuation systems [5]. Furthermore, fatigue assessment is becoming increasingly important during the verification and certification of aerospace electromechanical actuators [6].

Despite these developments, comparatively less attention has been devoted to the structural assessment of the mechanical transmission system responsible for transmitting the aerodynamic loads from the control surface to the actuator. In particular, finite element investigations focusing on stress distribution, deformation, and structural safety of missile fin transmission mechanisms subjected to maximum aerodynamic hinge moments remain relatively limited in the available literature. Structural verification at the design stage is therefore essential for identifying critical load-bearing components, evaluating the available safety margin, and providing a basis for subsequent structural optimization.

The present study builds upon the authors' previous research on the design and control of DC motor-driven electromechanical fin actuators [7] and on the mechanical design of a servo mechanism for controlling missile fins in the pitch and yaw planes [8]. While the earlier studies

addressed actuator control, kinematic design, and functional characteristics of the actuation system, the present paper focuses on evaluating the structural integrity of the mechanical transmission system using the finite element method (FEM). A three-dimensional finite element model was developed to evaluate stress distribution, deformation, and the most highly loaded structural components under the maximum aerodynamic hinge moment acting on the missile fin. The obtained results provide engineering guidance for future structural optimization while preserving the required strength, stiffness, and positioning accuracy.

2. SERVO MECHANISM DESCRIPTION

The servo mechanism analyzed in this study was developed for the actuation of missile control fins in the pitch and yaw planes. Its primary function is to convert the rotational motion of a brushed DC motor into the angular displacement of the control surfaces while providing sufficient torque and positioning accuracy under demanding aerodynamic loading conditions. The complete design procedure and kinematic analysis of the mechanism were presented in the authors' previous work [7, 8].

The actuation system consists of a brushed DC motor, a reduction gearbox, an actuator linkage, transmission shafts, crank elements, and output levers connected to the missile fins. Motion is transmitted from the motor through the mechanical transmission system to the output shafts, producing synchronized rotation of the control fins. The mechanism is designed to provide high structural stiffness while maintaining compact dimensions compatible with the available installation space inside the missile body.

Since the actuator is intended for operation during high-speed flight, the mechanical transmission is subjected to considerable aerodynamic hinge moments generated on the missile fins. These loads are transferred through the actuator linkage and crank mechanism, producing complex stress states in several structural components. Consequently, the mechanical integrity of the transmission system represents one of the principal design requirements.

For the purpose of structural analysis, a simplified three-dimensional CAD model was created by eliminating geometrical features that have negligible influence on the global stress distribution, such as small fillets, chamfers, and fastening details. This simplification significantly reduced computational cost while preserving the structural behaviour of the mechanism under operational loading. The simplified geometry used for the finite element analysis is shown in Figure 1.

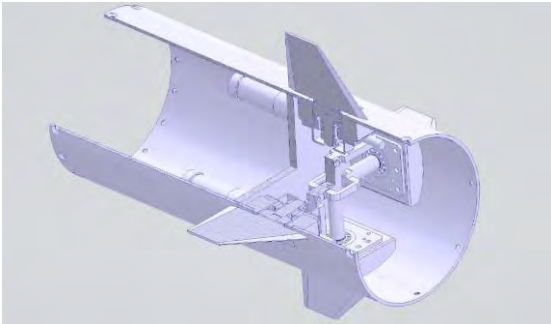

Figure 1. Cross-sectional view of the mechanical transmission system

The maximum aerodynamic hinge moment acting on the missile fin, equal to 15 Nm, was adopted as the governing design load for the structural assessment. This loading condition corresponds to the most demanding operational case considered during the design process and provides the basis for evaluating the strength, stiffness, and structural safety of the servo mechanism.

3. FINITE ELEMENT MODEL

To evaluate the structural integrity of the missile fin servo mechanism under operational loading conditions, a finite element model (FEM) was developed based on a simplified three-dimensional CAD assembly of the mechanical transmission system. The original geometry was simplified by removing small geometric features, such as fillets, chamfers, and fastening details, which have a negligible influence on the global structural response, while considerably increasing computational effort. The resulting model retained all load-carrying components essential for accurately representing the stress distribution within the transmission system.

The mechanical transmission system of the servo mechanism consists of transmission shafts, crank elements, actuator bushings, and output levers responsible for transferring torque from the brushed DC motor to the missile control fins. All structural components considered in the analysis were assumed to be manufactured from high-strength alloy steel Č.4732, characterized by a tensile strength of 1380 MPa, a yield strength of 1240 MPa, and a Young's modulus of elasticity of 210 GPa. These material properties were adopted throughout the numerical analysis.

The finite element analysis was performed using the MSC Nastran solver. The numerical model consisted of 508,663 eight-node three-dimensional hexahedral (Hex8) solid elements and 603,201 nodes. The adopted mesh density provided an appropriate representation of the structural response of the mechanical transmission system while maintaining acceptable computational efficiency. The interfaces between adjacent structural components were defined as bonded contacts, assuming perfect mechanical connection and no relative displacement between mating surfaces. The generated finite element mesh is presented in Figure 2.

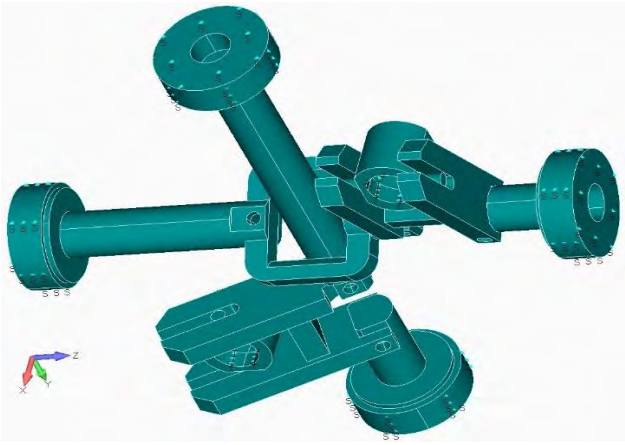

Figure 2. Finite element model of the mechanical transmission system

The applied boundary conditions were selected to represent the actual operating configuration of the mechanical transmission system. The transmission shafts were supported by bearings allowing free rotation while preventing axial displacement, whereas the actuator bushing was constrained in the operating position corresponding to a fin deflection angle of 25°.

The external loading was represented by the maximum aerodynamic hinge moment acting on the missile fin. A design torque of 15 Nm was applied to the fin shaft, representing the most severe loading condition considered during the design process. Under these assumptions, a linear static finite element analysis was performed to determine the equivalent (von Mises) stress distribution, total deformation, and critical load-bearing regions of the mechanical transmission system.

4. RESULTS AND DISCUSSION

The structural performance of the mechanical transmission system was evaluated by means of a linear static finite element analysis under the maximum operational load corresponding to an aerodynamic hinge moment of 15 Nm. The obtained stress and deformation fields provide valuable insight into the load transfer mechanism and the structural behaviour of the servo assembly.

The distribution of the equivalent (von Mises) stress for the complete mechanical transmission system is presented in Figure 3. The analysis indicates that the highest stress concentration occurs in the crank element of the transmission system, where the maximum equivalent stress reaches 604 MPa. This location corresponds to the region where the transmitted torque changes direction, resulting in combined bending and torsional loading.

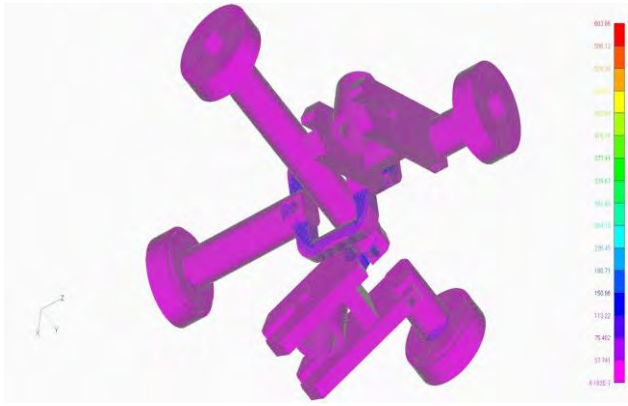

Figure 3. Equivalent (von Mises) stress distribution in the mechanical transmission system (σmax = 604 MPa)

Considering the yield strength of the selected structural material (1240 MPa), the calculated Factor of Safety (FoS) is approximately 2.05, confirming that the mechanical transmission system satisfies the structural strength requirements under the maximum design load. The obtained safety margin also indicates the existence of structural reserve, which may be utilized in future design optimization aimed at reducing the overall mass of the assembly while preserving the required mechanical performance.

A more detailed stress analysis of individual components is presented in Figures 4–6. The transmission shafts experience a maximum equivalent stress of 335 MPa, which is significantly below the allowable stress for the selected material, indicating a relatively low structural utilization. In contrast, the crank element represents the most highly loaded component, reaching the previously mentioned maximum stress of 604 MPa. The actuator bushings are subjected to substantially lower stresses, with a maximum equivalent stress of only 90 MPa, confirming that these components possess a considerable structural safety margin.

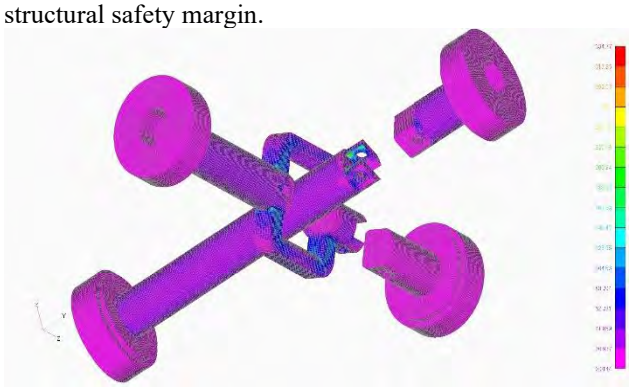

Figure 4. Equivalent (von Mises) stress distribution in the transmission shafts (σmax = 335 MPa)

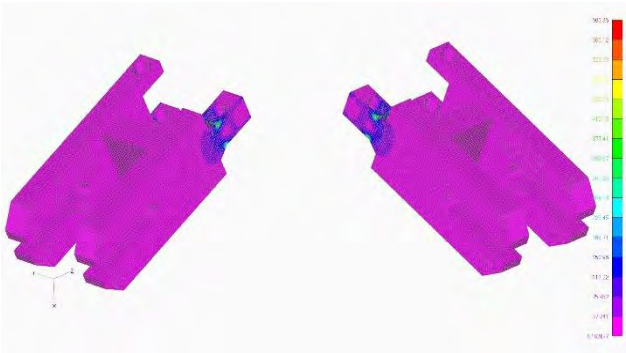

Figure 5. Equivalent (von Mises) stress distribution in the crank element (σmax = 604 MPa)

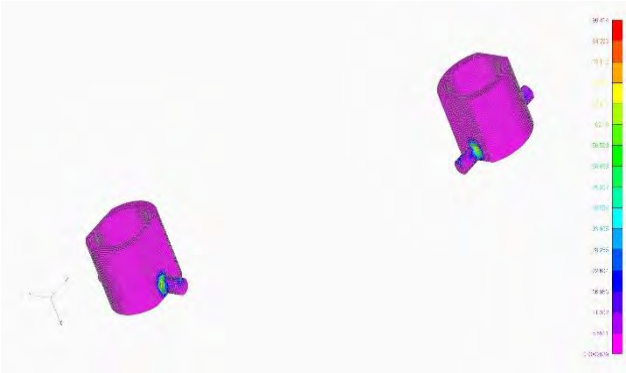

Figure 6. Equivalent (von Mises) stress distribution in the actuator bushings (σmax = 90 MPa)

The total deformation of the mechanical transmission system is shown in Figure 7. The maximum displacement amounts to 0.16 mm and occurs at the outer edge of the missile fin shaft. Such a small displacement demonstrates the high stiffness of the transmission system and ensures accurate transmission of the actuator motion to the missile control surfaces. Consequently, the positioning accuracy of the control fins is expected to be limited primarily by the actuator performance rather than by structural flexibility of the transmission mechanism.

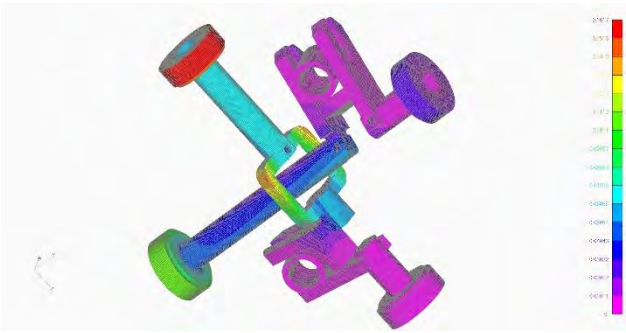

Figure 7. Total displacement of the mechanical transmission system (δmax = 0.16 mm)

Overall, the numerical results demonstrate that the proposed mechanical transmission system provides adequate structural strength and stiffness for the prescribed operating conditions. The stress distribution reveals no regions approaching the material yield limit, while the low deformation confirms the suitability of the selected structural configuration for high-precision missile fin actuation. Furthermore, the calculated safety factor suggests that the current design could be further optimized by reducing material in low-stress regions, thereby decreasing the overall mass without compromising structural integrity.

5. CONCLUSIONS

This paper presented a finite element structural assessment of the mechanical transmission system of a missile fin servo mechanism designed for pitch and yaw control. The analysis was performed under the maximum aerodynamic hinge moment acting on the missile fin, representing the most demanding operational loading condition.

The numerical results demonstrated that the proposed design satisfies the prescribed structural requirements. The maximum equivalent stress of 604 MPa was observed in the crank element, while the maximum displacement of 0.16 mm occurred at the output shaft of the missile fin. Both values remain within acceptable limits for the selected material, resulting in a calculated Factor of Safety of approximately 2.05. The relatively small deformation confirms the high stiffness of the mechanical transmission system, which is essential for accurate positioning of the missile control surfaces during operation.

The stress distribution further indicates that the transmission shafts and actuator bushings operate with considerable structural reserve, whereas the crank element represents the most highly loaded component of the assembly. These findings provide valuable guidance for future design improvements and identify the components that require particular attention during subsequent optimization.

The performed finite element analysis confirms the structural integrity of the proposed servo mechanism and provides a reliable basis for further development. Future research will focus on structural optimization aimed at reducing the overall mass of the mechanical transmission system while maintaining the required strength, stiffness, and positioning accuracy. Additional investigations will include fatigue assessment and experimental validation of the numerical model under representative operating conditions.

Abstract: *Thermovision monitoring provides an effective non-contact approach for the analysis of rapid thermal processes by enabling high-speed recording of infrared radiation response and reconstruction of temperature–time evolution. This paper presents an inverse thermovision reconstruction approach for the characterization of transient high-energy explosive processes based on radiometric analysis of fireball emission and a physics-based measurement model. Experimental validation was performed using RDX-based PBX thermobaric explosive formulations, with fireball development in static conditions in open-field tests, recorded by a high-speed infrared thermovision system operating at 1466 Hz. The reconstructed temperature-time profiles were analyzed to extract characteristic parameters, including maximum temperature, time to peak temperature, cooling rate, and integral temperature index describing the cumulative thermal response. Since thermovision systems measure radiometric signals and not the direct thermodynamic temperature, the reconstruction procedure considers emissivity, spectral response, and atmospheric transmission effects. The results demonstrate that different PBX formulations exhibit distinct thermal signatures, enabling comparative characterization based on fireball evolution and cooling dynamics. The proposed methodology confirms the potential of high-speed thermovision techniques combined with inverse reconstruction methods for quantitative non-contact analysis of transient high-energy explosion phenomena.*

Keywords: *infrared thermovision; infrared radiometry; inverse temperature field reconstruction; radiometric model; high-energy explosive phenomena; fireball dynamics; PBX explosive formulations*

1. INTRODUCTION

Thermovision technique represents one of the most important non-contact methods for spatial and temporal analysis of temperature fields and rapid thermal processes. It is based on the detection of infrared radiation emitted by the observed object and the determination of temperature-related parameters using a radiometric model that incorporates radiation source characteristics, optical system properties, atmospheric transmission, and detector response [1].

Unlike contact temperature measurement methods, thermovision systems enable non-invasive monitoring of dynamic processes with high spatial and temporal resolution, which has resulted in their application in material characterization, non-destructive evaluation, energy systems, biomedical applications, and analysis of complex thermal phenomena [1]. The physical basis of thermovision measurement relies on thermal radiation, where radiation intensity and spectral distribution depend on temperature and emission characteristics of the observed surface. However, real measurement systems deviate from the ideal black-body model due to material emissivity, detector spectral response, optical transmission characteristics, and atmospheric attenuation effects [2, 3].

For rapid thermal processes, such as high-energy explosive phenomena, temperature cannot be directly measured but must be reconstructed from the recorded infrared radiation signal. This represents an inverse thermovision problem, where the temperature field is determined from an indirectly measured detector response. Reliable reconstruction requires physically based radiation transfer models, additional constraints, and appropriate regularization methods to obtain stable and physically consistent solutions [4,5].

High-speed thermovision systems are particularly relevant for the analysis of explosive processes. Unlike nuclear explosive phenomena, where energy release is associated with nuclear transformations and intense high-energy radiation, conventional and thermobaric explosives involve rapid thermochemical reactions, heating of

Corresponding author: D. Knežević;
E-mail: dragankn@gmail.com
DOI: 10.5937/OTEH26071K

detonation products, fireball formation, and subsequent energy transfer through visible and infrared radiation [6-8].

The temperature evolution of an explosive fireball depends on chemical composition, charge density, fuel-to-oxidizer ratio, explosive geometry, and experimental conditions. Measurements of high-energy HMX-based systems have demonstrated temperature levels of approximately 3600 K during early stages of detonation product development [9]. However, the measured infrared signal is not a direct temperature value but a radiometric response affected by emissivity, spectral characteristics of the measurement system, and atmospheric propagation conditions. Therefore, accurate temperature estimation requires appropriate correction procedures and inverse thermovision reconstruction methods [10].

Modern high-speed infrared thermovision systems enable monitoring of fireball evolution, including temperature rise, maximum response, and cooling phase. The resulting temperature–time profiles provide characteristic thermovision signatures that can be used for comparative analysis of different explosive formulations [6,8,11].

The aim of this paper is to develop an inverse thermovision reconstruction approach for the characterization of transient high-energy explosive processes using high-speed infrared recording. The analysis focuses on the determination of maximum reconstructed temperature, time to peak temperature, cooling rate, and integral thermal response as physically based parameters for comparative characterization of PBX explosive formulations.

2. THERMAL-RADIATIVE PHENOMENA

2.1. Energy Balance of High-Energy Processes

Transient high-energy processes are characterized by extremely rapid changes in the internal energy state of a system, during which initially deposited energy is transformed into different energy components, including thermal, mechanical, and radiative energy. In explosive processes, this transformation occurs within a very short time interval and involves heating of detonation products, shock wave formation, expansion of gaseous products, and emission of electromagnetic radiation.

The total energy balance of the system can be expressed as:

$$E_{chem}=E_{th}+E_{mech}+E_{rad}+E_{res}$$

where E_{th} represents the thermal energy accumulated in detonation products, E_{mech} represents mechanical work and shock wave energy, E_{rad} represents energy emitted in the form of electromagnetic radiation, and E_{res} represents the residual energy component not directly included in radiometric measurement.

During the initial stage of explosive development, the dominant process is the transformation of chemical energy into the internal energy of detonation products and mechanical work:

$$Echem \rightarrow Eth+Emech$$

After reaching the maximum temperature response of the system, energy transfer mechanisms toward the surrounding environment become dominant:

$$Eres=Erad+Econv+Eexp+Emix$$

where the components represent energy losses due to thermal radiation, convection, expansion of detonation products, and mixing of products with the surrounding environment.

Thermovision systems measure only the radiative component leaving the system and do not provide direct information about the total released energy of the process. The measured signal depends on temperature, emissivity, spectral characteristics of the source, optical system properties, measurement geometry, and atmospheric attenuation [1–3].

Therefore, temperature determination from the infrared signal represents an inverse problem:

$$SIR(t) \rightarrow T(t) \rightarrow Eth(t)$$

where the temperature dynamics of the system and characteristic parameters of energy evolution are reconstructed from the measured radiometric signal.

2.2. Characteristics of Explosive Phenomena

The fundamental difference between nuclear and chemical explosive processes originates from the mechanism of energy release (Table 1). In nuclear explosions, energy is released through transformations of atomic nuclei (fission or fusion), resulting in the formation of an intense radiation field within an extremely short time interval.

From the viewpoint of thermovision technique, this difference is of fundamental importance. In nuclear phenomena, infrared emission represents a later stage of system evolution, occurring after the dominant radiation shifts toward lower-energy spectral regions. In chemical explosive processes, the infrared signal more directly corresponds to the development of the fireball temperature field and the cooling dynamics of detonation products.

Table 1. Fundamental physical differences between nuclear and conventional explosive phenomena

Parameter	Nuclear explosion	Conventional/Thermobaric explosion
Energy source	Nuclear reaction (fission/fusion)	Хемијска реакција
Characteristic temperature	10^6–10^7 K in the early radiative phase	Approximately 3000−5000 K
Dominant energy transfer mechanism	Radiative transfer	Thermochemical, radiative, and mechanical processes
Early development phase	X and γ radiation	Visible and infrared emission
Dominant spectral range	X → UV → VIS → IR	VIS + IR
Shock wave development	After the initial radiative phase	Practically simultaneous with detonation
Possibility of thermovision characterization	Limited due to early radiative effects	Direct analysis of thermal response

2.3. Temperature Reconstruction

The evolution of a high-energy source can be described through several characteristic stages. During the initial phase of nuclear processes, high-energy X- and γ-radiation dominates, rendering conventional infrared systems inapplicable because of the spectral limitations of infrared detectors.

As the fireball expands, its temperature decreases and the spectral distribution of emitted radiation gradually shifts toward the visible and infrared regions. At this stage, high-speed optical and thermovision techniques can be employed to determine:

- radiation temperature, T(t);
- fireball expansion dynamics, R(t);
- radiative energy flux.

However, the reconstructed temperature corresponds to the radiation temperature rather than the direct thermodynamic temperature of the entire source volume.

The principal limitations of infrared measurement arise from:

- the limited spectral range of the detector;
- the temporal response of the measurement system;
- the variable emissivity of the source;
- atmospheric absorption and scattering;
- the inverse nature of the temperature reconstruction problem.

Consequently, thermovision systems do not measure temperature directly; instead, they record a radiometric signal that is transformed into an estimate of the temperature field through a physics-based radiative transfer model [1-5].

2.4. Explosive Processes Characterization

For conventional and thermobaric explosives, thermovision provides an effective non-contact technique for analyzing the temporal evolution of the fireball. The temperature of detonation products typically ranges from approximately 3000 to 5000 K, depending on the chemical composition of the explosive and the conditions of the explosion [10], [11].

In this study, the explosive process is characterized by the following parameters: T_{max}, t_{max}, dT/dt, E; where T_{max} is the maximum reconstructed fireball temperature, t_{max} is the time required to reach the maximum temperature response, dT/dt denotes the cooling rate, and E is the integral energy index representing a relative measure of the overall thermal response during the observation interval.

These parameters do not represent a direct measure of the chemical energy released by the explosive. Instead, they provide a physics-based framework for comparing different high-energy systems through inverse thermovision reconstruction.

3. THERMOVISION OF EXPLOSIONS

Unlike nuclear explosive phenomena, where the initial stage of energy release is dominated by intense X- and γ-radiation, conventional and thermobaric explosives release most of their energy through thermochemical reactions, heating of detonation products, fireball formation, and subsequent radiative transfer within the visible and infrared spectral regions.

Consequently, the thermovision technique provides an effective non-contact approach for analyzing the temporal evolution of the explosive fireball, estimating its temperature regime, and reconstructing the characteristic energy-related parameters of the process [10], [11].

The temperature of detonation products for most conventional high-energy explosives typically ranges from approximately 3000 to 5000 K, depending on the chemical composition of the explosive, the fuel-to-oxidizer ratio, loading density, explosive geometry, and experimental conditions [10]. These values represent the thermodynamic characteristics of the system and should not be directly identified with the temperature reconstructed from the infrared radiometric signal.

For PBX-based explosive systems, published data indicate that the maximum fireball temperature is typically around 3600 K, representing the expected physical temperature range for comparison with and validation of the experimental results presented in this study [10], [11].

As with all radiometric measurement techniques, however, the recorded infrared signal does not represent the actual source temperature. Instead, it is the result of a thermal-radiative process governed by the source temperature, emissivity, detector spectral response, and atmospheric attenuation. Therefore, the actual fireball temperature can only be estimated using an appropriate inverse thermovision reconstruction model [1], [11].

Modern high-speed infrared thermovision systems enable time-resolved monitoring of explosive processes with high temporal resolution, allowing analysis not only of the maximum temperature but also of the complete temperature evolution of the fireball.

In the present study, the explosive process is characterized by the following parameters:

- maximum reconstructed fireball temperature, T_{max},
- time to reach the maximum temperature, t_{max},
- characteristic cooling rate, dT/dt;
- integral temperature response index,

$$E_I = \int_0^{t_{obs}} T(t)\, dt$$

which represents a relative measure of the overall thermal response during the observation period.

These parameters do not constitute a direct measure of the chemical energy released by the explosive. Instead, they provide a physics-based description of the temporal evolution of the thermal process and enable quantitative comparison of different explosive formulations using inverse thermovision reconstruction.

Table 2. Capabilities of the Thermovision Technique for Different Types of High-Energy Explosives

Explosive Type	Characteristic Temperature Range	Dominant Spectral Region	Principal Reconstructed Parameters
TNT	3000–4000 K	VIS + IR	T_{max}, cooling rate, fireball radius
PBX non-thermobaric	3200–3900 K	VIS + IR	Temperature field, cooling dynamics, energy distribution
Thermobaric mixtures	3000–5000 K	VIS + IR	Fireball duration, spatial temperature distribution, energy reconstruction

For TNT and other non-thermobarics, the temperature response originates from the short-lived emission of detonation products, whereas thermobaric formulations enable analysis of rapid temperature evolution and subsequent cooling. Unlike nuclear phenomena, these explosive systems are dominated by radiation within the visible and infrared spectral regions, making the thermovision technique suitable for monitoring the maximum temperature, cooling dynamics, fireball evolution, and the relative dynamics of thermal energy release (Table 2) [6-8].

4. INVERSE TEMPERATURE MODEL

An infrared thermovision camera does not measure the temperature of an observed object directly. Instead, it records a radiometric signal that depends on the surface temperature, material emissivity, atmospheric attenuation, the spectral characteristics of the optical system, and the temporal characteristics of image acquisition. Consequently, determining the actual temperature field constitutes an inverse problem, in which the temperature distribution is reconstructed from the measured infrared signal [1, 2].

The physical basis of the reconstruction is the law of thermal radiation. For the idealized case of total radiative emission, the Stefan–Boltzmann law can be expressed as

$$M = \varepsilon\, \sigma\, T^4$$

where M is the total radiative emittance, ε is the emissivity of the source, σ is the Stefan–Boltzmann constant, and T is the absolute temperature.

In a real measurement system, the recorded signal results from the interaction of the emitted radiation with the atmosphere, the optical system, and the detector. Therefore, temperature estimation requires the application of a correction and inverse reconstruction model, which can generally be expressed as

$$T_{max} = f(S_{IR}, \varepsilon, \tau, H(\lambda), t)$$

where S_{IR} is the measured infrared signal, ε is the emissivity, τ is the atmospheric transmittance, $H(\lambda)$ denotes the spectral response of the optical and detector system, and ttt is the acquisition time relative to the initiation of the process.

The proposed methodology is based on a physics-driven model that relates the spatial and temporal distribution of deposited energy to the resulting temperature field and the recorded infrared signal:

$$Q(x,y,z,t) \rightarrow T(x,y,z,t) \rightarrow M_\lambda(x,y,t) \rightarrow Sdet(t) \rightarrow T^*(x,y,z,t)$$

where $Q(x,y,z,t)$ denotes the volumetric heat source density, $T(x,y,z,t)$ is the temperature field, $M_\lambda(x,y,t)$ is the spectral radiance, $S_{det}(t)$ is the detector signal, and $T^*(x,y,z,t)$ is the reconstructed temperature field.

Unlike direct thermometry, temperature in thermovision is not a directly measured quantity but rather a parameter obtained through inverse thermovision reconstruction. Since this inverse problem is inherently ill-posed, its solution requires the incorporation of physical constraints, model assumptions, and appropriate regularization techniques to ensure stable and physically consistent reconstruction results [2, 9].

In addition to reconstructing the temperature field, the obtained results can be used to estimate the thermal energy loading of the investigated material. For this purpose, the accumulated specific thermal energy (thermal dose) is defined as

$$D = \int_0^t \frac{Q(x,y.z.\tau)}{\rho}\, dt$$

where D is the accumulated specific thermal energy (thermal dose) [J/kg], $Q(x,y,z,t)$ is the volumetric heat source density, i.e., the rate of energy deposition within the material [W/m^3], and ρ is the material density [kg/m^3].

Unlike conventional radiation dosimetry, this quantity represents the thermal energy dose, i.e., the amount of thermal energy accumulated per unit mass of the material

during the observation interval.

However, in explosive processes the spatial distribution of the heat source, $Q(x,y,z,t)$, cannot be determined directly from infrared measurements because the recorded signal represents the outcome of a complex thermal-radiative process. Consequently, the inverse thermovision reconstruction model is primarily employed to recover the spatiotemporal temperature evolution, while the corresponding energy-related parameters are derived from characteristic quantities extracted from the reconstructed temperature response.

5. EXPERIMENTAL RESULTS

5.1. Experimental Setup and Parameters

Experimental investigations were conducted on six explosive charges, each with a mass of 1 kg, prepared in three different PBX formulations (PBX-1, PBX-2, and PBX-3). Two independent experiments were performed for each formulation to evaluate the repeatability of the reconstructed temperature response.

The samples were designated as PBXij, where the first index (i=1,2,3) denotes the formulation type, while the second index (j=1,2) identifies the repeated measurement.

Measurements were performed using a high-speed infrared thermovision camera operating at 1466 Hz, equipped with a 50-mm focal-length lens and positioned at a distance of 60 m from the explosive charge. The resulting spatial resolution was approximately 36 mm/pixel, enabling continuous monitoring of the temporal evolution of the fireball throughout the explosive event.

From the reconstructed temperature–time histories, the following characteristic parameters were extracted:
- maximum reconstructed fireball temperature, T_{max};
- time to reach the maximum temperature, t_{max};
- characteristic cooling rate, $(dT/dt)_{cool}$;
- integral temperature response index, E_I.

These parameters were used to compare different PBX formulations based on their thermal-radiative response.

5.2. Analysis of the Temperature–Time Response

For each experiment, the following characteristics were analyzed:
- the reconstructed temperature evolution, $T=T(t)$;
- the maximum reconstructed temperature, T_{max}, corresponding to the highest temperature attained by the fireball during the explosive process;
- the cooling rate, $(dT/dt)_{cool}$, evaluated after the temperature peak as the slope of the descending portion of the temperature curve.

The cooling rate is governed by several simultaneous energy dissipation mechanisms, including:
- thermal radiation;
- convective heat transfer;
- expansion of detonation products;
- mixing with the surrounding air.

To provide an additional measure of the overall thermal response, the integral temperature response index was introduced:

$$E_I = \int_0^{t_{obs}} T(t)\,dt$$

which represents a relative measure of the accumulated temperature response during the observation interval.

It should be emphasized that E_I does not represent the actual chemical energy released by the explosive. Instead, it is an integral parameter derived from the reconstructed temperature signal, enabling quantitative comparison of different explosive formulations based on their thermal response.

In practical data processing, the discrete form was employed:

$$E_I = \sum_{i=1}^{n} T_i \Delta t$$

where T_i is the reconstructed temperature in the i-th frame, nnn is the total number of analyzed frames, and

$$\Delta t = 0{,}682\ ms.$$

5.3. Statistical Analysis

Two independent measurements were performed for each PBX formulation to evaluate the repeatability and variability of the experimental response.

The following statistical parameters were determined:
- individual values of the maximum reconstructed temperature, T_{max};
- mean temperature, $\bar{T}$;
- standard deviation, σ_T ;
- indicative confidence interval.

The mean value for each formulation was calculated as

$$\bar{T}_j = \frac{1}{n_j}\sum_{i=1}^{n_j} T_{ij}$$

where T_{ij} denotes the maximum reconstructed temperature obtained in the i-th experiment of formulation j.

The standard deviation was calculated as

$$\sigma_{T_j} = \sqrt{\frac{\sum_{i=1}^{n_j}\left(T_{ij} - \bar{T}_j\right)^2}{n_j - 1}}$$

To estimate the uncertainty of the mean value, a 95% confidence interval (used here as an indicative interval of variation) was determined using Student's t-distribution:

$$CI_{95} = \bar{T}_j \pm t_{0,975,n_j-1}\frac{\sigma_{T_j}}{\sqrt{n_j}}$$

Table 3. Statistical Parameters of the Maximum Reconstructed Temperature for the Investigated PBX Formulations

Formulat.	Sam. 1	Sam. 2	Mean (K)	SD (K)	95% CI (K)
PBX-1	2044.38	2030.87	2037.63	9.55	±85.83
PBX-2	2057.49	3090.05	2573.77	730.13	±6559.85
PBX-3	2255.55	2101.93	2178.74	108.63	±975.95

The results presented in Table 3 reveal different levels of variability among the investigated formulations. PBX-1 exhibits the highest repeatability, whereas PBX-2 shows substantially greater dispersion owing to the large difference between the two repeated measurements. PBX-3 demonstrates an intermediate level of variability.

Considering the limited number of repeated experiments (n=2), the calculated statistical parameters should be interpreted as indicators of experimental variability rather than as definitive estimates of the underlying statistical distribution.

The reconstructed temperatures fall within the physically expected range for RDX/HMX-based high-energy explosive systems, supporting the physical consistency of the applied radiometric reconstruction model [10].

The obtained results demonstrate that the thermovision technique enables effective characterization of the temporal evolution of the fireball and extraction of parameters sensitive to differences in the chemical composition of PBX formulations.

The principal limitations of the proposed methodology arise from the variable emissivity of the fireball, the spectral response of the detector, atmospheric attenuation, and the finite spatial and temporal resolutions of the measurement system. Nevertheless, the results confirm that inverse thermovision reconstruction provides a reliable and physically meaningful approach for the comparative characterization of the thermal response of different high-energy explosive systems.

6. CONCLUSONS

The capabilities and limitations of thermovision techniques for the characterization of transient high-energy explosive processes were investigated. An inverse thermovision reconstruction approach was developed using a physics-based radiometric model that relates the measured infrared signal to the reconstructed temperature–time evolution of the fireball.

Experimental analysis of PBX formulations demonstrated that thermovision techniques enable the extraction of characteristic thermal-response parameters, including the maximum reconstructed temperature, peak-time, cooling rate, and integral temperature index. The reconstructed temperatures were within the expected range for RDX/HMX-based high-energy systems, confirming the physical consistency of the proposed model and reconstruction procedure.

The analysis of nuclear explosive phenomena showed that conventional infrared systems are limited during the initial fireball phase due to dominant high-energy X-ray and ultraviolet radiation, while thermovision-based characterization becomes applicable during later evolution stages.

The obtained results confirm that thermovision techniques combined with physics-based radiative transfer models and inverse reconstruction methods provide an effective non-contact approach for the analysis and comparative characterization of conventional high-energy explosive systems.

Abstract: *This paper presents the reach and position workspace envelope analysis of the six-degree-of-freedom articulated robot ARma6 based on the solution of its forward kinematic problem. The robot reach is determined by combining Monte Carlo sampling with nonlinear optimization, while the limits of Tool Centre Point (TCP) in Cartesian space are obtained analytically using trigonometric relations. The rotational symmetry of the positional workspace is exploited to simplify the three-dimensional positional workspace's envelope determination, with two approaches considered: numerical extraction of the inner and outer radial boundaries and a geometric approach based on the circular TCP path corresponding to the effective robot reach. The obtained results characterize the reach and position workspace of the ARma6 robot and provide a basis for further evaluation of its geometry during the design process.*

Keywords: *robot, kinematics, reach, workspace, forward.*

1. INTRODUCTION

Growing customer demands and global competition are amongst the key drivers of the increasing need for integrating industrial robots with Industry 4.0 solutions [1]. Flexible robotic systems can adapt to a variety of tasks and products, making them particularly advantageous for high-mix, low-volume manufacturing, which is typical for small and medium-sized enterprises (SMEs) [1-2]. However, the wider adoption of industrial robots in SMEs remains limited by factors such as investment costs and the expertise required for robot programming [1-4]. These challenges encourage the development of more accessible robotic solutions for SMEs. In this context, the ARma6 robotic system, Fig.1, is being developed as a compact six degrees of freedom (DoFs) articulated robot supported by an extended reality (XR)-based platform for robot programming and interaction [5].

Solution of the robot forward kinematics problem (FK algorithm) is used to determine the position and orientation of the robot end-effector, i.e. frame attached to its TOOL CENTRE POINT (TCP) with respect to (w.r.t.) the BASE frame, for the input joint variables [6-7]. FK serves as the basis for robot simulation, inverse kinematics (IK) and motion planning, and workspace analysis.

Robot workspace and reach are amongst the key considerations in robot design, as they provide a quantitative measure of the range of tasks that the robot can perform. Additionally, before applying the IK algorithm, it is useful to verify whether the desired TCP position lies within the robot reach, position limits, or within its workspace, allowing the user to distinguish potential workspace-related errors from other IK failures. The workspace is often broken down into a reachable (position) workspace - the entire set of points reachable by the manipulator, and a dexterous workspace - points that the manipulator can reach with an arbitrary orientation of the end-effector [8-9].

In this paper, the FK algorithm, robot reach calculation, and position workspace envelope determination of the ARma6 articulated robot are presented. The robot reach is determined numerically using nonlinear optimization. Additionally, the limits of the TCP position in Cartesian space are obtained analytically using trigonometric identities. The methodology for the positional workspace envelope determination is presented.

This paper is divided as follows. In Section 2, the FK algorithm for the ARma6 robot is presented. The methodology for determining a robot reach and position

DOI: 10.5937/OTEH26072V

workspace envelope is presented in Section 3, and numerical simulation results are also presented herein. Discussion is given in Section 4, while concluding remarks are given in Conclusion.

Figure 1. 3D model of the ARma6 robot

2. FORWARD KINEMATICS ALGORITHM

One of the most used methods for kinematic modeling in robotics, the Denavit-Hartenberg (DH) convention [10], is adopted in this study. Robot DH parameters, Table 1, are defined based on frames attached to robot joints, Fig. 2 [5].

Table 1. Denavit-Hartenberg parameters for ARma6

Joint i	a_i	α_i	d_i	a_i
1	0	90°	d_1	θ_1
2	a_2	0	0	$\theta_2 - 90$
3	a_2	0	0	θ_3
4	0	90°	d_4	$\theta_4 - 90$
5	0	-90°	d_5	θ_5
6	0	0	d_6	θ_6

Joint-to-joint homogeneous transformation matrix (HTM) describing coordinate frame i relative to frame i-1 using DH parameters is given as follows [11]:

$$\mathbf{A}_i = \mathrm{Rot}(z_{i-1},\theta_i)\mathrm{Trans}(z_{i-1},d_i)\mathrm{Trans}(x'_{i-1},a_i)\mathrm{Rot}(x'_{i-1},\alpha_i) \quad (1)$$

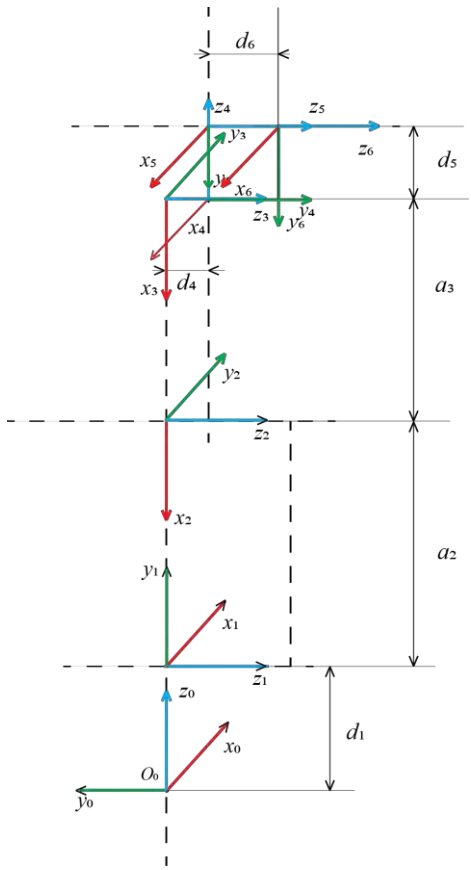

Figure 2. Frames assigned to ARma6 joints [5]

Based on joint-to-joint HTMs, the HTM of the frame attached to the robot's TCP w.r.t. the BASE frame is obtained as:

$$\mathbf{T}_{06}(\mathbf{q}) = \mathbf{A}_1\mathbf{A}_2\mathbf{A}_3\mathbf{A}_4\mathbf{A}_5\mathbf{A}_6 \quad (2)$$

In Eq. (2), $\mathbf{q} = [q_1 \ \ldots \ q_n]$ is a vector defining the robot configuration (joint positions q_i for i-1..n, where n is the number of DoFs, i.e. 6 for ARma6).

Hereinafter, the following notation is adopted: $c_i = \cos(q_i)$, $s_i = \sin(q_i)$, $c_{ij} = \cos(q_i + q_j)$, $s_{ij} = \sin(q_i + q_j)$, $c_{ijk} = \cos(q_i + q_j + q_k)$, $s_{ijk} = \sin(q_i + q_j + q_k)$

When the HMT $\mathbf{T}_{06}(\mathbf{q})$ is defined, the pose of the TCP w.r.t. the BASE frame can be calculated for every time instance t, i.e. the robot configuration $\mathbf{q}(t)$ given that $\mathbf{T}_{06}$ contains the rotation matrix and the position vector of the TCP frame and its origin w.r.t. the BASE frame [6]. X, Y, Z coordinates are obtained from the fourth column of the matrix $\mathbf{T}_{06}$ given in Eq. (2) as follows:

$$X(\mathbf{q}) = d_6(c_5 s_1 + c_{234} c_1 s_5) + d_4 s_1 - a_2 c_1 s_2 - d_5 s_{234} c_1 - a_3 c_1 c_2 s_3 - a_3 c_1 s_2 c_3 \quad (3)$$

$$Y(\mathbf{q}) = d_6(c_{234} s_1 s_5 - c_1 c_5) - a_2 s_1 s_2 - d_5 s_{234} s_1 - a_3 s_1 s_{23} - d_4 c_1 \quad (4)$$

$$Z(\mathbf{q}) = d_1 + a_3 c_{23} + a_2 c_2 + d_5 c_{234} + d_6 s_5 s_{234} \quad (5)$$

TCP frame orientation is obtained using the RPY angles convention [12] as given in [5].

3. DETERMINATION OF ROBOT REACH AND POSITION WORKSPACE ENVELOPE

Both the robot reach and the size of the workspace envelope are fundamental geometric characteristics that strongly influence the mechanical design and application of robotic manipulators. Increasing the workspace and reach typically requires longer links, which generally reduce manipulator stiffness and positioning accuracy. For the ARma6 robot and its adopted payload, a target reach of approximately 1 m was selected during the initial design stage, resulting in a compact robot configuration with a workspace suitable for the intended development and experimental activities.

3.1. Robot reach determination

In industrial robot specifications, the reach is commonly reported as the maximum distance from the robot BASE FRAME origin to the TCP, here denoted as $R_{\max}$, or as the maximum horizontal radial distance of the TCP to the BASE FRAME vertical axis, here denoted as $\rho_{\max}$.

$$R_{\max} = \max\sqrt{X^2 + Y^2 + Z^2} \quad (6)$$

$$\rho_{\max} = \max\sqrt{X^2 + Y^2} \quad (7)$$

Taking into account Eqs. (3) and (4), and by using simple trigonometric identities, the distance $\rho(\mathbf{q})$ from Eq. (7), i.e. the horizontal radial reach, can be calculated as

$$\rho(\mathbf{q}) = \sqrt{A^2 + B^2} \quad (8)$$

where

$$A = A(\mathbf{q}) = d_6 c_{234} s_5 - a_2 s_2 - d_5 s_{234} - a_3 s_{23} \quad (9)$$

$$B = B(\mathbf{q}) = d_4 + d_5 c_5 \quad (10)$$

The robot reach $R_{\max}$ can be calculated using several different approaches. Although the reach may be estimated by evaluating the FK over a discretized joint space, such an approach does not guarantee that the global maximum is found. Calculating reach for selected DH parameters can be regarded as a nonlinear optimization problem in which the joint variables $q_1,.., q_6$ are treated as optimization variables and the Euclidean distance from the robot BASE FRAME origin to the TCP is maximized. Given that the reach function is a highly nonlinear trigonometric function of multiple joint variables, obtaining a closed-form solution is generally challenging. In this study, numerical approaches are utilized.

It can be seen from Eq. (5-6) and Eqs. (8-10) that $Z(\mathbf{q})$ and $\rho(\mathbf{q})$ and consequently $R(\mathbf{q})$ do not depend on q_1 and q_6. Consequently, herein the maximum reach was determined numerically for the selected DH parameters by „optimizing“ the joint variables q_2, to q_5. The following two-stage procedure was applied for $R_{\max}(\mathbf{q})$ calculation:

1. Generate a large number of random initial configurations within the admissible joint space using Monte Carlo [13] sampling.
2. Starting from each initial configuration, locally optimize the objective function. The largest value obtained from all optimization runs is taken as the estimated global maximum reach.

On another note, since d_1 represents a fixed offset between the BASE FRAME and the second joint, it is convenient to define the effective robot reach $R_{1\max}$ w.r.t. the frame attached to the second joint, as illustrated in Fig. 3. The effective robot reach is calculated as:

$$R_{1\max} = Z_{\max} - d_1 \quad (11)$$

For calculation of $Z_{\max}$, the approach using trigonometric identities (without optimization methods) is applied herein. From Eq. (5), it can be seen that for the maximum TCP's Z coordinate w.r.t. the BASE FRAME, the robot configuration has to be the following: $q_2 = 0,\ q_2 + q_3 = 0 \rightarrow q_3 = 0,\ q_5 = \pi/2$. For the adopted values, the expression:

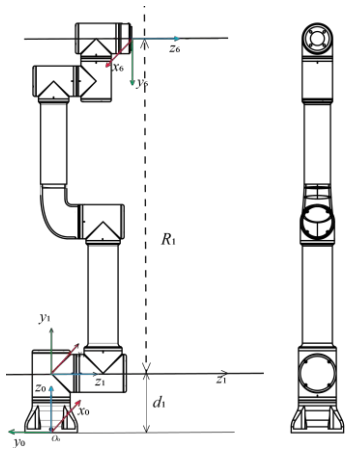

Figure 3. Robot ARma6 model selected frames.

$$d_5 c_{234} + d_6 s_{234} \quad (12)$$

has the maximum $\sqrt{d_5^2 + d_6^2}$ for the value of q_4:

$$q_4 = \alpha,\ \alpha = a\tan 2(d_6, d_5) \quad (13)$$

and the following is obtained:

$$Z_{\max} = d_1 + a_2 + a_3 + \sqrt{d_5^2 + d_6^2} \quad (14)$$

$$Z_{\min} = d_1 - a_2 - a_3 - \sqrt{d_5^2 + d_6^2} \quad (15)$$

3.2. Robot position workspace envelope determination

The workspace envelope encloses the workspace. Based on the FK algorithm, Eqs. (3-5), the position workspace can be calculated numerically. From Eq. (5) and Eqs. (8-10), it can be seen that neither the radial distance $\rho(Z)$ of the TCP from the BASE FRAME vertical axis, i.e., z_0 axis from Fig.2, nor the TCP's Z coordinate depend on the angle q_1. The joint angle q_1 changes only the azimuthal position of the TCP about the z_0 axis. From this, it can be concluded that the positional workspace of the ARma6 robot is rotationally symmetric around the BASE FRAME vertical axis.

In this study, the positional workspace envelope was determined using two approaches. In both approaches, the analysis was performed for an adopted constant value of q_1, and the obtained two-dimensional geometric representation was subsequently revolved about the z_0 axis, Fig. 2, to generate the three-dimensional workspace envelope. Approach 1 is based on the numerical determination of the inner and outer workspace boundaries in the ρ-Z plane. Approach 2 is based on the determination of the complete circular TCP path obtained by the rotation of the robot arm corresponding to the effective robot reach $R_{1\max}$, Eq. (11), Fig. 3, about the z_1 axis, $q_2 \in [0,\ 2\pi]$.

Approach 1

In Approach 1, the three-dimensional positional workspace is determined by one meridional cross-section (e.g. $q_1 = 0$). The Cartesian coordinates are transformed into cylindrical coordinates (ρ, Z). The inner $\rho_{\min}(Z)$ and outer $\rho_{\max}(Z)$ boundaries of the meridional section are determined using the following numerical procedure:

1. Perform a grid search [14] over the selected joint variables. Compute the TCP coordinates (X, Y, Z) using the FK for all sampled joint configurations and calculate the corresponding radial distance ρ, Eqs. (8-10).
2. Divide the range of Z-coordinates into a predefined number of horizontal layers of equal thickness. For each layer, identify all sampled points whose Z-coordinates lie within the corresponding interval.
3. Determine the inner and outer boundaries of all layers as the minimum and maximum values of $\rho(Z)$ among the selected points.
4. After obtaining the inner $\rho_{\min}(Z)$ and outer $\rho_{\max}(Z)$ boundaries for each layer in $Z \in [Z_{\min},\ Z_{\max}]$ as an array of discrete values, connect them by linear interpolation.
5. Revolve interpolated $\rho_{\min}(Z)$ and $\rho_{\max}(Z)$ curves about the the base-frame vertical z_0 axis.

Approach 2

The second approach in generating the outer workspace envelope is based on the complete rotation of the robot arm about the z_1 axis, $q_2 \in [0,\ 2\pi]$ in the configuration corresponding to the effective robot reach $R_1 = R_{1\max}$, for for an arbitrary adopted value of q_1 angle (herein it is adopted that $q_1 = 0$). The circular TCP path can be obtained either analytically, using the parametric equation of a circle with the previously determined center and radius $r = R_{1\max}$, or numerically, using the FK for a complete variation of the corresponding joint angle $q_2 \in [0,\ 2\pi]$. In both cases, the obtained TCP coordinates are subsequently transformed by the rotation matrix about the BASE FRAME vertical axis. The procedure consists of the following steps:

1. Determine the effective robot reach $R_{1\max}$, the corresponding robot configuration $q_{2\ldots}q_5$, and the center C_0 of the resulting TCP circle.
2. Generate the circular TCP path either from its parametric equation or directly from the FK by varying the corresponding joint angle through a complete revolution.
3. Revolve the obtained circular TCP path about the BASE FRAME vertical axis by applying the corresponding rotation matrix to the TCP position vectors $[\mathbf{X\ Y\ Z}]^T$.

3.3. Numerical results

For numerical calculation, the following DH parameters have been adopted: d_1=158.09mm, d_4=101mm, d_5=86mm, d_6=90.29mm, a_2=158.09mm, a_3=158.09mm.

For the selected DH parameters, 50000 random initial configurations of the joint variables q_2, q_3, q_4, q_5 were generated using Monte Carlo sampling within the range [0, 2π]. Starting from each initial configuration, a constrained local optimization was performed in Matlab [15]. The maximum reach obtained was $R_{\max} = 110.54$cm for $q_2 \approx$ -0.03°, $q_3 \approx$ 0.02°, q_4= -46.11°, q_5=-81.83°.

From Eq. (14-15), based on adopted DH parameters, it is obtaoned that $Z_{\max}$ =110.02 cm, $Z_{\min}$ =-78.4 cm. From Eq. (13) and Eq. (11), it is obtained that α=46.39°, and $R_{1\max} = 94.21$ cm.

The radial boundary values $\rho_{\min}(Z)$ and $\rho_{\max}(Z)$ were determined numerically using a uniform grid search over q_2, q_3, q_4, q_5 within [−π,π], with a discretization step of 5°, the resulting range of Z-coordinates was divided into 150 horizontal layers, and the following is obtained: $\rho_{\max} = 94.83$ cm.

Herein, since the q_6 angle does not affect the position of the TCP, it is adopted that $q_6 = 0$. For the adopted numerical values of DH parameters, the inner and outer boundaries of the meridional cross-section are depicted in Fig. 4.

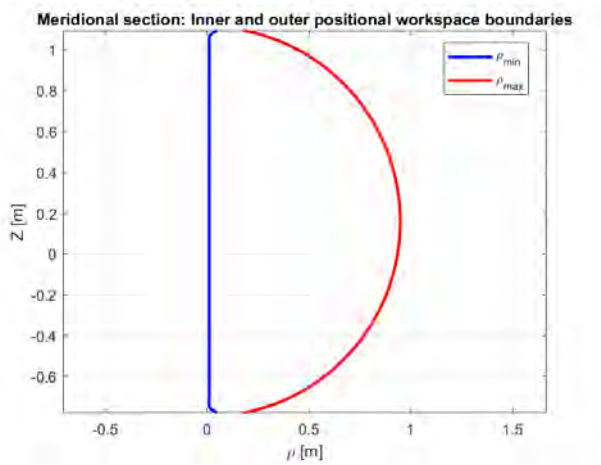

Figure 4 The inner and outer boundaries of the meridional cross-section.

The workspace envelope obtained using Approach 1 is shown in Fig. 5. By rotating $\rho_{\min}(Z)$ and $\rho_{\max}(Z)$ around the z_0 axis, the positional workspace envelope for the ARma6 robot is obtained from 120 angular samples.

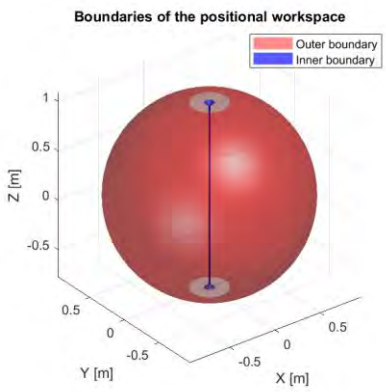

Figure 5 Positional workspace envelope for Arma6 robot obtained by applying Approach 1

To compare the two approaches, Fig. 6 superimposes 25 circular TCP paths corresponding to the effective reach $R_{1\max}$, onto the numerically determined workspace envelope by Approach 1. The circular paths closely follow the outer boundary obtained using Approach 1, indicating good agreement between the two approaches.

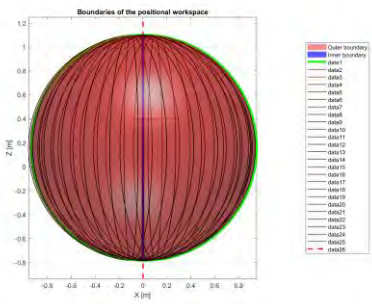

Figure 6 Positional workspace envelope for ARma6 robot obtained by applying Approach 1 and Approach 2 at 25 positions of the $R_{1\max}$ circle around the BASE FRAME vertical axis.

4. DISCUSSION

The proposed methodology combines analytical and numerical approaches for evaluating the kinematic characteristics of articulated manipulators. While the forward kinematic model provides analytical expressions for the TCP position, numerical optimization enables an accurate determination of the maximum reach without relying on exhaustive discretization of the joint space. Furthermore, exploiting the rotational symmetry of the manipulator positional workspace allows the analysis to be performed for a single value of the first joint angle, significantly reducing the computational effort required for three-dimensional workspace determination.

The obtained reach and position workspace envelope provide useful geometric information during the conceptual design stage, i.e. quantitative measures and quick assessment of the robot operating range and the comparison of different manipulator geometries. Since both characteristics depend directly on the selected DH parameters, the proposed methodology can support the selection of appropriate link dimensions in the early stages of robot design before detailed structural and dynamic analyses are performed. When designing a robot, an increase in reach is obtained by increasing the length of the robot's links, however this causes an increase in the mass of the links, the required motor torques, a decrease in stiffness and potentially the accuracy, and the robot may be more prone to vibrations.

In future work, the obtained reach and position workspace envelope can be incorporated into multi-objective optimization procedures aimed at identifying the optimal geometric parameters of the robot. Such optimization could simultaneously consider workspace characteristics, reach, structural stiffness, payload capacity, joint torques, and manipulator mass, resulting in improved overall robot performance. Additionally, the presented methodology should be extended by incorporating self-collision constraints.

5. CONCLUSION

This paper presented the determination of the reach and the position workspace envelope for the six DoF articulated robot ARma6 using its analytical FK model. The reach was obtained numerically using Monte Carlo sampling and nonlinear optimization, and the limits of Cartesian coordinates were determined analytically using trigonometric identities. Two approaches were applied to the position workspace envelope determination. In both approaches, the analysis was performed for a constant value of the first joint angle, and the resulting two-dimensional geometry was subsequently revolved about the base frame vertical axis in order to obtain the three-dimensional workspace envelope. In Approach 1, the rotational symmetry of the manipulator positional workspace was exploited to reconstruct the workspace envelope from the numerically determined inner and outer boundaries of a single meridional cross-section. In Approach 2, the outer workspace envelope was determined geometrically from the circular TCP path

corresponding to the effective robot reach. The obtained numerical results characterize the reach and position workspace of the current ARma6 geometry and provide a basis for further evaluation of the manipulator geometry during the design process. Future work will extend the workspace analysis by incorporating self-collision constraints and investigating the influence of the robot geometric parameters on the usable workspace using a multi-objective optimization framework. Additionally, the obtained workspace envelope will be integrated and visualized within the ARma6 XR environment to support intuitive robot task planning.

Abstract: *Micro-Electro-Mechanical Systems (MEMS) gyroscopes are widely used in modern inertial navigation and attitude determination systems due to their compact size, low power consumption, and high integration capability. However, their performance is limited by stochastic errors that significantly affect long-term measurement accuracy, especially in navigation applications. This paper presents the stochastic error characterization of a MEMS gyroscope from the STIM300 inertial measurement unit using Allan variance analysis. The main noise components, including angle random walk, bias instability, and rate random walk, are identified and quantified from experimental measurement data. The obtained noise parameters are used for the development of a Kalman filter model aimed at reducing the influence of stochastic errors and improving gyroscope output stability. Experimental results demonstrate the effectiveness of the proposed approach in reducing measurement drift and enhancing the reliability of MEMS-based inertial systems.*

Keywords: *MEMS gyroscope, STIM300, Allan variance, stochastic errors, angle random walk, bias instability, Kalman filter, inertial navigation system.*

1. INTRODUCTION

Inertial Measurement Units (IMUs) are fundamental components of modern navigation, guidance, stabilization, and control systems. By combining gyroscopes and accelerometers, they provide continuous measurements of angular velocity and specific force required for estimating the motion and orientation of a vehicle. The overall performance of inertial navigation systems is therefore strongly dependent on the accuracy and stability of inertial sensors, particularly gyroscopes.

Micro-Electro-Mechanical Systems (MEMS) gyroscopes have become widely adopted due to their compact size, low power consumption, high reliability, and compatibility with integrated electronic systems. Their favorable balance between cost and performance has enabled their application in unmanned aerial vehicles (UAVs) and unmanned ground vehicles (UGVs), autonomous platforms, robotics, industrial automation, and tactical-grade navigation systems [1], [2]. Despite these advantages, MEMS gyroscopes remain significantly more sensitive to stochastic error sources than navigation-grade fiber optic and ring laser gyroscopes, resulting in reduced long-term measurement accuracy [1], [3].

The dominant stochastic errors include angle random walk, bias instability, and rate random walk. Errors arise from inherent electronic noise, thermal effects, and other internal sensor imperfections. These noise processes accumulate over time and introduce drift into inertial navigation solutions, making accurate stochastic modeling essential for reliable attitude and navigation estimation. While deterministic errors can be compensated through calibration procedures, stochastic errors require statistical characterization and appropriate estimation techniques.

Among the available methods, Allan variance analysis has become the standard technique for stochastic characterization of inertial sensors and gyroscopes, as specified in IEEE Std 952-1997 [4]. It enables the identification and quantification of the dominant stochastic noise processes affecting inertial sensor performance [3], [5], [6]. By analyzing stationary sensor data over different averaging times, Allan variance enables the estimation of noise coefficients that serve as the basis for stochastic sensor modeling and filter design [3], [6], [7], [8].

This paper investigates the stochastic characteristics of the MEMS gyroscope integrated in the STIM300 inertial measurement unit (IMU) manufactured by Sensonor [9]. The stochastic parameters obtained from Allan variance analysis are incorporated into a Kalman filter model to estimate gyroscope bias and suppress measurement noise. The proposed methodology combines experimental noise characterization with model-based filtering to improve the stability and reliability of MEMS gyroscope measurements.

DOI: 10.5937/OTEH26073J

The paper is organized as follows. Section 2 describes the STIM300 MEMS inertial measurement unit and the experimental setup used for data acquisition. Section 3 presents the stochastic error characterization based on Allan variance analysis, with particular emphasis on Angle Random Walk, Bias Instability, and Rate Random Walk. In Section 4, a state-space model of the gyroscope is developed and a Kalman filter is designed for angular-rate estimation based on the identified stochastic error parameters. Section 5 presents the simulation and experimental results, including the evaluation of the filtering performance using statistical error metrics. Finally, Section 6 summarizes the main findings and conclusions of the study.

2. MEMS GYROSCOPES OPERATING PRINCIPLE AND ERROR SOURCES

2.1. Operating principle of MEMS gyroscopes

MEMS gyroscopes measure angular velocity by exploiting the Coriolis effect acting on a vibrating mechanical structure. A proof mass is continuously driven to oscillate along the drive axis. When the sensor experiences angular motion about the sensitive axis, the Coriolis force induces a secondary vibration perpendicular to the original motion. The amplitude of this vibration is proportional to the applied angular velocity and is converted into an electrical signal using capacitive, piezoresistive, or piezoelectric sensing elements.
The Coriolis force can be expressed as:

$$F_c = -2m(\vec{w} \times \vec{v}), \qquad (1)$$

where F_c represents the Coriolis force, m is the proof mass, $\vec{w}$ is the angular velocity vector, and $\vec{v}$ is the velocity of the vibrating mass.

The generated electrical signal is subsequently conditioned, compensated, and converted into the measured angular rate. The sensitivity and stability of the sensor depend on the mechanical characteristics of the vibrating structure, including its resonant frequency, quality factor, and damping. Advances in MEMS fabrication technology have significantly improved these characteristics, enabling devices such as the STIM300 IMU to achieve navigation-grade performance while maintaining compact dimensions and low power consumption.

2.2 Error sources in MEMS gyroscopes

The output of a MEMS gyroscope contains both deterministic and stochastic error components and can be generally expressed as:

$$w_m(t) = w(t) + \delta w_d(t) + \delta w_s(t)\,, \qquad (2)$$

where $w_m(t)$ represents the measured angular rate, $w(t)$ is the true angular rate, $\delta w_d(t)$ represents deterministic errors, and $\delta w_s(t)$ represents stochastic errors.

Deterministic errors, such as bias offset, scale factor error, axis misalignment, and temperature-dependent effects, are repeatable and can be significantly reduced through calibration procedures. Since the objective of this work is the characterization and filtering of stochastic errors, deterministic error sources are not considered further.

The stochastic component represents the dominant limitation of long-term gyroscope performance because it varies randomly with time and cannot be removed through calibration. Consequently, an appropriate stochastic model is required for accurate state estimation and filtering.

The stochastic component of the gyro output from expression (2) can be simplified as:

$$w_m(t) = w(t) + b(t) + n(t), \qquad (3)$$

where $w(t)$ is the true angular rate, $b(t)$ is the gyro bias, and $n(t)$ represents the measurement noise.

3. ALLAN VARIANCE – BASED NOISE CHARACTERIZATION

Allan variance is a widely used method for characterizing stochastic errors in inertial sensors. Unlike conventional variance analysis, Allan variance enables the identification of different noise processes by evaluating sensor stability over a range of averaging times. Dynamic extensions of Allan variance have also been proposed to analyze non-stationary stochastic processes and time-varying sensor characteristics [7], [10], [11].

For a discrete sequence of gyro measurements, the Allan variance is defined as:

$$\sigma_A^2(\tau) = \frac{1}{2(N-1)}\sum_{i=1}^{N-1}[\overline{w}_{k+1}(\tau) - \overline{w}_k(\tau)]^2, \qquad (4)$$

where τ is the averaging time, N represents number of non--overlapping averaging intervals and $\overline{w}_k(\tau)$ represents the average angular rate over the interval τ.

The Allan deviation is obtained as:

$$\sigma_A(\tau) = \sqrt{\sigma_A^2(\tau)}\,. \qquad (5)$$

The Allan deviation is usually presented on a logarithmic scale as a function of the averaging time. Different stochastic error sources produce characteristic slopes in the Allan deviation curve, as shown in Figure 1, enabling their identification.

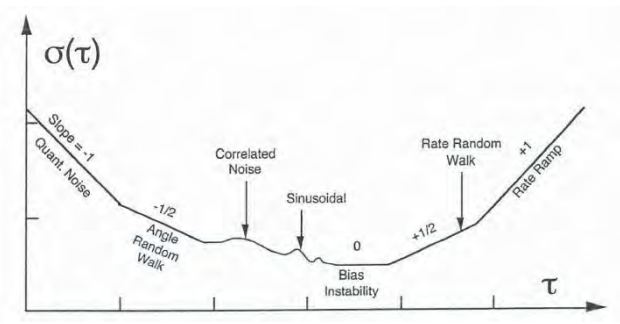

Figure 1 – Sample plot of Allan variance analysis results (IEEE 952 1997) [4]

The main stochastic error components considered in this work are:

3.1 Angle Random Walk

Angular Random Walk represents the high-frequency white noise component of the gyroscope output. In the Allan deviation plot, ARW is identified from the region where the curve has a slope of −1/2 logarithmic coordinates.

The Allan deviation in this region can be expressed as [4]:

$$ARW = \sigma_A(\tau)\sqrt{\tau}\,, \tag{6}$$

where ARW represents the angle random walk coefficient. Then,

$$\sigma_{ARW} = \frac{ARW}{\sqrt{T_s}}\,, \tag{7}$$

where σ_{ARW} is standard deviation of the discrete white Gaussian nosie used for syntetic signal generation and T_s is sampling period. The corresponding noise is modeled as a white Gaussian noise process:

$$n_{ARW} \sim N(0, \sigma_{ARW}^2). \tag{8}$$

3.2 Bias instability

Bias instability represents slow variations of the gyro bias and determines the long-term stability of the sensor. It is caused by low-frequency noise processes, including flicker noise. It appears as the minimum point of the Allan deviation curve. The bias instability coefficient is obtained from the corresponding Allan deviation value at the zero-slope region.

The corresponding Allan deviation value represents the bias instability coefficient:

$$BI = \frac{\sigma_{A,min}}{\sqrt{\frac{2\,ln(2)}{\pi}}}\,. \tag{9}$$

The averaging time at which this minimum occurs represents the characteristic time scale of the bias variation.

Unlike ARW, Bias Instability cannot be modeled as a white noise process. Therefore, the bias drift of a MEMS gyroscope is modeled as a first-order Gauss–Markov stochastic process. The continuous-time bias model is described by:

$$\dot{b}(t) = -\frac{1}{\tau_b}b(t) + w_b(t)\,, \tag{10}$$

where $b(t)$ represents the gyroscope bias, τ_b is correlation time and $w_b(t)$ is a zeromean white noise process.

The discrete-time form of the Gauss–Markov model is obtained as

$$b_{k+1} = e^{-\frac{\Delta t}{\tau_b}}b_k + w_k\,. \tag{11}$$

Here, Δt represents the sampling interval and τ_b defines the temporal correlation of the bias process. A larger value of τ_b corresponds to slower bias variations and stronger correlation between consecutive samples.

The covariance of the bias driving noise is:

$$Q_{BI} = BI^2(1-\phi^2), \tag{12}$$

where $\phi = e^{-\Delta t/\tau_b}$ and τ_b is the correlation time of the bias process.

The obtained BI parameter defines the magnitude of bias uncertainty, while the correlation time determines the temporal behavior of the bias drift.

3.3 Rate Random Walk

Rate Random Walk describes the long-term accumulation of angular rate errors. It appears as a slope of +1/2 on the Allan deviation curve. The corresponding coefficient can be estimated from:

$$RRW = \sigma_A(\tau)\sqrt{\frac{3}{\tau}}\,, \tag{13}$$

where RRW represents the rate random walk coefficient.

In the Kalman filter, RRW is modeled as a random walk process and contributes to the process noise covariance:

$$Q_{RRW} = RRW^2\Delta t. \tag{14}$$

4. STOCHASTIC ERROR MODEL PARAMETER ESTIMATION AND KALMAN FILTER DESIGN

The stochastic parameters obtained from Allan variance analysis provide a quantitative description of the gyro noise characteristics. These parameters are used to define the stochastic error model and determine the covariance matrices required for Kalman filter implementation [3], [12], [13]. The relationship between Allan variance coefficients and Kalman filter parameters has been extensively investigated and provides a practical methodology for selecting appropriate process and measurement noise covariance matrices [12].

In this work, the gyro bias is modeled as an additional state variable and estimated together with the angular velocity using a discrete Kalman filter. Such an approach enables simultaneous bias estimation and measurement noise suppression, resulting in improved long-term stability of the estimated angular rate [1], [2], [14].

The discrete state-space model can be expressed as:

$$x_{k+1} = Fx_k + Gw_k\,, \tag{15}$$

$$z_k = Hx_k + v_k\,, \tag{16}$$

where x_{k+1} is the state vector, F is the state transition matrix, w_k represents the process noise, G represents noise

gain matrix, z_k is the measurement vector, H is the measurement matrix, v_k represents the measurement noise.

The state vector is defined as:

$$x_k = \begin{bmatrix} w_k \\ b_k \end{bmatrix}, \tag{17}$$

where w_k represents the estimated angular rate and b_k represents the gyro bias.

The state transition matrix describes the dynamic behavior of the system between two consecutive sampling instants. The angular velocity is considered constant during one sampling interval, while the bias follows a first-order Gauss-Markov process.

Therefore, the state transition matrix is defined as:

$$F_k = \begin{bmatrix} 1 & 0 \\ 0 & \phi \end{bmatrix}, \tag{18}$$

where $\phi = e^{-\Delta t/\tau}$ is the correlation coefficient of the Gauss-Markov bias model. The parameter τ represents the correlation time of the bias. It determines how quickly the bias loses correlation with its previous value. The correlation time τ was selected according to the bias instability averaging time specified in the sensor datasheet.

The process noise covariance matrix is defined as:

$$Q = \begin{bmatrix} RRW^2 \Delta t & 0 \\ 0 & BI^2(1-\phi^2) \end{bmatrix}, \tag{19}$$

where RRW is the Rate Random Walk coefficient obtained from Allan variance analysis, BI is the Bias Instability coefficient, Δt is the sampling interval and ϕ is the Gauss-Markov correlation coefficient.

The first diagonal element represents the uncertainty of the angular velocity state caused by long-term rate variations. The second diagonal element represents the uncertainty of the bias state caused by the stochastic variation of the MEMS gyroscope bias.

The appropriate selection of the matrix Q is essential for Kalman filter performance. If the process noise is underestimated, the filter becomes insensitive to actual sensor variations, while excessive process noise leads to increased estimation uncertainty.

The measurement matrix defines the relationship between the system states and the measured gyroscope output.

The measurement equation is:

$$z_k = w_k + b_k + n_k. \tag{20}$$

Therefore, the measurement matrix is:

$$H_k = [\,1 \quad 1\,]. \tag{21}$$

This means that the measured angular velocity contains contributions from both the true angular velocity and the sensor bias.

The measurement noise covariance matrix describes the uncertainty of the gyroscope measurement.

The main short-term noise component of MEMS gyroscopes is Angle Random Walk (ARW), which appears as white noise in the angular rate measurement.

The measurement noise covariance matrix is defined as:

$$R_k = \frac{ARW^2}{\Delta t}, \tag{22}$$

where ARW represents the Angle Random Walk coefficient obtained from Allan variance analysis.

The R matrix determines how much confidence the Kalman filter assigns to the raw gyroscope measurement.

A larger value of R means that the measurement is considered less reliable, while a smaller value indicates higher confidence in the sensor output.

During the prediction stage, the previous state estimate is propagated using the state transition matrix:

$$\hat{x}_{\bar{k}|k-1} = F_k \hat{x}_{k-1|k-1}\,. \tag{23}$$

The predicted covariance matrix is calculated as:

$$P_{k|k-1} = F_k P_{k-1|k-1} F_k^T + Q_k\,, \tag{24}$$

where P_k is the state covariance matrix and Q_k represents process uncertainty.

The Kalman gain is calculated using:

$$K_k = P_{k|k-1} H_k^T \left(H_k P_{k|k-1} H_k^T + R_k\right)^{-1}. \tag{25}$$

The state estimate is corrected according to:

$$\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k(z_k - H\hat{x}_{k|k-1})\,. \tag{26}$$

The covariance matrix is updated as:

$$P_{k|k} = (I - K_K H_k) P_{k|k-1}\,. \tag{27}$$

5.EXPERIMENTAL SETUP AND RESULTS

The STIM300 inertial measurement unit, shown in Figure 2, was mounted on a laboratory table and remained stationary throughout the experiment to eliminate external rotational motion. Gyroscope data were collected for approximately three hours at a sampling frequency of 500 Hz using the manufacturer's communication interface. The recorded measurements were exported to MATLAB, where Allan variance analysis and Kalman filtering were performed offline. Stationary measurements were selected because they allow accurate identification of stochastic sensor errors without contamination by vehicle dynamics. As the gyroscope remained stationary with respect to the laboratory frame, the contribution of the Earth's rotation to the measured angular rate was neglected, and the true

angular rate was assumed to be zero for the purposes of stochastic error characterization and Kalman filter evaluation.

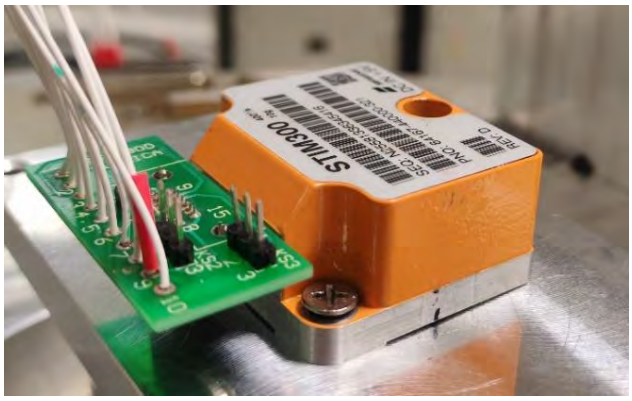

Figure 2. IMU STIM300

The Allan deviation curve, shown in Figure 3, clearly exhibits three characteristic regions corresponding to Angle Random Walk, Bias Instability and Rate Random Walk.

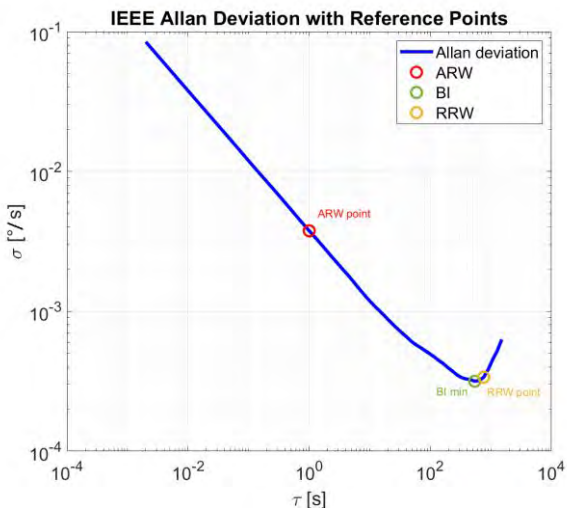

Figure 3. Allan Deviation

Their estimated coefficients, together with the corresponding datasheet values, are summarized in Table 1 and subsequently used for stochastic model identification.

Table 1. Value of stochastic error components

Noise parameter	Symbol	Value	Sensor datasheet specifications	Unit
Angle Random Walk	ARW	0.0038	0.0025	$°/\sqrt{s}$
Bias Instability	BI	0.0004734	0.0000833	$°/s$
Rate Random Walk	RRW	0.000021239	/	$°/s^{3/2}$

5.1 Simulation Results

A synthetic gyro signal was generated based on the stochastic error parameters identified from the Allan deviation analysis. The true angular rate was assumed to be zero, corresponding to the stationary condition of the sensor. The Angle Random Walk component was modeled as white Gaussian noise, with its standard deviation determined from the identified ARW coefficient. The Rate Random Walk component was generated as integrated white Gaussian noise, representing the slowly varying stochastic component of the angular-rate measurement. The Bias Instability component was modeled as a first-order Gauss–Markov process, whose parameters were selected according to the identified bias characteristics. The individual stochastic components were then combined to obtain the synthetic gyro output. In this way, the simulated signal reproduced the main stochastic characteristics identified from the experimental gyro data. The generated synthetic signal was subsequently used as the input to the proposed Kalman filter, allowing the performance of the stochastic model and the filtering algorithm to be evaluated under controlled conditions before their application to the experimental measurements. The corresponding filtering results are presented in Figure 4.

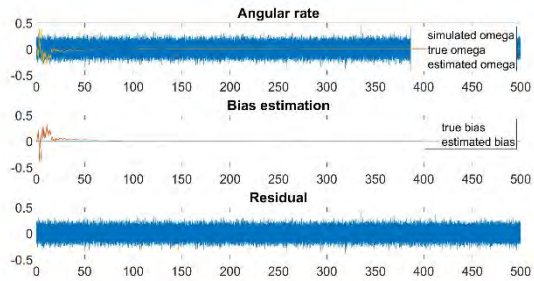

Figure 4. Kalman filter estimation results: simulated and estimated angular rate, true and estimated bias, and residual signal

5.2 Experimental Results

After validating the Kalman filter using simulated data, the same filter configuration was applied to measurements acquired from the STIM300 MEMS gyroscope. During the experiment, the sensor remained stationary in order to isolate stochastic error sources and eliminate the influence of external motion. The gyroscope data were sampled at a frequency of 500 Hz and processed offline in MATLAB.

Unlike the simulation, where the stochastic model is known, the experimental measurements represent the actual behavior of the sensor, including all dominant stochastic error components. The same Kalman filter configuration was subsequently applied to experimentally acquired STIM300 measurements. Since all stochastic parameters were obtained directly from Allan variance analysis, no empirical tuning of the covariance matrices was required. The filtered output exhibits significantly reduced short-term fluctuations while preserving the slowly varying gyro behavior. In addition, the estimated bias follows the expected low-frequency variations

predicted by the Gauss-Markov model.

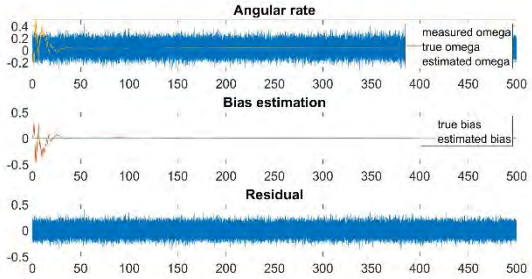

Figure 5. Kalman filter estimation results: measured and estimated angular rate, true and estimated bias, and residual signal

Figure 5 presents the measured and estimated angular rate, the true and estimated bias, and the residual signal. Since the gyroscope remained stationary throughout the measurement, the true angular rate was equal to zero. Consequently, the measured signal consisted only of stochastic errors, primarily white noise (ARW) and slowly varying bias drift.

The estimated angular rate converges rapidly toward zero, indicating that the Kalman filter successfully suppresses measurement noise while preserving the expected system dynamics. The estimated signal exhibits significantly lower variance than the raw sensor measurements, demonstrating the effectiveness of the proposed filtering approach.

The bias estimation initially exhibits relatively large oscillations. This transient behavior is expected because the filter starts from an initial estimate that differs from the actual bias. During the first several seconds, the Kalman filter gradually updates the state estimate as new measurements become available. As the estimation covariance decreases, the bias estimate converges toward the true bias generated by the Gauss–Markov model.

After the transient period, the estimated bias closely follows the true bias, indicating that the adopted stochastic model accurately represents the bias dynamics.

The innovation sequence remains centered around zero without any noticeable long-term trend, suggesting that the selected stochastic model adequately describes the measurement process and that no significant unmodeled dynamics remain.

Overall, the obtained results confirm that the Allan variance parameters, together with the Gauss–Markov bias model, provide an appropriate stochastic representation of the MEMS gyroscope and enable accurate estimation of both the angular rate and the sensor bias.

The performance of the proposed Kalman filter was evaluated using the standard deviation and root mean square error (RMSE), as summarized in Table 2. The standard deviation quantifies the achieved noise reduction, whereas RMSE evaluates the overall estimation accuracy.

Table 2. Performance indicators

Parameter	Value	Unit
Measured standard deviation	0.084858	deg/s
Estimated standard deviation	0.012279	deg/s
Noise reduction	85.46	%
Measured RMSE	0.090061	deg/s
Estimated RMSE	0.034220 deg/s	deg/s
RMSE improvement	62.00	%
Bias RMSE	0.01221466	deg/s

To quantitatively evaluate the filtering performance, the standard deviation and RMSE were calculated for both the measured and Kalman-filtered angular-rate signals. The measured standard deviation was used to quantify the dispersion of the raw gyroscope measurements, while the measured RMSE was used to quantify their error with respect to the assumed true angular rate. Similarly, the estimated standard deviation characterizes the dispersion of the Kalman-filtered signal, while the estimated RMSE quantifies its error with respect to the assumed true angular rate. The noise reduction was calculated from the reduction in standard deviation between the measured and estimated signals, whereas RMSE improvement represents the relative reduction in RMSE after filtering. The bias RMSE was calculated separately to quantify the error of the estimated gyroscope bias with respect to the reference bias. The standard deviation of the measured signal was 0.084858 deg/s, while the estimated signal exhibited a reduced standard deviation of 0.012279 deg/s, corresponding to an 85.46% reduction in noise level. The RMSE decreased from 0.090061 deg/s for the raw measurements to 0.034220 deg/s after filtering, representing a 62% improvement in overall estimation accuracy. The bias estimation error remained low, with a bias RMSE of 0.0122 deg/s, indicating that the Kalman filter successfully tracked the slowly varying gyro bias component.

6. CONCLUSION

This paper presented a methodology for stochastic modeling and filtering of a MEMS gyroscope using experimentally identified noise characteristics. The proposed approach combines Allan variance analysis with a Kalman filter whose covariance matrices are determined directly from sensor-specific stochastic parameters rather than empirical tuning.

The obtained results demonstrate that the proposed filter effectively reduces short-term measurement fluctuations while providing reliable estimation of the slowly varying gyroscope bias.

By linking experimental noise characterization with model-based state estimation, the proposed methodology

provides a practical framework for improving the quality of MEMS gyroscope measurements. Such an approach is particularly suitable for inertial navigation and attitude estimation systems, where accurate stochastic sensor modeling is essential for achieving stable long-term performance.

Future work will focus on extending the proposed methodology to a complete error-state Kalman filter for integrated inertial navigation systems and evaluating its performance under dynamic operating conditions.

A LAYERED COUNTER-UAS CONCEPT: FROM MULTI-SENSOR DETECTION AND CLASSIFICATION TO KILL-WEB INTEGRATION

ILIJA POPADIĆ, MILJAN VUČETIĆ, ZORAN BANJAC, BOŠKO BOŽILOVIĆ, IVAN VULIĆ
Vlatacom Institute of High Technologies, Belgrade, ivan.vulic@vlatacom.com

Abstract: *The proliferation of small unmanned aircraft systems (UAS), from commercial quadcopters to Shahed-class loitering munitions, has created a threat that legacy air defense was not designed to counter: low, slow, small, inexpensive, numerous and increasingly autonomous targets. This paper presents a layered counter-UAS (C-UAS) concept spanning the full engagement chain, grounded in engineering results and operational experience. We argue that no single sensing modality suffices: the sensor set must include a passive layer, with acoustic sensing — non-jammable and independent of line of sight — addressing the autonomous, fiber-guided and otherwise radio-silent platforms that defeat radio-frequency (RF) sensing. We then describe artificial-intelligence (AI) classification at the sensor edge, multi-sensor track fusion, and the integration of soft-kill and hard-kill effectors — operational directional jamming and, under development, the AURORA programmable airburst munition, a reusable kinetic micro-interceptor drone and a high-energy laser — into a kill web built on a C7ISTAR solution (command, control, communications, computers, cyber, combat systems and collaboration, with intelligence, surveillance, target acquisition and reconnaissance), whose ORAO (Observe, React, Analyze, Operate) command platform and ARES (Algorithmic Reconnaissance and Execution System) AI core have protected national critical infrastructure since 2024. The concept applies to counter-drone protection of fixed critical-infrastructure sites, vehicles, ships, and temporary sites, including operation in civilian environments.*

Keywords: *counter-UAS, layered defense, multi-sensor fusion, interceptor UAV, kill web.*

1. INTRODUCTION

Few threat classes have evolved as rapidly over the past decade as small unmanned aircraft systems (UAS). Platforms derived from commercial technology are cheap, numerous, simple to operate, and increasingly capable, and loitering munitions of the Shahed type extend the same logic to ranges once reserved for far more expensive weapons. Employed en masse, they impose an unfavorable cost exchange on the defender: over 14,700 one-way attack drones were launched against Ukraine between September 2022 and December 2024, at unit costs one to two orders of magnitude below those of the air-defense missiles initially expended against them [1]. On-board autonomy compounds the problem — a UAS navigating by waypoints or on-board perception offers no control link to detect or deny — and fiber-optically guided first-person-view (FPV) platforms are immune to jamming by construction [2]. It is now broadly recognized in the literature [3], [4], [5] and in strategy and doctrine [2], [6] that no single sensor and no single effector constitutes a counter-UAS (C-UAS) capability. Required is a layered system: complementary sensor modalities, machine-assisted classification, and a command-and-control (C2) layer connecting any sensor to the most appropriate effector — a kill web rather than a linear kill chain. Its measure, and the thread of this paper, is the path from sensor to shooter, which every layer must shorten without surrendering the operator's authority.

C-UAS is a demanding instance of the general command-support problem, whose vocabulary has grown from C2 through C4ISR (command, control, communications, computers, intelligence, surveillance and reconnaissance) to C7ISTAR — command, control, communications, computers, cyber, combat systems and collaboration, integrated with intelligence, surveillance, target acquisition and reconnaissance — which admits cyber defense, combat systems and collaboration as first-class capabilities [7]. The concept is grounded in an integrated anti-drone system — the ORAO (Observe, React, Analyze, Operate) C2 platform carrying the ARES (Algorithmic Reconnaissance and Execution System) artificial-intelligence (AI) core — that has protected a major critical-infrastructure facility in Serbia since 2024, and in research on electro-optical imaging [8], [9], target tracking [10], [11], radar [12], [13] and secure communications. Sections 2 to 6 treat detection, the sensor layer, classification and fusion, decision and effect, and deployment; Section 7 concludes.

2. THE DETECTION PROBLEM

The difficulty begins with physics. Small UAS present radar cross-sections (RCS) orders of magnitude below those of manned aircraft and fly where the radar picture is dominated by clutter, birds and multipath; their speeds reach down to hover, inside the rejection region of classical moving-target processing; thermal signatures are modest, acoustic output attenuates quickly, and visual size defeats unaided observation beyond short range. An emitting UAS offers a radio-frequency (RF) signature buried in congested spectrum; a non-emitting one offers RF sensing nothing — decisive for Shahed-class and other autonomous threats.

Corresponding author: I. Vulić;
E-mail: ivan.vulic@vlatacom.com
DOI: 10.5937/OTEH26074P

Detection ranges are short, closing times shorter, and whatever the architecture achieves must be achieved at a manageable false-alarm rate, because a system that alerts on every bird will be switched off. Experience with a thermal panoramic sensor is instructive [9], [14]: a head covering the full circle in 2.3 s produces some fifty raw detections per second, dominated by clouds and birds; tracking, cloud rejection, bird filtering and AI classification of close targets reduce that flow to about one plausible drone detection per second. Detection is cheap and noisy; tracking, classification and fusion of complementary modalities produce a usable picture [3], [15].

3. THE MULTI-SENSOR DETECTION LAYER

Radar is the backbone of volumetric search: all-weather, day and night, with direct measurement of range and radial velocity; against small UAS, its discriminative asset is the micro-Doppler signature of rotating rotors [15], [16]. In the described system, a compact X-band pulse-Doppler radar is integrated as a third-party component, detecting targets with an RCS of about 0.01 m² at a few kilometers; earlier radar research [12], [13], [17] informs its integration and interpretation of small-target returns. The electro-optical layer compensates for its weak elevation scanning.

RF sensing is passive and continuous, and two of its functions must be distinguished. A wideband receiver performing real-time spectrum analysis over roughly 20 MHz to 6 GHz detects and classifies control, telemetry, and video links, but spectrum analysis alone yields no direction. A direction-finding (DF) antenna array measures bearing by comparing amplitudes across directional elements or using phase interferometry; bearings from two or more DF sensors are triangulated into an approximate position of the platform and, when its controller transmits, of the operator [4]. The limitation is categorical: RF sensing cannot detect non-emitting platforms, such as fiber-guided drones or autonomous ones in radio silence, and must work in dense civilian spectrum.

Electro-optical and infrared (EO/IR) sensing provides what no other modality can: an image — identification, payload assessment, and the visual confirmation that engagement decisions in most settings legally require. The VMSIS3 multi-sensor imaging turret fills this role with a cooled mid-wave (MWIR) or uncooled long-wave infrared (LWIR) channel, a high-definition day channel with optical zoom, a low-light channel and a laser rangefinder from which target coordinates are computed [8], [9]. On an extremely agile pan-tilt positioner, the ROBIN configuration slews to a cued target, and its on-board AI verifies a drone, aircraft, helicopter, or bird in under two seconds. EO/IR is narrow-field and visibility-dependent: most effective when cued rather than searching.

Acoustic sensing detects the propulsion signature of the target: fully passive, non-jammable, effective without line of sight and against precisely the radio-silent platforms — autonomous or fiber-guided — that defeat the RF layer, with 360° coverage at low unit cost and power; propagation modeling draws on earlier acoustic work [18]. Recent peer-reviewed results confirm the modality's maturation [19], and doctrine now recommends passive RF and acoustic layers alongside active sensors [2]. Its physics defines its role — short-to-medium-range passive cueing and gap-filling — and it earns its place exactly where the other modalities are weakest. Table 1 summarizes the complementarity of the four modalities.

Table 1. Complementarity of sensor modalities in the C-UAS detection layer

Modality	Principal strengths	Principal limitations	Role in the layered system
Radar (X-band)	Volumetric all-weather search; range and radial velocity; micro-Doppler	Ground clutter; low-velocity regime; weak elevation scanning	Backbone of early warning and tracking
RF sensing	Passive; link classification; DF bearings and triangulation	Blind to non-emitting targets; congested spectrum	Wide-area passive tripwire and attribution
EO/IR (VMSIS3)	Identification and evidence; AI verification in < 2 s; laser ranging	Weather and visibility dependent; narrow field; requires cueing	Confirmation, identification and geo-location on cue
Acoustic	Passive, non-jammable, 360°; RF-silent UAS without line of sight	Short range; sensitive to wind and ambient noise	Persistent passive detection of azimuth, elevation and velocity

4. CLASSIFICATION AND TRACK FUSION

4.1. Separating targets from confusers

The first task of the intelligence layer is binary and unforgiving: is this track a UAS, or one of the innumerable confusers of the low-altitude environment — above all birds and clouds? In the described system, it is performed by ARES, the Algorithmic Reconnaissance and Execution System: the modular AI core of the C7ISTAR solution, which turns sensor data into a common operational picture and is organized in three tiers that follow the levels of command — ARES Edge (tactical) at the sensor, ARES Core (operational) for fusion across sites, and ARES Strategic (command) for language-model decision support. ARES Edge runs inference at the sensor itself, on a graphics processing unit (GPU) module delivering more than one hundred trillion operations per second, with deep-learning models distinguishing drone, bird, aircraft, and helicopter; only the track and its class label then traverse the network, which keeps the system usable on constrained links and limits data exposure, a concern formalized for distributed sensor networks in [20], [21]. With processing latency below 100 ms, it marks the target, assigns class and confidence, and drives automatic tracking; a Kalman filter with deep-learning re-identification holds the track through occlusion and maneuver, building on robust Kalman tracking in short-wave infrared (SWIR) imagery [10] and motion-triggered track activation [11]. Acoustic classification complements imagery when the target is beyond visual range or emits no visual signature.

4.2. Threat level, fusion and the model lifecycle

Beyond the binary decision, classification refines platform class, link type, payload indications, and signature type, and threat-level estimation combines what the object is with what it is doing — trajectory, altitude, speed, coordination — into a ranked picture. Fusion associates detections across modalities into single system tracks carrying classification, confidence, and full sensor provenance [22], [23]; gossip-type distributed estimation algorithms address consensus across heterogeneous, asynchronously communicating sensor networks [24]. The purpose is continuity — the acoustic layer holding a target behind cover, the radar holding one lost to glare — and credibility: a track confirmed by independent modalities justifies a response that a single-sensor track does not. Because the domain is adversarial and non-stationary, models are maintained assets — curated datasets, monitored in-service performance, controlled retraining [16] — and local training on the edge platform adapts them to the threat picture of a site without data leaving the security perimeter, a sovereignty requirement.

5. FROM SENSOR TO SHOOTER: DECISION, EFFECT AND KILL-WEB INTEGRATION

5.1. The ORAO command-and-control platform

ORAO (also the Serbian word for eagle) is the layer that turns sensing into effect: a C2 platform built on a scalable microservices architecture that underpins the C7ISTAR solution. It integrates sensors and effectors into a single operational picture, suppresses false alarms through fusion, and lets the operator act remotely; new sensors, effectors, or functions are added without altering the core, so that one architecture spans the configurations of Section 6. Figure 1 shows the platform fusing the bearing of the RF direction-finding sensor with electro-optical tracking of the same target, with jammer and sensor sectors on the map.

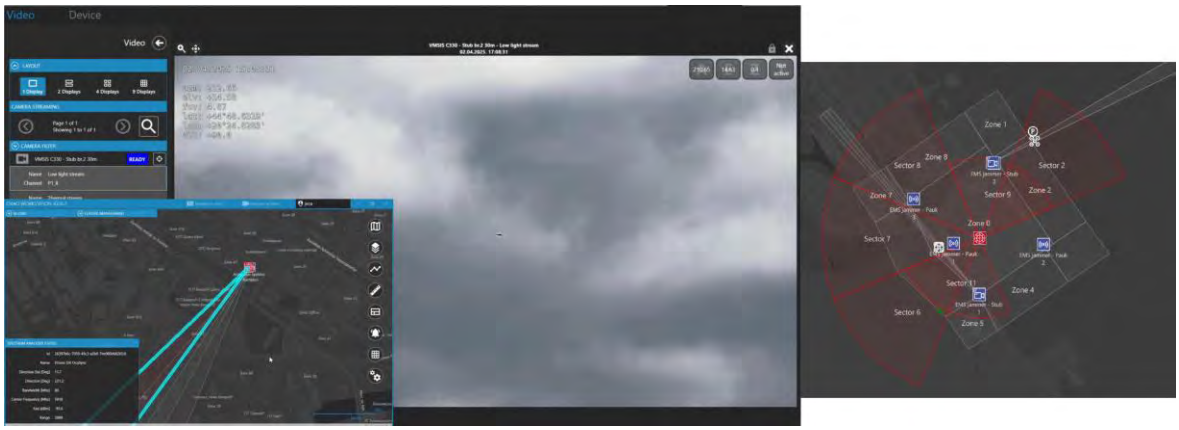

Figure 1. The ORAO console: live optical stream with telemetry, bearing lines of the RF direction-finding sensor with its status panel (classified link, bearing, standard deviation), and sensor and jammer sectors

5.2. The kill web

The integrating principle is the kill web (Figure 2): every sensor and every effector is a node on the common C2 fabric, and the system composes the engagement path best suited to each track — any sensor, best effector [25] — a principle the recent literature refines into federation scoped to concrete engagement chains rather than all-to-all interoperability [26]. The acoustic sensor may hold an RF-silent target the radar cannot separate from clutter; ORAO cues the VMSIS3 turret to that bearing, ARES Edge confirms the object in under two seconds and the rangefinder fixes its coordinates; ARES Core holds the fused track, while ARES Strategic couples the picture to language-model agents that give the operator situation reports and ranked courses of action; on the operator's decision, the appropriate effector is assigned. The fabric is resilient — redundant paths, graceful degradation — and efficient, using the cheapest adequate effector per engagement. It is also a security fabric: every node's identity must be established and its data protected, for which public key infrastructure (PKI) models for authenticating Internet-of-Military-Things devices [27], for interoperability across national and coalition PKI domains [28] and for time-stamped trust in device data [29] provide the design basis. ORAO is supervised-autonomous: AI and rule-based actions prepare and, where configured, execute responses, but authority over the use of force rests with the operator except where narrowly bounded, pre-authorized automatic responses have been deliberately enabled. Where a kill chain offers one path and fails when any link fails, the web offers many, selecting at each engagement the shortest path the rules of engagement allow.

5.3. Soft-kill and hard-kill effectors

Effectors divide into two families with complementary profiles. Soft kill — directional RF jamming of control, telemetry and satellite-navigation links in the standard drone bands — is low-cost per engagement, deep in magazine and comparatively benign; it is the proven method on which the operational system relies, driving the target to descend, return or land. It is ineffective against fiber-guided platforms and autonomous ones navigating without satellite signals, and its use of civilian spectrum is regulated. Hard kill is effective regardless of autonomy and is pursued along three complementary lines.

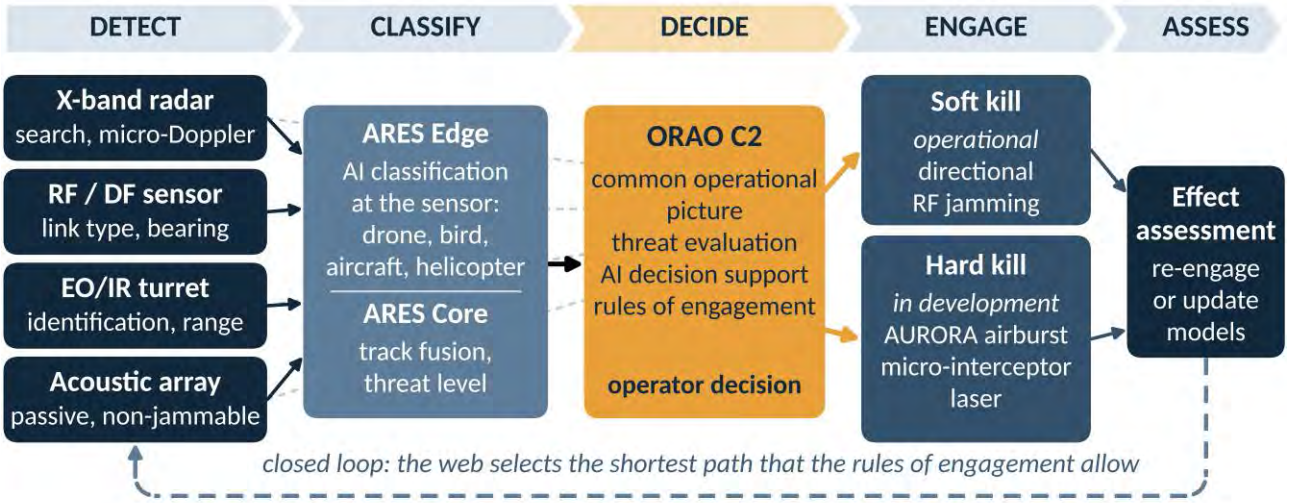

Figure 2. The C-UAS kill web along the engagement sequence: sensors, ARES classification and fusion, ORAO C2 under the rules of engagement, soft kill (operational), hard kill (in development), and effect assessment

Figure 3. Concept rendering of micro-interceptors of the 7-inch class at readiness in a five-position dock-and-launch module; launch is authorized through ORAO over a secure C7ISTAR link

The first line is gun-based: AURORA, a dual-caliber programmable airburst munition for 30 mm and 23 mm autocannons, at technology readiness level 2 with a roadmap to level 7. Instead of requiring a direct hit on a small, agile target, the round carries an electronic fuze built around a high-g-resistant field-programmable gate array (FPGA) timer, set inductively at the muzzle from the muzzle velocity measured for each round; it detonates at the computed intercept point, ejecting a forward cone of pre-formed tungsten fragments that saturates the flight path and defeats the target from a near miss. Timing accuracy is of the order of 2 ms, and the design objective is a kill probability above 85% against agile UAS at a cost per engagement that conventional high-explosive fire cannot approach. As a retrofit — a bolt-on muzzle programming unit and a fire-control interface — it upgrades existing guns without replacement. The program is phased: AURORA-30 (30 × 165 mm, 2A72-class guns, 150–200 tungsten sub-projectiles per round) proves the timer logic and power-source survival under launch loads before the design is scaled down to AURORA-23 (23 × 152 mm, ZU-23-2-class guns, 50–70 sub-projectiles).

The second line is a kinetic micro-interceptor unmanned aerial vehicle (UAV), another effector node of the kill web (Figure 3): a compact tail-sitting quadrotor of the 7-inch class (177.8 mm airframe height) with four electric propulsion units, vertical launch, and a forward-looking electro-optical camera for the terminal phase. Its effect is purely kinetic, by direct impact, with no explosive warhead — a property that matters in the populated settings of Section 5.4. Vehicles wait at readiness in five-position dock-and-launch modules with charging, health monitoring, and safety interlocks; two modules hold ten ready vehicles. The engagement follows the same accountable sequence as every other effector: ORAO holds the fused track, a designated operator authorizes the launch under the rules of engagement, the mission travels over the authenticated C7ISTAR data link, and the vehicle is guided into the intercept basket and completes the engagement with on-board terminal sensing; on a miss or abort, a commanded parachute-assisted recovery returns it for inspection, recharge, and readiness. A reusable interceptor thus extends the cost-exchange logic of AURORA beyond the gun envelope, engaging the fiber-guided and autonomous platforms that jamming cannot defeat, at a per-engagement cost that scales to mass attack — the reason interceptor drones have become the fastest-growing hard-kill layer internationally, up to the autonomous drone-on-drone interception now reported in the literature [2], [30]. Terminal-guidance performance and the recovery cycle are qualification objectives of the current phase.

The third line is a high-energy laser, past functional-model testing and progressing toward a prototype. Neutralization requires holding a small, agile target in a spot of the order of 10 mm for seconds — a collimator, a rangefinder and a pan-tilt and tracking chain of exceptional precision, all inherited from the VMSIS3 line, whose gyro-stabilization is studied in [31]. All three lines consume what the web already produces — fused track, range and authenticated tasking — and the layered system selects per engagement: soft kill first wherever the threat depends on its radio links, hard kill where soft kill cannot reach.

5.4. Operation in civilian environments

C-UAS operates over and around civilian life, making constraints design inputs rather than afterthoughts:

jamming interacts with regulated spectrum and legitimate users; kinetic and directed-energy effects over populated areas carry collateral risk; and interception of aircraft, however small, engages aviation law and requires a documented decision trail. The operational system therefore provides selective control of jammer power and coverage zones, safeguards against unauthorized triggering unless a fully automatic mode is explicitly enabled, geographic and functional zoning of permitted effects, and evidentiary logging of imagery, tracks and decisions in time-stamped, cryptographically verifiable records [29]. Among hard-kill options, a warhead-free kinetic interceptor with controlled recovery best fits these constraints, introducing neither blast nor fragmentation over the protected area.

6. DEPLOYMENT AND USE CASES

The clearest evidence that the architecture is more than conceptual is that it is deployed. Since 2024 the integrated anti-drone system has protected a major critical-infrastructure facility in an urban environment in Serbia, stopping small commercial and FPV drones before they come within 500 m of the perimeter: sensor towers with panoramic cameras, RF detection and direction-finding sensors and agile VMSIS optics cover roughly one square kilometer, and a countermeasure tower provides RF jamming with selective radiation and coverage control so that the surrounding area is unaffected, all operated through ORAO; because the site is urban, radar was omitted and the passive and optical layers carry detection. The site maps onto concentric functions — early warning at distance, confirmation in the middle zone, countermeasures in the inner zone — under continuous unmanned watch that alerts a small response element.

The same architecture has been engineered for mobility: a configuration on a 4×4 mine-resistant ambush-protected (MRAP) vehicle packages ORAO, the sensor suite, the edge-AI optoelectronic turret, and RF countermeasures onto a protected cross-country platform, rapidly movable to a threatened location and remotely commanded.

The maritime profile extends the architecture to vessels and offshore infrastructure, where operational experience has made the cost-exchange argument unanswerable: in the Red Sea, warships expended roughly 220 air-defense missiles — on the order of a billion dollars — against UAS and missile attacks in a single year [32]. In the configuration engineered for a very large crude carrier (VLCC), two radar heads with overlapping coverage, six acoustic nodes along the hull and four marinized Skua EO/IR turrets feed a shipboard ORAO instance, with two five-position micro-interceptor dock modules on the aft weather deck as the effector layer; the installation is a segregated security enclave with no control path into ship systems and no default external dependency. Maritime sensing experience — surface-wave radar for wide-area sea surveillance [12], [17] and fusion of automatic identification system (AIS) data with over-the-horizon radar tracks [23] — carries directly into this profile, and the low-altitude picture of the vessel federates into the same recognized picture as the shore-side sites.

Temporary sites and public events form a fourth profile: rapidly deployable, soft-kill-preferred and bound by the tightest civilian constraints. Across all profiles the same components scale from a self-contained site to federated regional coverage within the recognized air picture; the passive acoustic node is most valuable in mobile and temporary profiles, where emission control is itself protective.

7. CONCLUSION

There is no single-sensor, single-effector answer to the small-UAS threat: the threat is defined precisely by the properties — small, slow, low, cheap, numerous, increasingly autonomous — that defeat point solutions. The answer is architectural: a distributed multi-modal sensor layer including a passive component effective against non-emitting targets; a classification and fusion stage producing a credible, ranked threat picture at a manageable false-alarm rate; and a kill-web C2 layer connecting any sensor to the best available effector under explicit rules of engagement — the shortest defensible path from sensor to shooter, under human authority and recorded at every step.

The presented results substantiate each element: ARES discriminates drones from birds, aircraft, and helicopters at the sensor edge and fuses tracks into one picture; the agile optoelectronic turret confirms a cued target in under two seconds; the passive acoustic sensor addresses the radio-silent platforms that defeat the RF layer; and ORAO binds these sensors with the operational jammer and with the airburst gun, micro-interceptor, and laser under development into one kill web, whose operational core has protected national critical infrastructure since 2024. Future work covers integrating the acoustic layer into the wider air picture, maturing AURORA, qualifying the micro-interceptor and its recovery cycle, advancing the high-energy laser, and improving the adversarial robustness of classification; defense against coordinated multi-axis swarms remains the next open problem [3], [5]. Sensors, AI and effectors are becoming one sovereign loop, in which the decisive quantity is the time — and the trust — with which an observation becomes an effect.

Acknowledgment

The Vlatacom Institute of High Technologies funded this work through its projects VMSIS3_Advanced and AI-DECIDE. Passive acoustic sensing was developed jointly with the School of Electrical Engineering, University of Belgrade.

Abstract: *The rapid development of robotics, artificial intelligence, computer vision, and autonomous navigation has significantly expanded the potential applications of unmanned ground systems in military environments. Among the most interesting developments are quadrupedal robots, commonly known as robotic dogs. Unlike traditional wheeled or tracked unmanned ground vehicles, quadrupedal robots are designed to move across complex terrain while maintaining stability and adapting their walk to environmental conditions. Their ability to operate without continuous direct human control makes them particularly relevant for reconnaissance, surveillance, logistics, hazardous-area inspection, communications support, and other military tasks. Autonomous locomotion is one of the most important technological capabilities of a robotic dog. It involves the integration of sensors, perception systems, localization algorithms, path planning, obstacle avoidance, motion control, and artificial intelligence. The robot must be capable of understanding its surroundings, determining its position, selecting a safe route, and controlling its legs in real time. These requirements become considerably more difficult in military environments, where terrain can be unpredictable, communication links can be unreliable, and environmental conditions may change rapidly. This paper examines the principles behind autonomous locomotion in robotic dogs and discusses their potential military applications. Particular attention is given to navigation technologies, sensor fusion, artificial intelligence, locomotion control, operational advantages, technical limitations, cybersecurity, human supervision, and ethical considerations. The paper also considers the future development of quadrupedal military robots and the importance of maintaining meaningful human control over autonomous systems.*

Keywords: *robotic dogs, autonomous locomotion, military robotics, unmanned ground vehicles, autonomous systems.*

1. INTRODUCTION

Robotics has become an increasingly important area of technological development in the defense sector. Modern military forces operate in environments that can be dangerous, unpredictable, and difficult for human personnel to access [1]. Unmanned systems provide an opportunity to perform certain tasks while reducing the exposure of soldiers to physical hazards. Although unmanned aerial vehicles have received considerable attention, unmanned ground robots are also becoming increasingly capable.

One particularly interesting category of unmanned ground systems is the quadrupedal robot, often referred to as a robotic dog. These machines use four legs instead of wheels or continuous tracks. This configuration allows them to negotiate terrain that may be difficult for conventional ground vehicles, including stairs, uneven surfaces, rubble, narrow passages, and natural terrain [2].

The military interest in robotic dogs is not based only on their ability to walk. Their greater significance comes from their potential to combine mobility with advanced perception and autonomy [3]. A robot that can independently navigate through an environment can perform tasks without requiring an operator to control every individual movement. Instead, the operator can provide a higher-level objective while the robot handles many aspects of movement and navigation autonomously.

Autonomous locomotion is therefore a multidisciplinary problem. It combines mechanical engineering, robotics, artificial intelligence, computer vision, control theory, embedded computing and sensor technology. A successful system must continuously perceive its surroundings, estimate its own position, construct an understanding of the terrain, determine an appropriate path, and coordinate its legs to maintain balance [4].

In military applications, these challenges are particularly significant. A robotic dog may need to operate in darkness, dust, rain, snow, confined spaces or environments where satellite navigation is unavailable. They can also temporarily lose communication with its human operator. Consequently, autonomous operation must be designed to remain predictable and safe under uncertain conditions.

The objective of this paper is to examine the technological foundations and potential military applications of autonomous locomotion in robotic dogs. The discussion focuses on mobility, navigation, sensing, artificial intelligence, operational advantages, limitations, and others.

2. AUTONOMOUS LOCOMOTION

The idea of using four-legged machines for transportation and military purposes (figure 1) is not new. Early robotic systems were generally limited by mechanical complexity, inadequate computing power and the lack of sufficiently advanced sensors [3]. A four-legged robot must coordinate several joints simultaneously while maintaining balance, which makes its control problem significantly more complicated than that of a simple wheeled platform [5].

Figure 1. Four-legged robot.

Advances in electric motors, batteries, embedded processors, inertial sensors, cameras, and machine-learning algorithms have changed this situation. Modern quadrupedal robots can perform dynamic movements that were previously extremely difficult for machines. They can walk, turn, climb stairs, recover from disturbances, and adapt their movements to different surfaces [6].

A major advantage of the quadrupedal configuration is the ability to maintain contact with the ground at several points. Depending of the moving, the robot can distribute its weight across multiple legs and adjust its center of mass. This is useful when operating on uneven terrain.

The mechanical design of a robotic dog generally includes four legs with multiple degrees of freedom. Each leg may contain several actuated joints, allowing the foot to be positioned in three-dimensional space. Sensors within the joints provide information about position and movement, while inertial sensors provide information about the orientation and acceleration of the robot.

2.1. Sensors and sensor fusion

One of the major advantages of quadrupedal robots is their ability to negotiate irregular terrain. However, this ability requires the robot to understand what type of terrain lies in front of it. A robotic dog may encounter stairs, rocks, holes, rubble, mud, vegetation, cables, walls, doors, and other obstacles. Each situation requires a different movement strategy. For example, a flat floor allows the robot to use a regular walking pattern. A staircase requires the robot to raise its feet to a different height and coordinate its legs appropriately. Rubble may require slower movement and continuous adjustment of foot placement.

Terrain perception can be based on depth information obtained from cameras or LiDAR. The robot can construct a three-dimensional representation of the environment and identify areas that appear suitable or unsuitable for walking [7].

Modern platforms may also incorporate cameras, sensors, depth cameras, microphones, thermal sensors, and other instruments (figure 2). These systems transform the robotic dog from a simple walking machine into a mobile autonomous sensing platform.

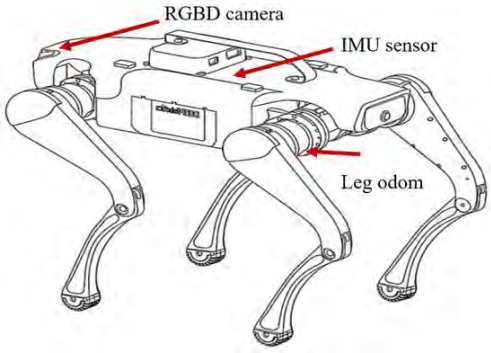

Figure 2. Sensors on four-legged robot.

Perception is the process through which the robot collects and interprets information about the environment. Cameras provide visual information, while LiDAR systems can provide three-dimensional measurements of surrounding objects and terrain. Inertial Measurement Units (IMUs) measure acceleration and angular velocity. These measurements help determine whether the robot is tilting, accelerating, or rotating. Joint encoders provide information about the positions of the robot's legs. No individual sensor is perfect, cameras can be affected by darkness, smoke, dust, or poor visibility, LiDAR can be affected by certain environmental conditions and may provide incomplete information and Inertial sensors accumulate measurement errors over time.

For this reason, modern autonomous robots frequently use sensor fusion [8]. Sensor fusion combines information from several sensors to produce a more reliable representation of the robot and its surroundings.

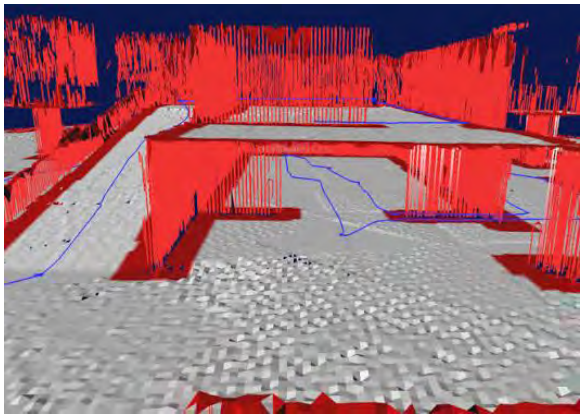

Figure 3. Traversability map example.

An important concept is the traversability map (figure 3). Instead of treating the environment simply as a collection of obstacles, the robot can assign different levels of

difficulty or risk to different areas. A flat surface may be considered highly traversable, while a steep or unstable surface may be considered less desirable.

2.2. Artificial intelligence in autonomous locomotion

Autonomous locomotion refers to the ability of a robot to move through an environment with limited or no continuous human control. In the case of a robotic dog, autonomous locomotion involves several interconnected processes. First, the robot must perceive its environment. It needs to identify obstacles, terrain characteristics, and possible paths. Second, it must estimate its own position and orientation. Third, it must determine a route to its destination. Finally, it must transform the selected route into physical movements of its legs. The robot can then use this information during path planning.

Obstacle avoidance is another essential component. When the robot detects an obstacle, it can modify its planned trajectory. In a simple environment, this may involve moving around the obstacle. In a more complex environment, the system may need to evaluate several possible routes. The ability to perform obstacle avoidance autonomously reduces the workload of the human operator. Instead of manually controlling every movement, the operator can monitor the robot and intervene when necessary.

Artificial intelligence plays an increasingly important role in autonomous robotics [9]. Traditional robotic control systems rely heavily on mathematical models and predefined rules. These approaches remain important, but machine learning can provide additional capabilities. Neural networks can be trained to recognize objects, classify terrain, and interpret visual information. A robot can potentially distinguish between different types of surfaces and identify objects that may affect its movement.

Machine learning can also be applied to locomotion. A robot can learn how to coordinate its joints to achieve stable movement under different conditions. Reinforcement learning, for example, allows an agent to improve its behaviour through repeated interaction with a simulated or physical environment.

Simulation is particularly valuable for this purpose. Training a physical robot through millions of failed attempts would be expensive and potentially damaging. Instead, researchers can create virtual environments in which a robot learns different movement strategies. Successful strategies can then be transferred to a physical system, although differences between simulation and reality must be carefully addressed.

Artificial intelligence can also contribute to adaptive control. If the robot detects that a surface is slippery or uneven, its control system can modify its movement accordingly. Nevertheless, artificial intelligence should not be treated as a perfect solution. Machine-learning systems can make mistakes, particularly when they encounter situations that differ significantly from their training data. Military systems therefore require careful validation, testing, monitoring, and human oversight.

3. AUTONOMOUS NAVIGATION IN MILITARY ENVIRONMENTS

Military environments present several challenges that are less common in civilian robotic applications. Terrain may be damaged, visibility may be poor, communications may be unreliable, and the robot may need to operate for extended periods without direct supervision.

Urban environments are especially complicated like buildings rooms, corridors, staircases, doorways, narrow passages and numerous obstacles (figure 4). A robot must be able to construct and update a map while moving through such spaces. Natural environments create different challenges, forests, fields, mountains, and areas affected by natural disasters may contain irregular ground surfaces and unpredictable obstacles.

Figure 4. Robot dog moving down the stairs.

A major advantage of quadrupedal robots is their ability to adapt to terrain without requiring prepared roads. This makes them potentially useful for reconnaissance and inspection in areas where conventional vehicles cannot easily operate. Another important characteristic is the possibility of autonomous return behaviour (back to HOME). If a robot loses communication with its operator, an appropriately designed system could enter a predefined safe state or attempt to return to a known location. Such functions are important because autonomous systems should not become unpredictable when communication is interrupted.

However, autonomous navigation does not necessarily mean completely independent operation. A more realistic approach for many military applications is **human-supervised autonomy**. In this model, the robot performs low-level navigation autonomously while a human remains responsible for higher-level decisions.

3.1. Military Applications

Robotic dogs can potentially support a wide range of military activities. Many of these applications do not require the robot to carry weapons. Instead, their value comes from mobility, sensing, and the ability to operate in hazardous areas. One of the most obvious applications is reconnaissance [10]. A robotic dog equipped with cameras and other sensors can investigate an area while allowing personnel to remain at a safer distance (figure 5).

The robot may transmit visual information to an operator, helping personnel understand the physical characteristics of an unfamiliar environment. Autonomous navigation can allow the robot to move through an area while the operator focuses on interpreting sensor information. This can reduce the amount of direct manual control required.

Figure 5. Robotic dog in reconnaissance application.

Robotic dogs can also be useful for inspecting potentially dangerous locations (figure 6), like damaged buildings, industrial facilities, areas affected by explosions, and environments containing unknown hazards.

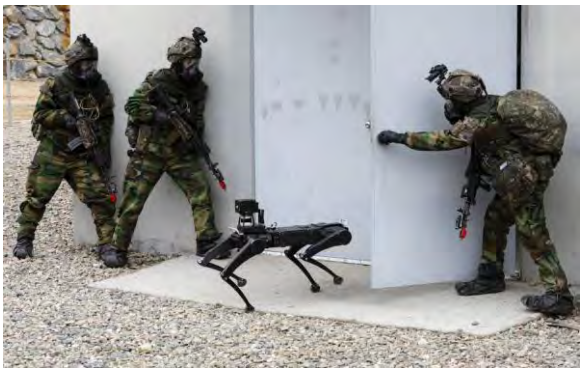

Figure 6. Using of Robot dogs in potentially dangerous locations.

A robot can enter an area that may be unsafe for humans and collect information using cameras or other sensors. The primary benefit is risk reduction. Instead of immediately exposing a person to an unknown environment, personnel can first use an unmanned platform to gather information.

Another possible application is transportation of equipment (figure 7). Quadrupedal robots can potentially carry supplies across terrain that is difficult for wheeled systems.

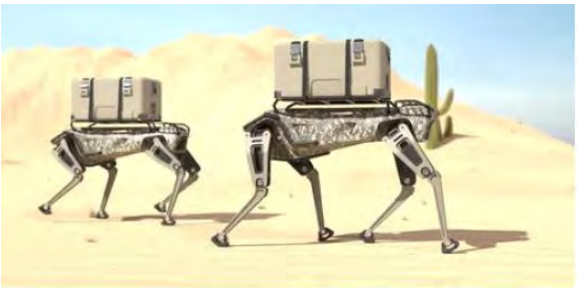

Figure 7. Robotic dogs in logistic application.

Their ability to follow a person or navigate toward predefined locations could make them useful as robotic pack animals. The practical usefulness of this application depends heavily on battery capacity, payload, reliability, and terrain. A robot that can carry equipment for only a short period may have limited value compared with conventional transportation methods.

A robotic dog equipped with communication equipment could potentially serve as a mobile communications node. Its mobility could allow it to reposition itself when required. Such systems could be useful in environments where fixed communication infrastructure is damaged or unavailable. However, communications equipment adds weight and consumes energy, so system designers must balance communication capabilities against mobility and endurance.

Although search and rescue is not exclusively a military mission, armed forces frequently participate in disaster response and emergency operations. A quadrupedal robot can potentially search damaged structures or difficult terrain while carrying cameras and sensors. Autonomous navigation can help it cover areas systematically.

In this context, the robot's ability to climb obstacles and maintain balance may provide advantages over conventional wheeled platforms.

4. CONCLUSION

Autonomous locomotion represents one of the most important capabilities of modern quadrupedal robots. By combining advanced mechanical systems with sensors, artificial intelligence, localization, mapping, path planning, and control algorithms, robotic dogs can move through environments that are difficult for traditional ground vehicles.

Military applications include reconnaissance, surveillance, hazardous-area inspection, logistics, communications support, and search and rescue. In many of these roles, the most significant benefit is the ability to perform useful tasks while reducing the exposure of personnel to dangerous environments.

At the same time, robotic dogs remain subject to important technical limitations. Battery endurance, environmental conditions, communication reliability, localization errors, maintenance requirements, cost, and cybersecurity all affect their practical usefulness.

Autonomy also raises ethical and legal questions, particularly when autonomous mobility is combined with other military capabilities. Maintaining meaningful human control over consequential decisions is therefore an important principle for responsible development.

The future of robotic dogs will probably not involve simply making machines more autonomous. Successful systems will combine autonomy with reliability, human supervision, cybersecurity, explainability, and robust performance in unpredictable environments.

Autonomous quadrupedal robots represent an important step in the development of unmanned ground systems. Their ability to combine mobility, sensing, and intelligent

navigation makes them potentially valuable tools for military and emergency applications. However, technological capability should be developed alongside appropriate human oversight and responsible operational policies. The ultimate value of robotic dogs will depend not only on how well they can walk, but also on how safely, reliably, and responsibly they can be integrated into human-centered systems.

The future development of robotic dogs will likely involve improvements in several areas. The first one is energy efficiency. More efficient motors and batteries could significantly increase operational endurance. The second is artificial intelligence. Improvements in perception and machine learning could allow robots to better understand complex environments. The third is sensor technology. Smaller, lighter, and more capable sensors will allow robots to collect more information without a corresponding increase in size or weight.

Another important development is multi-robot cooperation. Several robots could potentially share information about an environment and coordinate their movement. Such systems could improve coverage and reduce the dependence on a single platform. However, increasing the number of autonomous systems also increases the complexity of coordination and cybersecurity.

Future robotic dogs may also become more modular. Different equipment packages could allow the same basic platform to perform different roles, such as reconnaissance, logistics, communications support, or search and rescue.

The most important development, however, may be improved reliability. Military users require systems that behave predictably under difficult conditions. A robot that performs impressively in a laboratory but fails in dust, rain, or damaged terrain has limited operational value.

Union University – School of Computing, 6/VI Kneza Mihaila, Belgrade, sarapavlovic1977@gmail.com

Abstract: *Accurate position estimation is a fundamental requirement for the autonomous navigation of unmanned aerial vehicles (UAVs). Most modern drones rely on Global Navigation Satellite Systems (GNSS), such as GPS, to determine their geographical position. However, satellite navigation can become unreliable in environments with signal obstruction, interference, or poor satellite visibility. An alternative approach is visual localization, which estimates the position of a drone by comparing images captured by its onboard camera with reference maps or georeferenced satellite imagery. This paper presents the principles and methods of UAV position estimation through image matching between drone imagery and maps. The main stages of the process include image acquisition, preprocessing, feature extraction, image matching, geometric transformation, and geographical coordinate estimation. Particular attention is given to traditional computer vision techniques, such as Scale-Invariant Feature Transform (SIFT), Oriented FAST and Rotated BRIEF (ORB), and feature matching using geometric models. The paper also discusses deep learning-based approaches, image registration, and the challenges associated with differences in viewing angle, image resolution, illumination, and environmental conditions. Finally, evaluation metrics and possible applications are examined. Visual localization can provide an additional source of positioning information and may complement conventional navigation systems. Its effectiveness, however, depends on the quality of reference maps, the reliability of image correspondences, and the accuracy of the geometric transformation.*

Keywords: *unmanned aerial vehicle, visual localization, image matching, satellite imagery, geographical positioning, computer vision, image registration, GNSS-denied navigation.*

1. INTRODUCTION

Unmanned aerial vehicles have become increasingly important in modern engineering, scientific research, and commercial applications. They are used for aerial photography, agricultural monitoring, infrastructure inspection, environmental observation, surveying, and search-and-rescue operations. Many of these applications require accurate knowledge of the UAV's geographical position.

The Global Navigation Satellite System is the most common source of positioning information for modern drones. By receiving signals from navigation satellites, a UAV can estimate its latitude, longitude, and altitude. This information is used by the flight controller to maintain a planned trajectory and execute autonomous missions.

Despite its widespread use, satellite-based positioning has several limitations. Buildings, mountains, and other obstacles can obstruct satellite signals. Signal reflections may introduce positioning errors, while interference can reduce the availability or reliability of navigation information. These limitations have encouraged research into alternative localization techniques, including inertial navigation, visual odometry, and image-based geolocation [1].

One of approaches is to determine the UAV's position by comparing an image captured by its onboard camera with a reference map. The reference image may be obtained from satellite imagery, aerial photographs, or a previously constructed georeferenced map. If a sufficiently accurate correspondence is established between the two images, the geographical location of the camera can be estimated.

This process is commonly referred to as visual localization or visual geolocalization. In aerial applications, it often involves matching images captured from a relatively low altitude with satellite images acquired from a much higher viewpoint.

The main objective of this paper is to explain the theoretical foundations and practical implementation of image-based UAV position estimation. The paper describes the image-matching process, presents commonly used computer vision algorithms, discusses geographical coordinate estimation, and examines the main factors influencing localization accuracy.

2. THEORETICAL FOUNDATIONS OF VISUAL LOCALIZATION

Visual localization is the process of determining the position of a camera or mobile platform by analyzing visual information. In the case of a UAV, the system

Corresponding author: R, Pavlović;
E-mail: rade.pavlovic@mod.gov.rs
DOI: 10.5937/OTEH26076

attempts to identify the geographical location corresponding to the area visible in the camera image [2].

The general principle is based on comparing two sources of visual information (figure 1):

- query image captured by the UAV's onboard camera.
- reference image with known geographical coordinates.

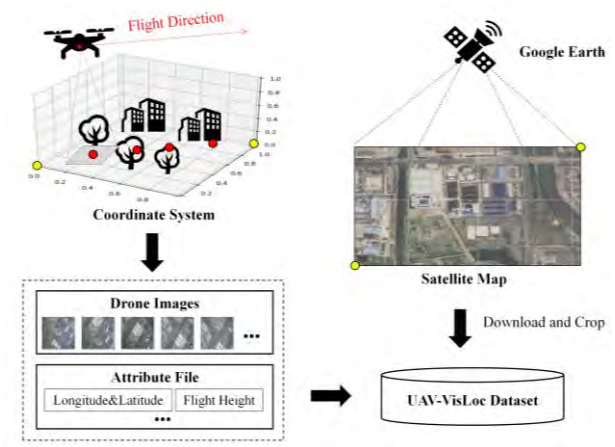

Figure 1. The dataset collecting process [3].

The query image contains visual features of the terrain, buildings, roads, fields, rivers, and other objects. The reference map contains corresponding geographical structures. By identifying common features, the system can estimate where the UAV is located.

The reference map must be georeferenced, meaning that its image coordinates are associated with real-world geographical coordinates. These coordinates may be expressed as latitude and longitude or as projected coordinates, such as easting and northing.

The localization process can be divided into two principal tasks. The first is identifying the correct geographical area represented in the UAV image. The second is estimating the precise alignment between the UAV image and the reference map [4].

The first task is often described as image retrieval or place recognition, while the second involves image matching and geometric registration. Combining these stages creates a coarse-to-fine localization pipeline.

2.1. Coordinate Systems

Accurate position estimation requires an understanding of the coordinate systems involved. A digital image uses a two-dimensional pixel coordinate system. A pixel is typically represented by coordinates ((u,v)), where (u) represents the horizontal position and (v) represents the vertical position in the image.

A map, in contrast, represents locations in a geographical coordinate system. In the WGS 84 system, a location is commonly expressed using latitude and longitude. Projected coordinate systems represent locations using linear coordinates, such as metres [5].

The purpose of image registration is to establish a mathematical relationship between these coordinate systems. For example, if a pixel in the UAV image can be matched to a known point in a georeferenced map, its corresponding geographical location can be determined. Multiple reliable correspondences can be used to estimate the transformation between the images.

However, the camera's position is not always identical to the geographical coordinates of the matched ground point. The camera is located above the Earth's surface, and its viewing direction affects the relationship between image coordinates and ground coordinates. Camera altitude, orientation, and terrain elevation must therefore be considered when estimating the UAV's actual position.

2.2. Absolute and Relative Localization

Two important localization concepts are absolute localization and relative localization. Absolute localization estimates the UAV's position within a global or geographically referenced coordinate system. Matching a camera image to a georeferenced satellite map is an example of absolute visual localization [6].

Relative localization estimates the movement of the UAV with respect to a previous position or observation. Visual odometry, for example, estimates motion by analyzing changes between consecutive camera frames.

Relative localization can provide useful motion information, but errors may accumulate over time. Absolute localization can correct this drift by connecting the current observation to a reference map.

A system that combines both approaches can use visual odometry to estimate movement between frames and map matching to periodically correct its geographical position.

3. IMAGE MATCHING ALGORITHMS

Feature-based image matching is one of the traditional approaches to visual localization. Instead of comparing every pixel directly, the algorithm identifies distinctive points in each image and establishes correspondences between them. A feature point may represent a corner, intersection, or other locally distinctive image structure. Each point is associated with a descriptor that describes its surrounding visual pattern.

The matching algorithm compares descriptors from the UAV image with descriptors from the reference map (figure 2). Similar descriptors indicate potential correspondences. Feature-based approaches are particularly useful when the images differ in scale, rotation, or moderate changes in illumination.

Figure 2. Drone images and satellite map from dataset [3].

Several algorithms have been developed for this purpose, including SIFT (Scale-Invariant Feature Transform), SURF (Speeded-Up Robust Features), and ORB (Oriented FAST and Rotated BRIEF). Their performance depends on image characteristics, computational resources, and the degree of difference between the two viewpoints.

3.1. Scale-Invariant Feature Transform (SIFT)

The Scale-Invariant Feature Transform is a widely used algorithm for detecting and describing local image features [7]. SIFT identifies distinctive keypoints at different image scales (figure 3). It then constructs descriptors based on the local gradient orientations surrounding each keypoint.

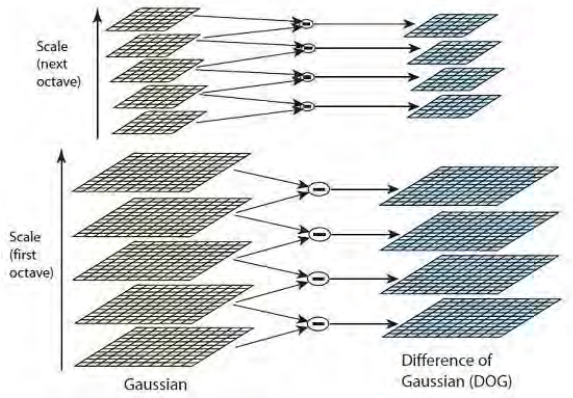

Figure 3. Diagram of SIFT process [8].

One of the principal advantages of SIFT is its relative robustness to changes in image scale and rotation. This makes it useful when a UAV image and a reference map represent the same geographical area at different resolutions. For example, a road intersection may appear relatively large in a low-altitude drone image and much smaller in a satellite image. SIFT can identify corresponding local structures even when their apparent sizes differ.

However, SIFT can require considerable computational resources when processing high-resolution images or large collections of map tiles. It may also produce unreliable matches in areas with repetitive patterns, such as similar rooftops or agricultural fields.

3.2. ORB Feature Detection

ORB combines the FAST keypoint detector with the BRIEF descriptor and an orientation estimation procedure [9]. Compared with traditional floating-point descriptors, ORB uses binary descriptors that can be matched efficiently using Hamming distance. This makes ORB attractive for real-time applications and embedded computing platforms. It can process images relatively quickly and is available in widely used computer vision libraries.

However, ORB may be less robust than some alternatives when there are substantial changes in scale, viewpoint, or image appearance (figure 4). Its effectiveness therefore depends on the particular environment and camera configuration.

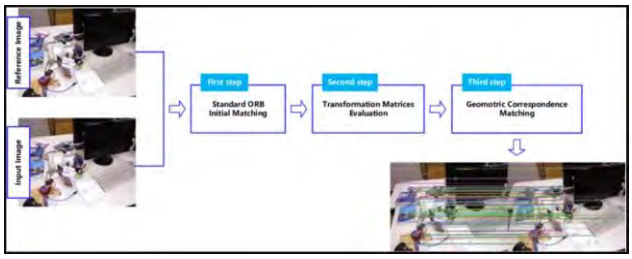

Figure 4. The framework of Oriented FAST and Rotated BRIEF [10].

For a UAV operating on a limited computational budget, ORB can provide a useful starting point. Its performance should nevertheless be evaluated against the expected range of flight altitudes and viewing angles.

3.3. Deep learning Matching

Deep learning provides an alternative approach by learning image representations directly from large datasets. Instead of relying exclusively on manually designed descriptors, a neural network can learn features that are more robust to changes between the drone image and the reference map [11]. A deep learning matcher can therefore be designed to extract high-level semantic and geometric information from both images and estimate their similarity or spatial correspondence (figure 5).

The general architecture of a deep learning-based image-to-map matching system consists of three main stages: feature extraction, feature matching, and geographical localization [12]. The first stage generates compact feature representations from the drone image and the map. The second stage establishes correspondences between the extracted representations. Finally, the matched information is transformed into an estimated geographical position.

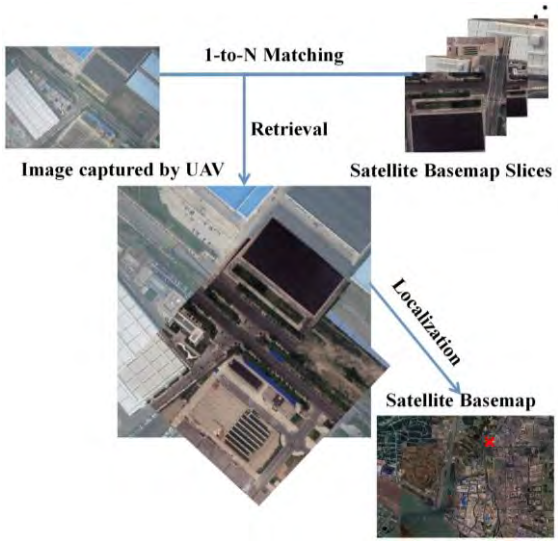

Figure 5. General architecture of a deep learning-based image-to-map matching system.

A major advantage of deep learning-based matching is its ability to learn robust representations directly from data. The learned features can be more tolerant to variations in illumination, viewpoint, scale, and scene appearance than traditional hand-crafted descriptors.

Another advantage is the possibility of combining global and local information. Global descriptors allow efficient candidate retrieval, while local matching provides accurate spatial correspondence.

However, several limitations remain. Training a reliable model requires a sufficiently large and representative dataset. Performance can decrease when the deployment environment differs significantly from the training data. Large changes in terrain, construction, vegetation, weather, or seasonal appearance may reduce the visual similarity between the drone image and the reference map.

Computational requirements are another important consideration. Deep neural networks can require significant GPU resources during both training and inference. For real-time UAV applications, model compression, quantization, efficient architectures, and hardware acceleration may therefore be necessary.

4. EXPERIMENTAL RESULTS AND POSITIONING ERROR ANALYSIS

To evaluate the effectiveness of image-based UAV localization, experiment is considered in which drone images are matched against a georeferenced satellite map. The objective is to estimate the geographical position of the UAV and measure the difference between the estimated coordinates and the known reference position. In this study dataset containing 200 UAV images is assumed. The images represent different camera orientations, flight altitudes, and environmental conditions. Each image is associated with a reference position obtained from an independent positioning system.

Three image-matching approaches are considered: SIFT, ORB, and deep learning-based feature matcher. All three methods are evaluated using the same image set and reference map. The experiment assumes that the reference map is accurately georeferenced and that the ground-truth positions are expressed in a suitable projected coordinate system, with distances measured in meters. The results of deferent measure for image-matching algorithms are shown in Table 1.

According results the deep learning-based matcher produces valid position estimates for 183 out of 200 images, corresponding to a localization success rate of 91.5%. The SIFT method produces 169 valid estimates, while ORB produces 155. Also, the mean positioning errors are 5.2 m for the deep learning-based approach, 7.5 m for SIFT, and 12.1 m for ORB. The corresponding RMSE values are 8.4 m, 11.5 m, and 19.4 m. In general, the deep learning-based matcher algorithm shows better results for all parameters**.**

Table 1. Results of comparison of image-matching algorithms.

Evaluation metric	**SIFT**	**ORB**	**Deep learning matcher**
Total test images	200	200	200
Valid position estimates	169	155	183
Localization success rate	84.5%	77.5%	91.5%
Mean error (m)	7.5	12.1	5.2
Median error (m)	4.7	7.7	3.2
RMSE (m)	11.5	19.4	8.4
90 percent error (m)	15.6	26.2	10.8

CONCLUSION

Determining a UAV's position by comparing camera images with maps is an important approach to visual localization. The method uses visual features shared by the captured image and a georeferenced reference map to establish the geographical location of the observed area.

The complete process includes image acquisition, preprocessing, feature extraction, descriptor matching, geometric verification, image registration, and coordinate transformation. Algorithms such as SIFT and ORB provide established methods for identifying and matching image features, while deep learning-based techniques offer additional possibilities for handling substantial differences in appearance and viewpoint.

The conversion from image coordinates to geographical coordinates requires an accurate reference map and a suitable geometric model. The estimated ground location must also be distinguished from the UAV's actual position, which depends on camera orientation, altitude, and terrain geometry.

Deep learning-based image-to-map matching provides a powerful framework for visual localization of drones. The proposed approach combines learned feature extraction, global image retrieval, local feature matching, attention-based correspondence estimation, and geometric verification.

The main advantage of this architecture is that it transforms the problem from direct pixel-level comparison into comparison of learned visual representations. This makes the system more robust to changes in viewpoint, scale, illumination, and image appearance. A hierarchical matching architecture is particularly suitable for large-scale applications. Global descriptors can first identify a small number of candidate

map regions, after which a local deep learning matcher performs detailed correspondence estimation. Finally, geometric verification can remove inconsistent matches and provide a reliable estimate of the drone's geographical position.

The resulting system can serve as the basis for GNSS-independent UAV localization and can be further extended by incorporating temporal information from consecutive drone frames, inertial measurements, digital elevation models, and multi-modal map information.

Although visual localization offers an alternative source of positioning information, its accuracy is affected by image quality, map resolution, environmental changes, and the reliability of feature correspondences. A robust implementation should therefore include geometric verification, performance evaluation, and methods for identifying uncertain or failed matches.

Further development of deep learning methods, multi-sensor fusion, and efficient image registration techniques may improve the reliability of visual positioning in complex environments.

GENETIC ALGORITHM PARAMETER CONTROL FOR THE OPTIMAL DESIGN OF SPECTRALLY SELECTIVE 1D PHOTONIC CRYSTALS

ANJA PERIĆ
PhD student at Faculty of physics, University of Belgrade, Belgrade, anja.bartula994@gmail.com

OLGA JAKŠIĆ
Department of Microelectronic Technologies, Institute of Chemistry Technology and Metallurgy - National Institute of the Republic of Serbia, University of Belgrade, Belgrade, Serbia, olga.jaksic@ihtm.bg.ac.rs

Abstract: *This paper evaluates the impact of Genetic Algorithm (GA) parameter control and layer count on the optimization efficiency and performance of aperiodic 1D SiO2/TiO2 photonic crystals on glass. The target is a dual-band reflector at 1064 nm and 1550 nm. Calculated via the Transfer Matrix Method (TMM), robust GA parameters (Population 200, 300 Generations) present a bottleneck requiring 10,836.6 minutes (7.52 days) of CPU runtime. To resolve this, we analyze restricted GA parameters (Population 20, 10 Generations) across 2 to 17 pairs. Traditional quarter-wave stacks fail this dual-band requirement (fval = 0.2552). Under limited GA budgets, simpler designs yield poor reflectance: 2 pairs achieve R < 15% (fval = 0.0145), 5 pairs reach R ≈ 43% at 1064 nm and R ≈ 35% at 1550 nm (fval = 0.0807), and 14 pairs yield R ≈ 50% and R ≈ 62% (fval = 17.0666). High-performance spectra emerge only with larger stacks: 16 pairs achieve R ≈ 95% and R ≈ 80% (fval = 0.1918), while near-ideal response (R ≈ 98-99%) requires 17 pairs (fval = 0.0062). These findings establish a tuning framework to balance computational cost and optical design performance.*

.

1. INTRODUCTION

Photonic crystals (PCs) are artificial nanostructured materials whose dielectric properties can be engineered to control the propagation of electromagnetic waves. One-dimensional (1D) PCs, formed as multilayer stacks of alternating high and low refractive index materials, have been widely utilized in applications such as infrared signature management, radiative cooling, and laser eye protection. In these practical contexts, the primary engineering task is to tailor the spectral characteristics - namely, absorptivity A(λ), reflectivity R(λ), and transmissivity T(λ) - across various electro-optical sensor bands. [1] A summary of key signature threats and sensor bands is shown in Table 1.

A particularly critical defense application is the dual-band high-reflection filter, capable of simultaneously attenuating reflection or providing laser shielding at key military laser wavelengths: the Nd:YAG laser operating at 1064 nm and the Er:Glass laser (often using Er-doped glass or solid-state materials) emitting at 1540 nm or 1550 nm.

Table 1. Signature threats and spectral regions in praxis

Region µm	Sensor threat	Practical example
0.7–1.1	NIR camera / laser range finder	Reflected ambient / laser light
1–2.5	SWIR imager	Reflected solar, thermal glow of hot objects
3–5	MWIR thermal imager	Thermal emission of warm objects (~300-800 K)
8–14	LWIR thermal imager	Th. emission, near-ambient objects (~250–350 K)

Table 2 outlines the characteristics of military lasers in praxis. Achieving high reflection (R > 99%) at these distinct, separated wavelengths while maintaining a neutral spectral response or high transmission in the visible and other infrared bands is a highly non-linear design problem. Traditional periodic dielectric mirrors, such as Bragg reflectors designed with quarter-wave optical thickness (QWOT), are intrinsically limited to a single fundamental bandgap and its higher-order harmonics.

Table 2. Military lasers in praxis

Laser	Wavelength	Use
Nd:YAG	1064 nm	Rangefinders, target designators

Diode	800-980 nm	Pumps, some direct-use systems

A QW stack optimized for 1064 nm cannot provide high reflectivity at 1550 nm, as it falls within a transmission window. Mixed QW designs, which combine multiple periodic stacks, suffer from destructive interference at the interface boundaries, shifting the bandgap edges and failing to yield a clean dual-band response.

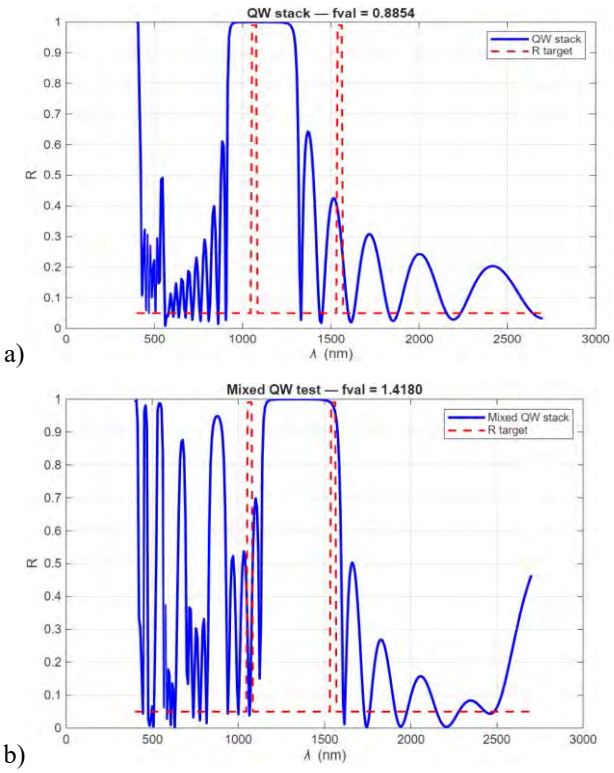

Figure 1. Spectral response comparison of traditional periodic quarter-wave (QW) stacks: a) A standard QW stack optimized for 1064 nm shows high reflection at the target but zero reflectance at 1550 nm; b) A Mixed QW stack shows severe band-edge shifting and interference oscillations in the background, resulting in a poor optimization score.

To break the symmetry constraints of periodic structures, aperiodic multilayer designs are required. In an aperiodic stack, the individual layer thicknesses are treated as independent variables, creating an extremely large, non-convex parameter space. Global optimization algorithms, such as Genetic Algorithms (GAs), are ideally suited for searching this complex landscape. However, direct optimization using GA is hindered by a severe, hidden computational bottleneck. Computing the electromagnetic response of a multi-layer stack using the Transfer Matrix Method (TMM) repeatedly across hundreds of generations and large populations is computationally prohibitive. For instance, executing a standard GA search with a population size of 200 over 300 generations requires an estimated 10,836.6 minutes (7.52 days) of continuous CPU runtime on standard platforms. This bottleneck forces engineers to utilize restricted GA options (e.g., small populations and limited generations), which risks premature convergence and poor spectral performance.

This paper addresses this challenge by systematically evaluating how the restriction and control of Genetic Algorithm parameters impact both the computational runtime and the optimized spectral profile. We analyze the performance of aperiodic SiO2/TiO2 stacks across different layer counts (from 2 to 17 pairs) and establish precise tuning guidelines to balance real-world computational budgets with high-performance optical requirements.

2. DESIGN METHODOLOGY AND TRANSFER MATRIX MODEL

The physical system under consideration consists of an interleaved, aperiodic stack of silicon dioxide (SiO2) and titanium dioxide (TiO2) layers deposited on a thick glass substrate (n = 1.5). The incident medium is air (n = 1.0). To ensure physical and industrial feasibility, the design is 'foundry-aware'. The overall thickness of any individual layer is strictly bounded between d_min = 20 nm and d_max = 400 nm, which complies with standard thin-film deposition limitations (such as magnetron sputtering or electron-beam evaporation).

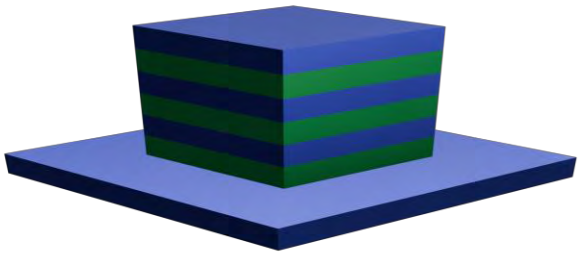

Figure 2. Schematic of the proposed 1D multilayer SiO2/TiO2 aperiodic stack on a glass substrate.

The electromagnetic response of the stack is modeled using the Transfer Matrix Method (TMM). For an N-layer system, the characteristic matrix of each layer is computed by relating the electric and magnetic fields at the boundaries. Refractive indices of SiO2 and TiO2 are dynamically evaluated to account for material dispersion across the target spectral range (400–2700 nm). TiO2 exhibits significant normal dispersion in the visible and near-infrared regions, which must be modeled accurately using experimental dispersion data to prevent model mismatch.

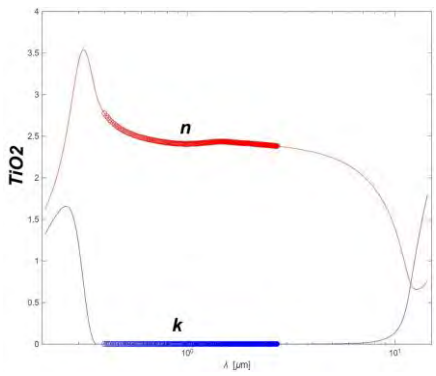

Figure 3. Refractive index (n) and extinction coefficient (k) dispersion of TiO2

To guide the optimizer toward achieving a dual-band high-reflection profile at 1064 nm and 1550 nm, while keeping reflectance low elsewhere, the objective function (fitness value, fval) is defined as a weighted mean-squared error between the calculated reflectance R_calc and the target reflectance R_target:

Fitness = Mean(W * (R_calc - R_target)^2)

The target reflectance profile R_target is set to 1.0 (100% reflection) in narrow bands centered around 1064 nm and 1550 nm, and 0.05 (5% reflection) elsewhere. Crucially,

the optimization weights (W) are heavily unbalanced: inside the two target laser bands, the weights are set to 100, while in the rest of the 400–2700 nm range, the weights are set to 1.

This spectral weight segmentation forces the genetic algorithm to prioritize satisfying the high-reflection criteria at the laser lines, preventing the optimizer from stalling in flat, non-critical spectral regions.

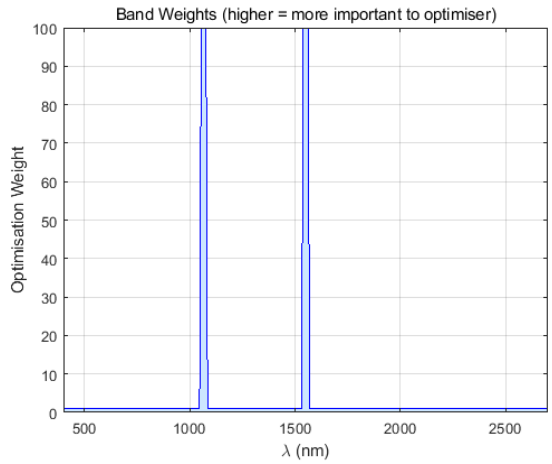

Figure 5. Target reflectance profile and corresponding band weights: The segmented optimization weights, highlighting the high-priority bands (Weight = 100) at the target laser wavelengths.

3. GENETIC ALGORITHM PARAMETER TUNING&CONVERGENCE ANALYSIS

The optimization was implemented in MATLAB using the global optimization toolbox. The search options are configured to explore the design space within the bound constraints [d_min, d_max] for N layers. The key parameters of the GA options block are configured as follows:

- **Population Size:** Controls the number of candidate designs in each generation. In comments of our original source, a size of 200 was desired but reduced to 20 to avoid extreme computational latency.
- **Max Generations:** The stopping criterion for the algorithm. A value of 300 was desired but reduced to 10 for rapid exploration.
- **Elite Count:** Set to 10. This ensures that the top 10 best-performing designs are copied directly to the next generation without modification, preventing the loss of high-quality designs.
- **Crossover Fraction:** Set to 0.8, meaning 80% of the next generation is produced by blending parent designs, maintaining a high rate of information recombination.
- **Mutation Function:** The adaptive feasible mutation function ('@mutationadaptfeasible') was chosen, generating small, random, self-adaptive changes to layer thicknesses while strictly respecting the 20 nm to 400 nm bounds.
- **Function Tolerance:** Set to 1e-8, defining the convergence threshold for termination.

To understand the optimization dynamics, a convergence run was analyzed for a stack with 10 pairs of layers (20 layers in total) over 100 generations. This analysis is critical for determining whether restricted GA parameters can yield stable, high-quality results.

The convergence behavior exhibits two distinct physical regimes. First, in the initial 0 to 15 generations, the mean fitness of the population drops exponentially from over 38.0 to less than 1.0. This represents the rapid elimination of highly unfit, random layer distributions. Second, the best fitness value (black dots) begins below 1.0 and exhibits a step-like stabilization, settling on a value of 0.338843 after 20 generations. This indicates that while the population is converging, the local search stagnates. This finding mathematically proves that restricting the algorithm to only 10 generations (as done in the quick-run mode) is premature. While the most drastic gains occur early, at least 20 to 50 generations are required for the best fitness value to mature and stabilize.

4. RESULTS AND DISCUSSION

We systematically evaluated the performance of optimized aperiodic SiO2/TiO2 filters across a range of layer pairs (N = 2 to 17 pairs, corresponding to 4 to 34 physical layers) under the restricted GA budget. The optimization results reveal a highly non-linear relationship between stack complexity, achieved minimum fitness values (fval), and spectral dual-band performance.

At low complexity, the structures are physically incapable of establishing a dual-band profile; with N = 2 pairs, the reflectance is flat and stays below 15% across the entire wavelength range (fval = 0.0145).

As the pair count increases to N = 5, distinct peaks emerge exactly at 1064 nm and 1550 nm, but under the restricted GA budget (PopulationSize = 20, MaxGenerations = 10), peak reflectance is limited to 43% at 1064 nm and 35% at 1550 nm (fval = 0.0807).

At N = 7 pairs, a severe optimization trade-off emerges: Case A yields a clean, quiet background (fval = 0.0792) but limits peaks to approximately 36%-37%; conversely, Case B achieves higher peaks of ~65% but at the cost of massive,

destructive oscillations (exceeding 90%) in the transmission bands (fval = 21.5104), violating the neutral background requirement.

Mid-complexity stacks with N = 14 pairs suffer from severe peak splitting and high noise across the spectrum (fval = 17.0666).

A critical performance threshold is crossed at N = 16 pairs, where reflectance rises to 95% at 1064 nm and 80% at 1550 nm (fval = 0.1918). Finally, with N = 17 pairs (34 layers) and a well-converged GA run, near-perfect dual-band reflection is achieved (fval = 0.0062), exceeding 98% and 99% reflectance respectively. However, as shown on the 17-pair spectrum, the resulting layer thicknesses are highly aperiodic and irregular (ranging from 48.02 nm to 397.06 nm). This spatial complexity is necessary to establish the localized cavity modes that trap and reflect the target laser lines.

However, manufacturing such a precise, 34-layer aperiodic stack with nanometer-scale tolerances represents a major physical fabrication challenge.

5. CONCLUSION

In this work, we successfully analyzed the impact of Genetic Algorithm (GA) parameter control and physical layer count on the optimization of aperiodic 1D multilayer SiO2/TiO2 photonic crystals. By systematically evaluating the trade-offs between computational budgets and optical performance, we draw several critical conclusions for the design of dual-band spectrally selective filters:

- **Parameter Optimization Balance:** While a full-scale GA search (Population Size = 200, Generations = 300) is computationally expensive, requiring over 7.5 days, a severe restriction (Population Size = 20, Generations = 10) leads to premature convergence, limiting peak reflectance to under 43%. Balanced configuration of Population Size = 50 and 50–100 Generations, runs in less than 24h while preventing local minima trapping.
- **Physical Complexity Threshold:** A minimum of 16 to 17 layer pairs (32 to 34 layers) is physically required to construct a dual-band bandgap with high reflectance (>95%) at both 1064 nm and 1550 nm. Low-complexity stacks (under 7 pairs) cannot provide dual-band selectivity regardless of the optimization duration.
- **Weight Segmentation Necessity:** The use of a heavily weighted objective function (W = 100 at target lines, W = 1 elsewhere) is absolutely critical. It prevents the genetic algorithm from stagnating and guides the search toward establishing high-reflection bands in highly localized spectral regions.

Future work will focus on integrating experimental fabrication tolerances directly into the GA mutation function and exploring the optical performance of these optimized aperiodic stacks under oblique angles of incidence.

Abstract: *Methods for calculating the interception point of the trajectory of a projectile and a moving target are the subject of many projects and are being solved in several directions. Initially, these were trigonometric methods, while nowadays probabilistic methods or methods of integrating differential equations are used. The paper proposes a classical method of integrating differential equations of projectile motion using the Runge-Kutta method, based on the initial azimuth and elevation angles of the projectile launch parameters, using the known initial projectile velocity. Future target positions are predicted based on the radar target tracking and calculated meeting time of the projectile and the target, using the interpolation method of the target's position coordinates and acceleration. The simulation results showed satisfactory accuracy for targets in the air at a distance of 2000 m with standard deviation of error position on 15 m.*

Keywords: *Target tracking, Kalman filter, Taylor extrapolation polynom, ballistic trajectory.*

1. INTRODUCTION

Intercepting an incoming artillery or mortar round is receiving interest as an area-protection mechanism. A problem has been that estimation, based on 6-degrees of freedom -(DoF) equations for both the incoming round and the interceptor round or missile, is to time consuming from a computational perspective. This calculation is used to find the maneuver control and the aimpoint or lead angle needed to intercept an incoming round. The method uses reduced dynamics flight models for the interceptor and the incoming round. Also, questions relating to the probability of a hit given a specific standard deviation and bias are addressed [1].

Guidance laws that aim to achieve desired impact angle, as well as zero miss distance, are pushed forward by a number of techniques [2]. Some authors derived guidance laws with impact angle constraint based on proportional navigation guidance (PNG). These PNG-based impact angle control guidance techniques are simple in form and cost little in the calculation, but some constraints on the impact angle cannot strictly be satisfied when the initial heading coincides with the line-of-sight (LOS). The sliding mode control (SMC) technique is another commonly used technique in the field of impact angle control guidance (IACG). Other authors use SMC to achieve desired impact angle. Guidance laws based on a conventional SMC can only ensure asymptotic convergence. A guidance law based on terminal sliding mode control was proposed in [3], which satisfied the finite-time convergence. So, it is also posible for combined SMC and virtual target strategy to control collision time and angle. Guidance laws based on SMC have strong robustness, which are even effective on maneuvering targets. However, the discrete terms in the guidance formula always cause inevitable oscillations in the guidance commands, which is not suitable for actual implementations. The SMC technique was introduced to design a guidance law that makes multiple missiles hit the target in a preset direction at the same time [4], and it utilized range-to-go and radial relative velocity rather than time-to-go to construct the sliding surface to avoid performance degradation. Some authors combined SMC, backstepping, and super-twist extend state observer to propose a robust guidance law [5] and verified its performance by a dynamics model.

This paper is aimed at proposing a novel algorithm, which calculates firing parameters (cannon barrel azimuth and elevation) only the data obatined from from radar sensor. When the target enters the projectile's zone of action, an algorithm is activated that, in the first step, extrapolates the future position of the target in the time interval required for the projectile to reach the target. Given that the projectile's speed is an order of magnitude greater than the target's speed of movement, the integration of the projectile's differential equations of motion calculates the azimuth and elevation angle of the gun barrel in order to meet the target, under

DOI: 10.5937/OTEH26077R

the condition of a minimum distance between the target and the projectile.

The paper is organized as follows: after introductory considerations, theoretical models of the target and projectile are given. The third chapter describes the proposed algorithm for predicting the collision of the target and projectile, while the fourth chapter is dedicated to presenting the results of numerical simulations. Finally, concluding considerations are given.

2. PROBLEM STATEMENTS

2.1 Targets and measurements models

Consider a discrete-time stochastic hybrid system:

$$x_k = f(x_{k-1}) + q_{k-1} \tag{1}$$

$$y_k = h(x_k) + r_k \tag{2}$$

where $x_k \in R^n$ is the state vector in effect at sample time k with dynamic model function $f(.)$ and transition matrix F_k, $y_k \in R^m$ is the vector of observations in effect at time k, $q_{k-1} \approx N(0, Q_{k-1})$ is the Gaussian process noise, $r_k \approx N(0, R_k)$ is the Gaussian measurements noise.

2.2 Missile dynamic models

Consider a 3D motion scenario for a missile against a moving target. Inertial, moving and bound coordinate systems are used to model the movement of the target and projectile (Figure 1).

Positions are x, y and z and velocities are v_x,v_y and v_z and θ and φ their azimuth and elevation flight path angles, respectively. State vector is given by the $X = [x\ v_x\ y\ v_y\ z\ v_z]$. R stands for the distance between the missile and the target. The engagement kinematics for this problem can be given as follows [8]:

$$\begin{aligned} x &= x_0 + v_{x0} t \\ y &= y_0 + v_{y0} t \\ z &= z_0 + v_{z0} t - g\frac{t^2}{2} \end{aligned} \tag{3}$$

$$\begin{aligned} v_{x0} &= v_0 \cos\varphi \cos\theta \\ v_{y0} &= v_0 \cos\varphi \sin\theta \\ v_{z0} &= v_0 \sin\varphi \end{aligned} \tag{4}$$

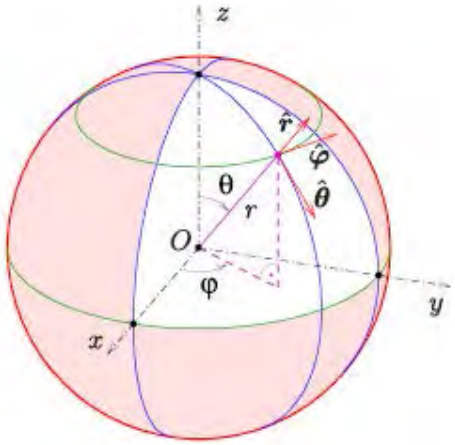

Figure 1. Kugel model

For ease of calculation, the problem can be reduced to 2D dimension (x,y). Due to the action of gravity, at time t the vertical component of the initial velocity decreases by the value of gravity, while the horizontal component remains unchanged. At that position, the velocity vector v makes an angle with the horizontal. The differential equations of motion in this case are [9]:

$$\begin{aligned} m\ddot{x} &= 0 \\ m\ddot{y} &= -mg \end{aligned} \tag{5}$$

or

$$\begin{aligned} \ddot{x} &= 0 \\ \ddot{y} &= -g \end{aligned} \tag{6}$$

The general solution of this system of equations is:

$$\begin{aligned} x &= C_1 t + C_2 \\ y &= -\frac{1}{2} g t^2 + C_3 t + C_4 \end{aligned} \tag{7}$$

The integration constants are determined by the initial conditions at the time:

$$\begin{aligned} x_0 &= 0, \\ y_0 &= 0, \\ (\dot{x})_0 &= v_0 \cos\alpha_0, \\ (\dot{y})_0 &= v_0 \sin\alpha_0, \end{aligned} \tag{8}$$

The final equations of motion of the projectile now are:

$$\begin{aligned} x &= v_0 t \cos\alpha_0 \\ y &= -\frac{1}{2} g t^2 + v_0 t \sin\alpha_0 \end{aligned} \tag{9}$$

By eliminating t from these parametric equations, the equations of the trajectory are obtained

$$y = -\frac{g}{2 v_0^2 \cos^2\alpha_0} x^2 + tg\alpha_0 x \tag{10}$$

This is the parabola that lies symmetrically with respect to

the coordinates of the vertex of the trajectory, i.e. parabola with a vertical axis and a concave side downward. If it is assumed that $0<\alpha_0<\pi/2$ the value is positive and according to (5) the abscissa x increases with time i, i.e. the projectile is constantly moving to the right. To determine the range l, expresses the range of the projectile:

$$l=\frac{v_0^2}{g}\sin(2\alpha_0) \tag{11}$$

The total flight time t_A of the projectile from 0 to A is obtained by the equation:

$$t_A=\frac{l}{v_0\cos\alpha_0}=\frac{v_0{}^2\sin(2\alpha_0)}{gv_0\cos\alpha_0}=\frac{2v_0}{g}\sin\alpha_0 \tag{12}$$

The projections are twice the values for the abscissa of the vertex of the path and the duration of the flight to it, which must also be for reasons of symmetry. The height of the vertex of the path is obtained by the:

$$h=-\frac{g}{2}t_T^2+v_0\sin\alpha_0 t_T=\frac{v_0^2}{2g}\sin^2\alpha_0 \tag{13}$$

where t_T is time necessary to rich h.

3. DESCRIPTION OF PROPOSED ALGORITHM

3.1 Taylor polynomials

Definition.
Let f be a function that has all derivatives up to order n at a. Then we define the **Taylor polynomial** of f of degree n with center a as [10]:

$$T_n(x)=f(a)+f'(a)(x-a)+\frac{1}{2!}f''(a)(x-a)^2+\ldots+\frac{1}{n}=\sum_{k=0}^{n}\frac{f^{(k)}(a)}{k!}(x-a)^2 \tag{14}$$

Theorem (Taylor's theorem).

Consider two distinct real numbers a and x. Let I be the closed interval with these two points as endpoints. Assume that a function f has continuous derivatives up to order n on I and $f^{(n+1)}$ on the interior Int(I). Then

$$Rn(x)=\int_a^x\frac{f^{(n+1)}(t)}{n!}(x-t)^n\,dt \tag{15}$$

Moreover, there exists a number c between a and x such that

$$Rn(x)=\frac{f^{(n+1)}(c)}{(n+1)!}(x-a)^{n+1} \tag{16}$$

The first result is called the **integral form** of the remainder, the second is called the **Lagrange form**. In fact, these precise results are also not exactly useful, since the integral may easily be too difficult to evaluate, while the second statement is existential, we know that such a c exists, but we have no idea what it is. However, the Lagrange form can be approximated from above and with a bit of luck it turns out that the upper estimate is small.

3.2 Projectile-target interception

Basic idea was devised to indicate the time needed to hit an incoming target, with a defined angle of hitting the target. The incoming round was modeled using the point interpolation equations and the interceptor round was modeled with a single dimension differential equation. Using these equations, it was possible to compute the lead angle needed for the gun interceptor round. This calculation is based on estimated time of arrival of the interceptor at predicted points of the target trajectory.

The expected time of the interceptor's arrival at each point can be calculated. At each point, the predicted time until arrival of the target and the interceptor are differenced. An aim point/lead angle can be selected for any positive difference by adjusting the firing time of the interceptor so that the time difference is zero. It is also possible to search the interval that goes from negative to positive for the zero delay aim point. The terminal geometry could also be considered in selecting an aim point. Post launch adjustments are made by selecting a different predicted target trajectory point for the interceptor to hit. After the interceptor is fired, it could only adjust its course by one degree at a time; thus, corrections could only take place if there was over one degree of error in the predicted impact point. The accuracy of the target track would have to meet certain criteria before an interceptor could be fired. Meeting this accuracy requirement would ensure that the target would be within the interceptor's maneuver space. Likewise the estimate of the interceptor's trajectory is of equal concern. As time increases, the accuracy of both the estimate of the target trajectory and the interceptor trajectory will increase. Many times, polynomial filters are discussed as candidates for trajectory estimation; these filters do not attempt to capture the dynamics of the situation and for longer prediction times are inadequate. Although filters based on *6-DoF* models are conceivable, they impose a computational load that cannot be met at this time [11].

3.3 Steps of proposed method

Let's assume the *3D* movement of a target in the air (e.g. a drone or quad copter), which moves in a straight line and with a slight maneuver (not larger than 3g). The target is tracked during the experiment by a Kalman filter (KF) using a CV (constant velocity) motion model. At the moment the target enters the weapon's engagement zone, an automatic 'encounter' calculation is activated. It is basically a three-dimensional problem of the kinematics

of the movement of the projectile and the target. It is necessary to solve the pure pursuit ballistic problem and its 'encounter' with the target that has entered the engagement zone of the weapon. For this calculation, the known laws of motion of a projectile fired from a known location, with a known initial velocity, are used. The algorithm should determine the angle at which the projectile is fired. The algorithm is performed in five main steps. These are the steps of the algorithm:

1. The target is tracked using a radar sensor in the C band, moving the state estimator (*Kalman filter*)

2. Calculation of the target distance from the weapon

3. Extrapolation by Taylor polynomial (most often of the third degree) of the future state of the target for the time it takes for the projectile to cover the calculated distance to the target. The order of the Taylor polynomial depends on the target trajectory until the moment of entering the zone of action. Based on the azimuth and elevation angles, the weapon is positioned towards the target

4. Integration of the differential equation of motion of the projectile by the *Runge-Kutta* method, using the ode 45 function. the parameter (i.e. condition) that needs to be met to complete the integration is the distance of the projectile to the target, which should be below 10m

5. Firing a sequentially with different (close) angles, so that the proximity fuses on the projectiles are activated

4. RESULTS OF SIMULATION

For experimental purpose we use the two type of scenario:

A) Simulated scenario with constant velocity of target (Fig.3)

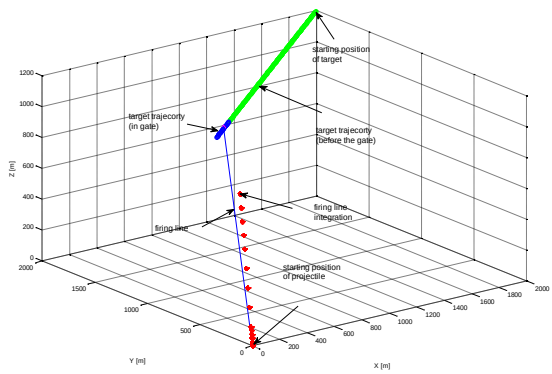

Figure 3. Simulated scenario with constant velocity

Using the known initial conditions, an expected projectile path can be generated. Range and velocity measurements can be used to improve the estimate of the projectile's path. The differential equation and the measurement process are combined to form a Kalman filter. The differential equation models the physics of the trajectory while the measurement updates the parameters of the equation based on least squares estimation.

$$F_{cv} = \begin{bmatrix} 1 & dt & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & dt & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & dt \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (17)$$

The simulation has 500 time intervals of duration dt=0.1[s] from the radar. The target state vector has $x=[x\ v_x\ y\ v_y\ z\ v_z\ ]$. The initial target parameters are: $x_t= 2000$, $v_{xt} = -80$, $y_t = 2000$, $v_{yt} = -60$, $z_t = 1200$, $v_{zt} = -5$. The cannon is launched at the coordinate origin. The target moves from the initial position, towards to the zone of action and when it enters the zone of action, the differential equation of motion of the projectile is integrated until the time of flight of the projectile until the encounter with the target is obtained.

B) Real data scenario (Fig.4).

These times are given in Table 1 for both scenarios. The distance of the cannon's effective range is 2000 m. The initial velocity of the projectile is 950 m/s. The target continues to move until the condition is met that it meets the projectile within the calculated time, in some delta environment. Transition matrix of constant acceleration (CA) target dynamic motion is:

$$F_{ca} = \begin{bmatrix} 1 & dt & dt^2/2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & dt & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & dt & dt^2/2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & dt & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & dt & dt^2/2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & dt \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (18)$$

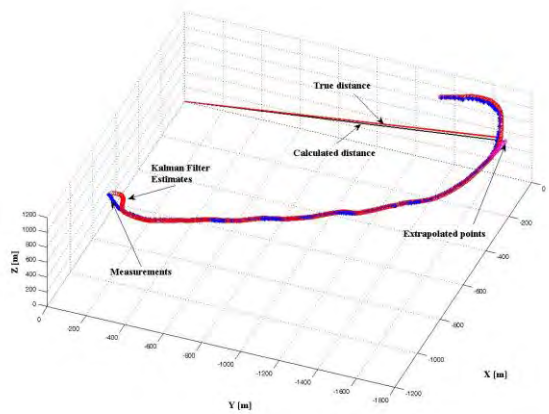

Figure 4. Simulation with real radar data

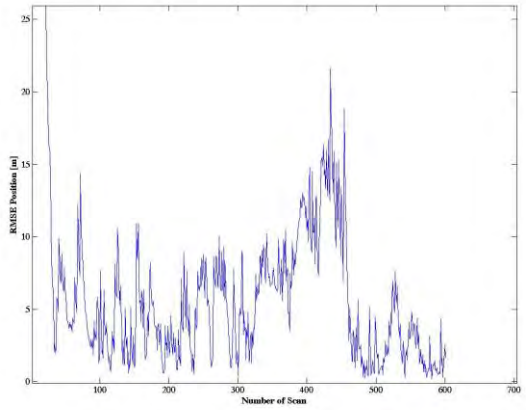

Figure 5. RMSE position diagram for real data scenario

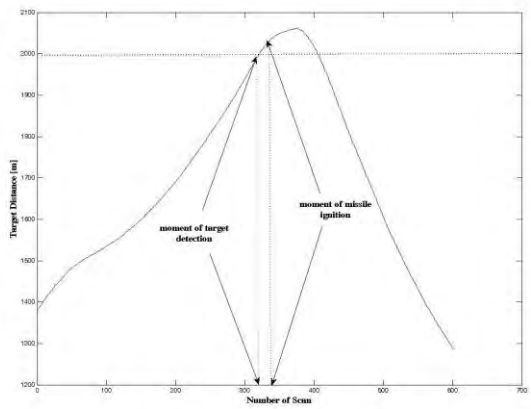

Figure 6. Distance of target diagram

The experimental results are given in the form of diagrams of the mean square error per position (real data – state estimate when tracking the target with the Kalman filter) given in Fig. 5. Figure 6. shows a diagram of the distance between the gun position (the initial position of the projectile) and a moving target. When the target enters the projectile's zone of action, an algorithm is activated that, in the first step, extrapolates the future position of the target in the time interval required for the projectile to reach the target. Given that the projectile's speed is an order of magnitude greater than the target's speed of movement, the integration of the projectile's differential equations of motion calculates the azimuth and elevation angle of the gun barrel in order to meet the target, under the condition of a minimum distance between the target and the projectile.

5. CONCLUSION

A complete algorithm for detecting, tracking and engaging low-flying targets using radar band range was proposed and tested in this paper. The algorithm showed good results in engaging moving targets in the air, using the Taylor polynomial (in the domain of extrapolation of future target states) and in the domain of predicting the missile and target collisions, using the Kalman filter. Preliminary research results are presented. The errors in approaching the bullet and targets are between 10 and 15 [m]. In future, a functional model for the complete detection, tracking and engaging low-flying targets in the air is envisaged.

Abstract: *In recent years, there has been a rapid development of deepfake technology, and it has become increasingly widespread. It appears that there are virtually no limitations to this technology, which has advanced to the point where anyone's likeness or voice can now be replicated. Distinguishing between authentic and artificially generated multimedia content is becoming increasingly difficult, and an average person can hardly detect discrepancies. The misuse of deepfake technology can occur in various ways – including the creation of pornographic content, the dissemination of fake news, and the execution of different types of fraud. In contemporary conflicts, fabricated audio and video recordings can provoke panic and influence decision-making processes. Deepfake technology has already been used as a supporting instrument of warfare, serving to spread panic and destabilize societies. The likenesses of current political leaders have been exploited to create fabricated content. The implications of such developments may be significant, and it appears that a transformation of trust in contemporary information systems has occurred. Therefore, the aim of this paper is to analyze the development of deepfake technology and to examine the role that the misuse of this technology – including the manipulation of multimedia content – plays in contemporary conditions.*

Keywords: *deepfake, contemporary information systems, trust, fabricated content*

1. INTRODUCTION

Information technologies have developed to such an extent that today it seems as though almost anything is possible. The widespread availability of the Internet, along with various artificial intelligence tools, has significantly facilitated everyday life. Nevertheless, despite the numerous benefits associated with technological progress, there are also certain risks and negative consequences. Deepfake technology first emerged several years ago, primarily in the form of applications designed for entertainment purposes. Through these applications, users could place their own or another person's face onto the body of someone else, or create videos in which individuals appeared to say things they had never actually said. During the early stages of its development, deepfake technology was still relatively limited, making it easy to recognize such content as artificial and unrealistic. Today, however, the line between authentic and fabricated content has become increasingly blurred, leaving individuals unable to place complete trust in what they see with their own eyes. In addition to its many positive applications, the development and refinement of deepfake technology have also generated numerous concerns. The growing difficulty of distinguishing between authentic and manipulated content has resulted in various forms of misuse. It is estimated that the consequences of deepfake technology extend beyond individual victims and may also pose threats to national security [1, p. 1443]. Detecting deepfake content has become increasingly challenging because the technology has advanced considerably, while detection methods remain complex and often inaccessible to the average user. What began as a technology intended primarily for entertainment now possesses the potential to "create fake news within communities, spread hate and disinformation that manipulate public opinion, and facilitate malicious activities such as extortion, blackmail, spoofing, identity theft, reputational damage, and deepfake pornography" [2, pp. 143296–143297]. In the context of pornography, celebrities, singers, and actresses were once the primary targets of deepfake content. Today, however, due to the widespread use of social media and the rapid advancement of deepfake technology, virtually any woman can become a target. Similarly, numerous fraud cases involving the use of deepfake technology have already been reported worldwide. As the technology continues to improve, distinguishing between genuine and fabricated content becomes increasingly difficult. Moreover, "if deepfakes or synthetic media are weaponized, trust in digital content may erode, making it difficult for individuals to rely on media even when the

DOI: 10.5937/OTEH26078V

content is authentic" [3, p. 243]. Consequently, the aim of this paper is to analyze the development of deepfake technology and examine the role that its misuse plays in contemporary conditions. The first section of the paper presents the development of deepfake technology and the methods used to detect deepfake content. The second section focuses on the transformation of trust in contemporary societies and the broader consequences associated with the use of this technology. Finally, the paper concludes with a summary of the findings and provides a list of references used in its preparation.

2. PRODUCTION AND DETECTION OF DEEPFAKE CONTENT

A significant number of deepfake videos can be viewed as harmless entertainment or artistic works that make use of the likenesses of public figures, whether living or deceased [4, p. 43]. However, in many cases, this technology is not used solely for positive purposes. Consequently, Nasiri and Hashemzadeh raise a logical question: "Should artificial intelligence developers bear some degree of responsibility for the actions of malicious actors who misuse their products?" [3, p. 244]. The first widely known deepfake content was a pornographic video featuring a celebrity that appeared on Reddit in 2017. Shortly thereafter, applications such as FakeApp and FaceSwap emerged, while the greatest concern was generated by the application DeepNude, which became known as a "digital undressing application" [5, p. 607]. Deepfake technology enables the creation of images and videos depicting events that never actually occurred. As a result, the face or voice of virtually any individual can be exploited to generate fabricated content. Deepfake refers to "an artificial intelligence-based technology capable of manipulating images, audio recordings, and videos to depict an event that never actually happened" [6, pp. 178–179]. More specifically, "the term 'deepfake' originates from the underlying deep learning (DL) technology, which enables face swapping in digital content and creates the false impression of an individual in a realistic environment" [2, p. 143297]. Such content is produced through various techniques, including autoencoders and Generative Adversarial Networks (GANs) [5,6]. As this technology continues to advance, the differences between genuine and manipulated content, which were once relatively easy to detect, have become increasingly difficult to identify. Consequently, "these manipulated media can portray individuals saying or doing things they never actually said or did, potentially leading to serious consequences in political, legal, and social contexts" [7, p. 73]. Owing to the widespread use of social media and the extensive sharing of photographs and videos, individuals today are more exposed than ever before. Likewise, the likenesses and voices of public figures - including actors, singers, and politicians - can be exploited to create deceptive and misleading content.

As Sophia observes, "early deepfake models primarily focused on manipulating video and audio content, whereas more recent advances have enabled artificial intelligence to generate highly convincing synthetic media in the form of text, images, and even entire virtual personas" [7, p. 83]. In addition to the creation and distribution of deepfake pornographic material, such content represents "a serious threat to society, political systems, and the business sector, as it places pressure on journalists who struggle to distinguish truthful information from falsehoods, threatens national security through the dissemination of propaganda capable of influencing elections, undermines citizens' trust in information provided by authorities, and raises significant cybersecurity concerns for both individuals and organizations" [4, p. 47]. Deepfake technology has already been used to create videos depicting political leaders expressing opinions and making statements that they would be highly unlikely to utter in reality. Furthermore, particularly during election campaigns, this technology enables candidates to "appear more attractive, younger, better-looking, and more energetic; communicate with multiple audiences simultaneously in different languages; and personalize their messages for individual voters" [8, p. 468]. As a result, the distinction between truth and falsehood becomes increasingly blurred, while public trust and confidence in institutions may be seriously undermined. Due to the rapid advancement of this technology, individuals can no longer be certain whether a video recording or photograph is authentic or artificially generated. Trust is an essential prerequisite for the effective functioning of institutions. Without it, "when disinformation undermines institutions, their ability to implement policies, enforce laws, and manage public crises is severely compromised" [7, p. 78]. Therefore, contemporary information systems must be capable of providing citizens with relevant, accurate, and reliable information, while also detecting deepfake content in a timely manner and preventing its further dissemination.

Methods for detecting deepfake content vary considerably, while the technology itself has advanced so rapidly that ordinary individuals can no longer confidently trust their own eyes. Whereas early deepfake videos often contained visible flaws that could be identified by human observation, this is no longer the case. Regarding detection techniques, Cinar identifies two primary approaches: the analysis of biological signals and the detection of pixel-level irregularities [6, pp. 182–183]. The detection of manipulated content has become a major challenge. As Koopman et al. note, "it is increasingly likely that everyday video evidence has been manipulated, creating a growing need for verified authentication methods capable of detecting deepfake alterations" [9, p. 133]. In response to this challenge, Westerlund identifies four principal approaches to combating deepfake content: legislation and regulatory measures; corporate policies and voluntary initiatives by private companies; education and training; and technological countermeasures, including deepfake detection, content authentication, and the prevention of deepfake creation [4, p. 44]. States are increasingly classifying deepfake content as a potential security threat and are seeking to establish appropriate legal frameworks to address this issue. In this regard, the European Union has adopted the Digital Services Act (DSA) and the Artificial Intelligence Act (AIA), both of which aim to regulate harmful and deceptive online

content. In the United States, various federal and state-level initiatives have been introduced to address the challenges posed by deepfakes, including the "Deepfake Accountability Act." A similar initiative exists in China through the "Regulations on the Administration of Deep Synthesis of Internet Information Services." In addition, major technology companies and online platforms, such as Meta and Google, have recognized the need for greater oversight of artificially generated content [7, p. 81]. Nevertheless, the transformation of trust in contemporary information systems has already occurred, to a considerable extent, as a consequence of the widespread development and misuse of deepfake technology.

3. TRANSFORMATION OF TRUST IN CONTEMPORARY SOCIETY

The inability to identify flaws when viewing manipulated content raises an important question: how can individuals distinguish between authentic and fabricated information? The use of deepfake technology "raises questions about human perception and challenges the ability to trust one's own eyes and ears when watching a video of a politician discussing important international, regional, and national issues" [1, p. 1449]. As a result, trust in contemporary information systems, political structures, and public institutions may be directly undermined, potentially leading to various political and social crises. In many countries, the use of deepfake technology remains insufficiently regulated by law. Consequently, individuals who create and distribute such content often face little or no legal accountability for their actions. Some scholars characterize the present era as an age of post-truth, in which the distinction between reality and fiction becomes increasingly difficult to establish. In this context, they warn that "when audiences lose trust in established media organizations, they may turn to alternative sources that prioritize sensationalism over accuracy, thereby further deepening the disinformation crisis" [7, p. 77]. The spread of disinformation and fake news has been significantly facilitated in recent years by deepfake technology and artificial intelligence tools. Consequently, "the manipulation of public discourse through AI-driven disinformation campaigns can shift political priorities, complicate legislative processes, and create an environment in which evidence-based policymaking becomes increasingly difficult" [7, p. 77]. Numerous political leaders have become targets of deepfake content, while others have reportedly used this technology themselves for propaganda purposes [1]. Although deepfake technology was initially developed primarily for entertainment and recreational purposes, its continuous advancement has led individuals, organizations, and governments to reconsider the risks associated with its use. Within only a few years of its emergence, deepfake technology has demonstrated a wide range of harmful applications, prompting growing efforts to place its use under stricter oversight and to establish comprehensive legal regulations governing its development and deployment.

As previously noted, many celebrities, singers, and actresses have become victims of the misuse of deepfake technology through the creation of fabricated pornographic content. Furthermore, numerous women were placed at risk following the emergence of the so-called "digital undressing application." Similarly, many politicians have been confronted with highly realistic videos depicting them making statements that they never actually uttered. Such videos can spread rapidly through social media and various online platforms. By the time it is established that a recording is fabricated or generated through deepfake technology, significant damage may already have occurred. In 2018, a deepfake video created by a Belgian political party was released with the aim of encouraging citizens to sign a petition. In the video, Donald Trump appeared to advise Belgian citizens on climate change, provoking considerable public outrage [4, p. 43]. In the same year, an attempted military coup took place in Central Africa following the release of a video featuring the President of Gabon, Ali Bongo Ondimba. At the time, many citizens believed that the president was either seriously ill or had already died due to his prolonged absence from public life, which fueled suspicions regarding the authenticity of the recording [4, p. 44]. This case serves as an illustrative example of the consequences that may arise when the public loses confidence in the authenticity of video evidence. Deepfake technology was also employed during the COVID-19 pandemic, when "deepfake videos and audio recordings circulated online, often falsely attributing statements to prominent public health officials, politicians, or celebrities" [3, p. 237]. During a global health crisis of this magnitude, individuals not only faced fears concerning their own health and the well-being of their loved ones but were also confronted with an overwhelming volume of both accurate and false information circulating simultaneously. The coexistence of reliable information and fabricated content further complicated public understanding of the crisis and contributed to the spread of uncertainty and distrust.

The use of deepfake technology during election campaigns is not a recent phenomenon. As Nasiri and Hashemzadeh observe, "while traditional election interference techniques involved the dissemination of misleading information through text-based fake news, the 2020 elections were marked by the increasing use of deepfakes and AI-generated content to manipulate voters, undermine trust in institutions, and influence electoral outcomes" [3, p. 238]. An increasing number of scholars have examined the impact of deepfake content in the electoral context. For example, Łabuz and Nehring analyzed the use of deepfake technology in eleven countries - the United States, Turkey, Argentina, Poland, the United Kingdom, France, India, Bulgaria, Taiwan, Indonesia, and Slovakia - during 2023, with the aim of identifying its potential implications for future electoral processes. Their conclusion is particularly noteworthy: "we believe that none of the cases in which deepfake content has thus far been used in the context of elections has had a decisive impact on the outcome of the elections themselves. This does not mean, however, that there has been no effect. (...) Although dystopian predictions of an 'information apocalypse' have not (yet?) materialized, there are already visible signs of declining trust in

information, politics, and the media, which reinforce feelings of uncertainty within society and create new opportunities for manipulation" [8, p. 468]. These findings suggest that deepfake technology can have a significant impact on public trust in information systems, even when it does not directly alter election results. Nevertheless, the use of deepfake technology is not limited to peacetime conditions. On the contrary, it has increasingly been employed during armed conflicts. According to Twomey et al., "the Russia–Ukraine war represents the first real-world example of the use of deepfake technology in warfare, with a number of incidents involving deepfake content featuring Russian and Ukrainian government officials being used for purposes of disinformation and entertainment" [10, p. 1]. In this context, several notable examples emerged, including a fabricated video of a Ukrainian fighter aircraft, a deepfake video depicting Vladimir Putin announcing peace with Ukraine, and a deepfake recording of Volodymyr Zelenskyy purportedly surrendering to Russia [10].

4. CONCLUSION

With each passing day, deepfake technology continues to advance, increasingly blurring the boundary between reality and fiction. Technology itself is neutral, and "a moral judgment can only be made about the person who uses technology in a particular way - not about the technology itself" [11, p. 25]. Nevertheless, many individuals misuse deepfake technology to create fabricated content. Owing to social media and various online platforms, photographs and videos of countless individuals are readily available without significant restrictions. Today, deepfake pornography threatens not only famous actresses and singers but also virtually any woman. As a result of the rapid development of deepfake technology, the risks of cyberbullying and various forms of fraud cannot be excluded. Artificial intelligence has advanced so rapidly within a short period of time that the human eye can no longer reliably determine whether content is authentic or fabricated. Videos of politicians appearing to say things that never actually occurred in reality frequently circulate on social media ahead of election campaigns. Such content has the potential to provoke a wide range of emotions among the public. Consequently, relations between states may be seriously damaged. The use of deepfake technology during elections has been observed in numerous countries, and the number of such cases continues to grow each year. Although deepfakes may not always have a direct impact on election outcomes, they raise serious concerns regarding public trust. Today, fake news can be created and disseminated much more easily than during the era of traditional media. Deepfake technology has also begun to be used as an auxiliary instrument of warfare. In this context, it can be employed to weaken troop morale and contribute to incorrect political assessments and decisions. The consequences may be severe, including the loss of military victories, human lives, and material resources. Detection methods are unable to keep pace with the parallel development of deepfake technology. Despite the existence of various detection techniques, some recordings may appear so authentic that it becomes difficult to determine whether and how their falsity can be proven. However, one fact remains certain: trust in information and communication systems is increasingly eroding. Today, individuals can hardly trust their own eyes. The consequences of losing confidence in the authenticity of media content are illustrated by the case from Central Africa discussed earlier in this paper. It is likely that those who initially conceived and developed this technology did not anticipate the harmful consequences that its misuse would produce within only a few years. Nevertheless, it is evident that not only individuals are endangered, but also the security of corporations and states. Therefore, public education and the adoption of appropriate legal regulations governing the use and distribution of artificially generated content are of paramount importance. In this regard, the European Union currently appears to be the most advanced actor and may serve as an example of good practice for other states seeking to address the challenges posed by deepfake technology.
