Abstract: *Selecting cost-efficient, highly available, and reliable virtualized infrastructure is a critical challenge for military data centers. This paper extends a prior two-objective optimization framework by introducing reliability as a third objective alongside cost minimization and availability maximization. The framework uses the Non-dominated Sorting Genetic Algorithm II (NSGA-II) to model trade-offs among three conflicting objectives within a virtualized military data center, where services are deployed as virtual machines across physical nodes with heterogeneous failure characteristics. Five VM types with distinct cost, availability, and failure rate profiles are defined to model realistic military infrastructure. Experimental results with the pymoo library demonstrate that the three-objective approach yields 119 Pareto-optimal solutions spanning \$0.18–\$4.94/h in cost, 98.0–100.0000% in availability, and 23.7–99.9996% in reliability over a 720-hour horizon. Critically, at matched cost points, the three-objective approach achieves up to 20.5 percentage points higher reliability than the two-objective baseline by diversifying VM type selection rather than stacking identical low-cost instances.*

Keywords: *multi-objective optimization, NSGA-II, Pareto optimality, military data center, virtualization, availability, reliability*

1. INTRODUCTION

Modern military operations depend on robust digital infrastructure to support command and control (C2), intelligence, surveillance, and reconnaissance (ISR), logistics management, and secure communications [1, 2]. These services are increasingly deployed on virtualized platforms within military data centers, both in garrison facilities and in field-deployable configurations. Unlike commercial cloud environments where downtime results in financial loss, failures in military IT infrastructure can compromise mission execution, situational awareness, and force protection [3].

Military data centers operate under unique constraints. They are often isolated from public networks, must function in austere or contested environments, and face rigid procurement budgets. The selection of virtual machine (VM) types and their allocation across physical servers is a critical planning decision that directly affects operational readiness. From the requirement to ensure uninterrupted support for command, control, and intelligence functions, availability and reliability arise as fundamental system objectives. Availability, the probability that a system is operational, determines acceptable outage duration [4]. Reliability, the probability of continuous failure-free operation over time T, is equally critical, as even brief C2 or ISR interruptions during operations have tactical consequences [5].

Traditional single-objective optimization approaches fall short in addressing this multi-faceted problem. The authors proposed a two-objective NSGA-II framework in [6] to balance cost and availability. However, it did not explicitly optimize reliability, instead assuming that higher availability implies higher reliability, an assumption that fails when VM types have heterogeneous failure characteristics.

This paper extends [6] by incorporating reliability as a third objective and adapting the optimization framework to military data centers. The results show that optimizing only cost and availability systematically favors homogeneous VM deployments, typically using multiple low-cost instances to maximize availability while reducing reliability because of their higher failure probability. Similar to a military force relying on a single weapon system, such configurations are efficient but vulnerable to type-specific weaknesses. Adding reliability

E-mail: nikola.zogovic@pupin.rs
DOI: 10.5937/OTEH26079Z

as a third objective diversifies VM portfolios by failure-rate profile, providing a computational analogue of defense in depth. This optimization increases modeled reliability by up to 20.5 percentage points at the same cost.

This paper makes three contributions: (1) it introduces reliability as a third optimization objective for virtualized military data centers; (2) it defines a five-tier VM model capturing the heterogeneous failure characteristics of military-grade hardware; and (3) it demonstrates that VM type diversification, rather than redundant replication of identical instances, improves reliability. Unlike prior multi-objective cloud studies that optimize cost and availability or task scheduling without reliability [6–10], the proposed formulation explicitly captures the cost–availability–reliability trade-off, providing actionable guidance for infrastructure planners.

2. RELATED WORK

Multi-objective optimization (MOO), particularly using NSGA-II, has been widely applied to cloud infrastructure optimization. Tan et al. [7] applied NSGA-II to microservice allocation in containerized clouds, while Verma et al. [8] identified it as a state-of-the-art method for Pareto-based combinatorial optimization.

In military computing, virtualization is a key enabler of deployable C2 systems and tactical data centers. Fault-tolerant VM placement for redundant server clusters was studied in [3], [9] presents NSGA-II application to cloud task scheduling, while [10] presents heterogeneous IoT–fog–cloud environments. More recent work [11,12] has extended multi-objective, QoS-aware fault-tolerant VM placement to data-center-scale systems.

In previous work [6], the authors proposed a two-objective NSGA-II framework balancing cost and availability, and Stanišić [13] investigated Docker file-system performance for containerized workloads. However, existing studies do not explicitly optimize reliability, often consider only a limited range of VM types, and largely overlook VM type diversification as a mechanism for improving system resilience. This paper addresses these gaps by introducing reliability as a third optimization objective and modeling heterogeneous VM failure characteristics.

3. METHODOLOGY

The optimization framework uses NSGA-II [14] to simultaneously minimize cost and maximize availability and reliability for a virtualized military data center.

3.1. Problem Formulation and Military VM Tier Model

The decision vector $x = [n_1, n_2, n_3, n_4, n_5]$ represents the number of VM instances of each type to deploy, where $n_i \in \{0, 1, \ldots, 10\}$. The uniform upper bound of 10 is a scenario-specific capacity proxy based on data center resource constraints (compute, memory, space, and power). For operational use, it must be replaced by tier-specific limits derived from the actual host inventory. Five VM types are defined to model the range of hardware typically available in military data centers, from commercial off-the-shelf (COTS) servers used for administrative workloads to hardened, fault-tolerant platforms designed for mission-critical C2 systems. The specifications are shown in Table 1.

Table 1. Military Data Center VM Tier Specifications

VM Tier	Cost ($/h)	Avail.	λ (/h)	Typical Use
T1: COTS Basic	$0.18	0.980	0.002	Admin, logs
T2: COTS Enhanced	$0.37	0.990	0.001	Logistics
T3: Hardened	$0.52	0.995	0.0005	SIGINT proc.
T4: Mission-Crit.	$0.78	0.999	0.0002	ISR feeds
T5: Fault-Tolerant	$1.15	0.9995	0.0001	C2 systems

The tier model reflects real-world military procurement trade-offs. Tier 1 (COTS Basic) represents commodity servers suitable for non-critical workloads such as administrative systems and log aggregation. Tiers 3–5 represent progressively hardened platforms with redundant power supplies, ECC memory, and hot-swappable components, designed for signal intelligence processing, ISR data feeds, and command and control systems respectively. The failure rate λ decreases by an order of magnitude from T1 to T5, reflecting the engineering investment in higher-tier hardware.

The failure rate parameters are derived from representative mean time between failures (MTBF) values: T1 corresponds to MTBF ≈ 500h (commodity COTS hardware), T2 to MTBF ≈ 1000h (enterprise-grade with ECC RAM), T3 to MTBF ≈ 2000h (ruggedized platforms, e.g., MIL-STD-810 compliant), T4 to MTBF ≈ 5000h (mission-critical with redundant PSU and cooling), and T5 to MTBF ≈ 10000h (fault-tolerant systems with hot-standby components). Availability values are derived from failure rates assuming a mean time to repair (MTTR) of 1 h (T1–T2) and 0.25 h (T3–T5), reflecting the faster repair of modular, hot-swappable hardware in higher tiers.

3.2. Objective Functions

Three objectives are defined. All objectives are formulated as minimization for NSGA-II compatibility.

Objective 1: Cost Minimization. The total infrastructure cost is the sum of per-instance costs:

$$C(x) = \sum_i n_i \cdot c_i \tag{1}$$

where c_i is the hourly cost of VM type i, given in column 2 of Table 1. The optimization minimizes $f_1 = C(x)$.

Objective 2: Availability Maximization. Service availability is modeled using the classical parallel-system

availability model, assuming independent VM failures. The probability that at least one VM remains operational is

$$A(x) = 1 - \prod_i (1 - a_i)^{n_i} \quad (2)$$

where a_i is the per-instance availability of VM type i (Table 1). The optimization minimizes $f_2 = 1 - A(x)$.

Objective 3: Reliability Maximization. System reliability over the time horizon T is modeled using the classical exponential lifetime model and parallel-system reliability assumption, yielding the probability that at least one VM remains operational:

$$R(x) = 1 - \prod_i (1 - e^{-\lambda_i \cdot T})^{n_i} \quad (3)$$

where λ_i is the failure rate of VM type i (Table 1), and $T = 720\text{h}$ (30 days). The time horizon is mission-dependent and reflects the operation or deployment duration (Table 3). The optimization minimizes $f_3 = 1 - R(x)$. Unlike availability, reliability depends on the failure rate λ_i rather than the availability a_i; consequently, a VM type may exhibit high availability through rapid recovery yet low reliability due to frequent failures, or vice versa.

Equations (2) and (3) assume independent VM failures and omit common-cause failures from shared infrastructure. Thus, the calculated availability and reliability may be optimistic when instances share a physical fault domain. Incorporating common-cause failures and fault-domain placement is left for future work.

3.3. Constraints and Problem Statement

The optimization is subject to a budgetary constraint $C(x) \leq B$, where B is the predefined operational budget. Two scenarios model distinct military contexts: $B = \$5/h$ represents a field-deployable tactical data center with limited power and hardware, while $B = \$15/h$ represents a garrison facility with greater infrastructure capacity. The per-type instance count is bounded as described in Section 3.1; no explicit floor is imposed on availability or reliability, so the reported Pareto fronts span the full feasible range of these objectives.

Combining the three objectives with the budget and instance-count constraints, the complete optimization problem is stated as:

$$x* = argmin_x \left(f_1(x), f_2(x), f_3(x)\right), \; s.t. \; C(x) \leq B, \; n_i \in \{0, \ldots, 10\} \quad (4)$$

Each component n_i takes one of 11 integer values, so the decision space comprises $11^5 = 161{,}051$ candidate configurations, over which NSGA-II searches for the Pareto-optimal set.

3.4. Algorithm Configuration

NSGA-II is configured with a population size of 120, 300 generations, simulated binary crossover (SBX; probability 0.9, η = 15), polynomial mutation (probability 0.2, η = 20), and integer-rounding repair. For the algorithm comparison in Section 4.6, NSGA-III is configured with the same population size, generation count, and genetic operators, using Das–Dennis reference directions to guide selection. The implementation uses the pymoo library (v0.6.1). Hypervolume convergence is tracked to verify algorithm convergence.

4. EXPERIMENTAL RESULTS

4.1. Two-Objective Baseline

The two-objective optimization (cost vs. availability), the problem originally defined in our prior work [6], under the \$5/h budget produces 10 Pareto-optimal solutions. Fig. 1 shows the Pareto front.

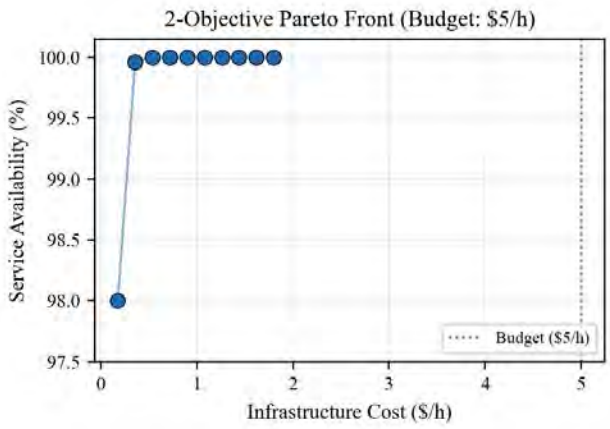

Figure 1. 2-Objective Pareto Front (Budget: \$5/h)

A critical observation is that all solutions consist exclusively of GP-Low instances (the cheapest VM type). The algorithm maximizes availability by stacking identical low-cost VMs, ranging from 1 instance (\$0.18/h, 98.0%) to 10 instances (\$1.80/h, 100.0%). This monoculture strategy is optimal for availability but ignores reliability implications.

4.2. Three-Objective Optimization

The three-objective optimization, defined by the objectives in Eqs. (1)–(3) and the constraints of Section 3.3, under the $\$5/h$ budget yields 119 Pareto-optimal solutions spanning cost $\$0.18 - \$4.94/\text{h}$, availability $98.0 - 100.0000\%$, and reliability $23.7 - 99.9996\%$ (T = 720h). Fig. 2 shows the 3D Pareto front.

The Pareto surface reveals the three-way trade-off. Low-cost solutions (bottom-left) sacrifice both availability and reliability. As cost increases, both metrics improve, but the rate of improvement differs, with reliability showing steeper gains at moderate cost levels due to the exponential nature of the failure rate model.

Under the relaxed budget of $\$15/\text{h}$, the Pareto front extends to 119 solutions with reliability reaching 100.00% (Fig. 3).

4.3. Key Finding: Reliability Improvement over the Two-Objective Baseline through VM Diversification

The central finding of this study is revealed by comparing 2-objective and 3-objective solutions at matched cost points. Fig. 4 presents this comparison and Fig. 5 shows the cost-reliability projection for both budget scenarios.

The mechanism is clear: the 2-objective approach, optimizing only cost and availability, consistently selects homogeneous configurations of the cheapest VM tier (T1: COTS Basic, $\lambda = 0.002/\mathrm{h}$). While stacking many T1 instances achieves near-perfect availability through redundancy, the high per-instance failure rate degrades reliability over the 720h (30-day) evaluation horizon, a duration representative of a typical military deployment rotation or exercise cycle.

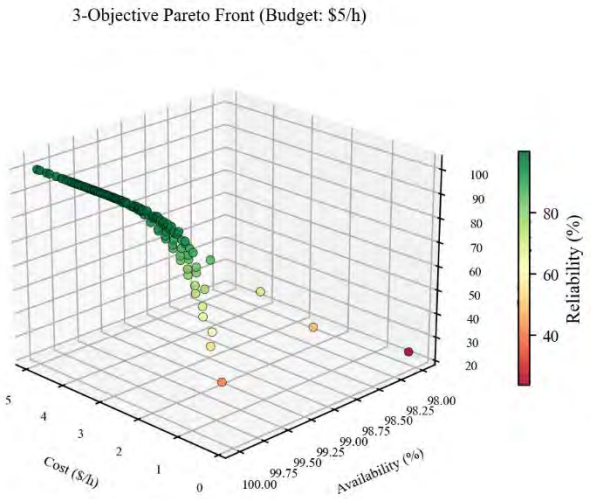

Figure 2. 3-Objective Pareto Front (Budget: $5/h)

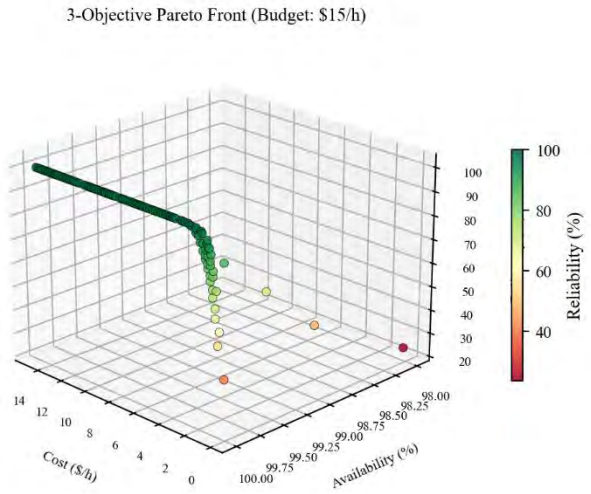

Figure 3. 3-Objective Pareto Front (Budget: $15/h)

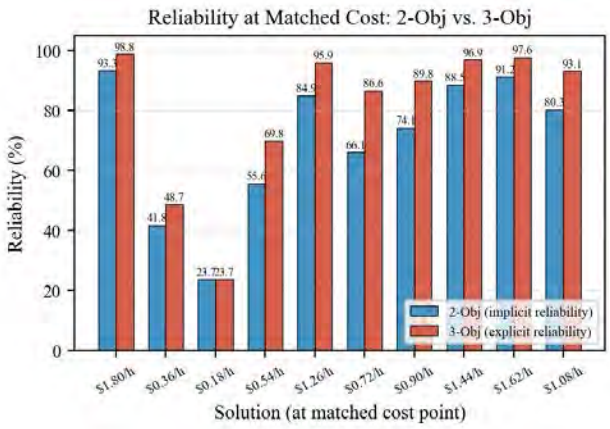

Figure 4. Reliability Comparison at Matched Cost Points

The 3-objective approach discovers that mixing VM tiers, particularly by including T3: Hardened ($\lambda = 0.0005/\mathrm{h}$) and T4: Mission-Critical ($\lambda = 0.0002/\mathrm{h}$) instances, dramatically improves reliability. For example, at $\$0.72/\mathrm{h}$, the 2-objective solution deploys 4×T1 instances and achieves 66.1% reliability, while the 3-objective solution deploys 1×T4 instance and achieves 86.6%, a relative gain of 20.5 percentage points over the two-objective baseline at the same cost. In military terms, this is the difference between a C2 system that is expected to fail multiple times during a 30-day deployment and one that has an 87% probability of continuous operation.

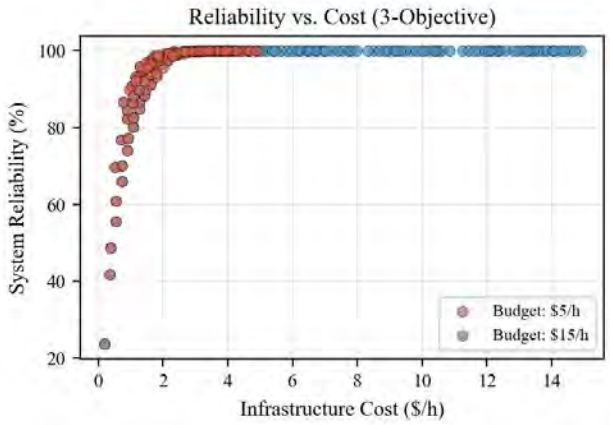

Figure 5. Reliability vs. Cost Projection

Table 2. Reliability Improvement: 2-Obj vs. 3-Obj at Matched Cost

Cost ($/h)	2-Obj Rel.(%)	3-Obj Rel.(%)	Δ Rel.(pp)
$0.54	55.6	69.8	+14.2
$0.72	66.1	86.6	+20.5
$1.08	80.3	93.1	+12.9
$1.26	84.9	95.9	+11.0
$1.44	88.5	96.9	+8.4

This result is a computational manifestation of the defense-in-depth principle: heterogeneous systems are more resilient than homogeneous ones because they are not susceptible to common-mode failures. A vulnerability or hardware defect affecting T1 COTS servers would

simultaneously compromise all 4 instances in the 2-objective solution, while the 3-objective solution's T4 mission-critical hardware operates on a fundamentally different failure profile.

4.4. VM Type Allocation Patterns

Fig. 6 shows how VM type allocation varies across the Pareto front.

Low-cost Pareto solutions use T1 COTS instances exclusively, mirroring the 2-objective behavior. As budget increases, the optimizer progressively introduces higher-tier hardware. At moderate cost levels ($\$0.52 - \$1.30/h$), the algorithm discovers mixed configurations combining T1 and T3/T4 instances, providing both the redundancy benefits of multiple instances and the low failure rates of hardened hardware. At higher budgets, T4 Mission-Critical and T3 Hardened instances dominate, reflecting the military planning principle that mission-critical services should run on mission-critical hardware when resources permit.

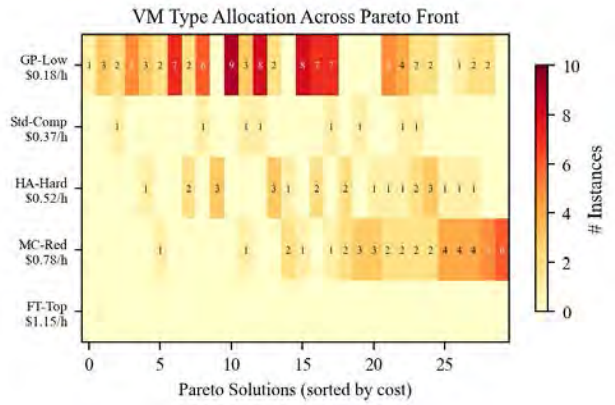

Figure 6. VM Type Allocation Across Pareto Front

4.5. Sensitivity Analysis: Effect of Time Horizon

A key question for military planners is how the operational time horizon affects the value of three-objective optimization. Figure 7 shows the reliability gap between the two- and three-objective formulations across four operationally relevant time horizons.

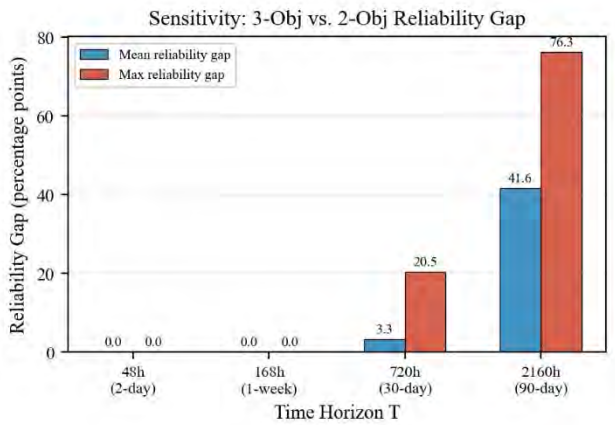

Figure 7. Reliability Gap vs. Time Horizon

The results reveal a clear pattern. For short operations ($T \leq 168$h), all VM types remain sufficiently reliable, and the two-objective formulation performs as well as the three-objective approach. As the time horizon increases to 720h (30-day deployment), a reliability gap emerges, reaching up to 20.5 percentage points. At $T = 2160h$ (90-day rotation), the gap becomes substantial, with an average of 41.6 and a maximum of 76.3 percentage points. These results indicate that while explicit reliability optimization provides little benefit for short missions, it becomes essential for sustained deployments exceeding one week.

4.6. NSGA-II vs. NSGA-III comparison

Fig. 8 compares the convergence of NSGA-II and NSGA-III on the three-objective optimization problem. NSGA-II produces 119 Pareto-optimal solutions with a final hypervolume of 14.45, whereas NSGA-III produces 12 solutions with a hypervolume of 14.26. NSGA-II performs better because NSGA-III is designed for many-objective optimization (four or more objectives), where reference directions are needed to maintain diversity. In contrast, the present three-objective problem has a small, bounded integer search space, allowing NSGA-II's crowding-distance mechanism to preserve diversity more effectively. These results justify the use of NSGA-II for military data center optimization with integer VM allocation variables.

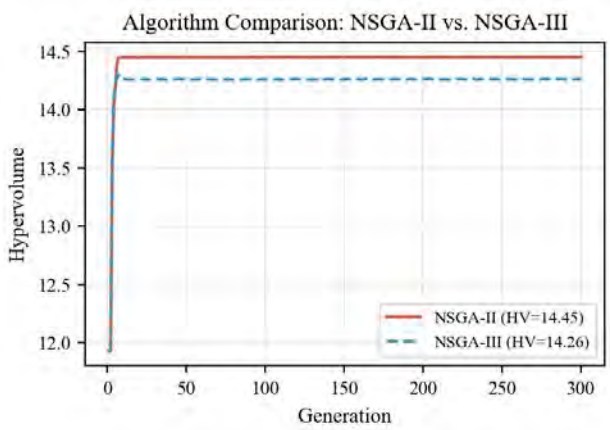

Figure 8. NSGA-II vs. NSGA-III Convergence

Hypervolume analysis further shows that both algorithms reach 99% of their final hypervolume within the first few tens of generations. The three-objective formulation converges as quickly as the two-objective formulation, indicating that adding reliability as a third objective incurs negligible computational overhead.

4.7. Full Objective Space and Objective-Level Constraints

Sections 4.1–4.2 present only Pareto-optimal solutions. To characterize the search space more completely, all $11^5 = 161{,}051$ VM configurations were exhaustively evaluated using Eqs. (1)–(3). Fig. 9 shows the resulting objective space projected onto the cost–reliability plane for the tactical budget (B = \$5/h), under which 2,503 configurations satisfy the budget constraint. Reliability

ranges from 23.7% (a single T1 COTS instance) to 99.9996% (highly redundant mixed configurations), demonstrating that the budget constraint alone permits configurations with widely different mission suitability.

The formulation in Section 3.3 imposes no minimum reliability, so all budget-feasible configurations are included in the Pareto analysis. In practice, however, missions often require a minimum reliability. Applying an objective-level constraint, $R(x) \geq R_{min}$, removes the lower portion of the objective space. For a three-nines requirement ($R_{min} = 99.9\%$ over the 720h horizon, dashed line in Fig. 9), 625 of the 2,503 budget-feasible configurations (25.0%) are eliminated, leaving 1,878 feasible configurations. A four-nines requirement ($R_{min} = 99.99\%$) excludes 1,582 configurations (63.2%). Most eliminated configurations are the low-cost, low-redundancy monocultures identified in Section 4.3.

These results show that realistic mission-reliability requirements eliminate many of the cheapest solutions, leaving diversified, higher-reliability VM portfolios as the feasible design choices. When mission reliability is specified a priori, the threshold can be incorporated directly as an additional optimization constraint.

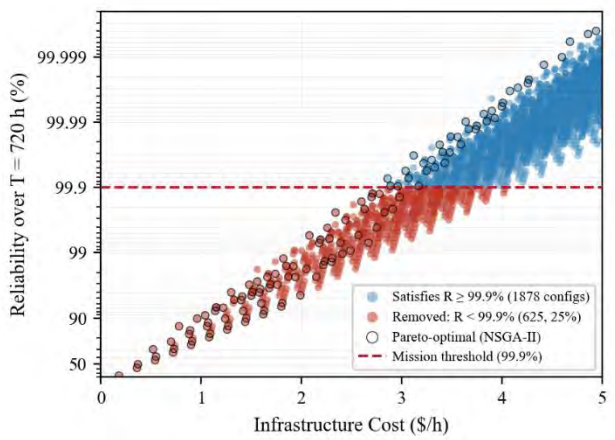

Figure 9. Full objective space for B = $5/h

5. CONCLUSION

This study extends the two-objective cloud optimization framework in [6] by introducing reliability as a third objective for virtualized military data centers. The results show that optimizing only cost and availability systematically favors homogeneous COTS-tier VM deployments, which achieve high availability through redundancy but poor long-term reliability. Incorporating reliability fundamentally changes the optimal solutions, with diversified VM portfolios combining COTS, hardened, and mission-critical hardware improving reliability by up to 20.5 percentage points at the same cost.

The findings provide three practical recommendations. First, budget-constrained tactical data centers should deploy mixed T1–T4 VM configurations rather than replicate identical low-cost instances. Second, higher-budget garrison facilities should reserve T3–T5 hardware for mission-critical workloads while using T1–T2 for non-critical services. Third, the resulting Pareto front provides a decision-support tool for balancing cost, availability, and reliability according to mission priorities.

Future work will extend the framework by incorporating adversarial failure models, workload-specific reliability targets, anti-affinity constraints for physical fault-domain separation, complete analysis of the objective space, and AI-based adaptive reconfiguration [15] for dynamic optimization under changing mission conditions.

Abstract: *This paper addresses the Threat Evaluation and Weapon Assignment (TEWA) problem in Ground-Based Air Defence (GBAD) systems. GBAD systems incorporate sensors, effectors, command and control (C2), and telecommunication systems to provide efficient short-to-medium-range air defence. At the functional level, GBAD systems are designed to detect, track, and engage aerial targets. The decision-making problem in GBAD systems is characterised by short response time and human factors. Combined with limited engagement time, automation of the decision-making process becomes imperative. In modern-day asymmetric warfare conditions, GBAD systems must provide a high level of efficiency and automation in the decision-making process. This paper proposes an approach based on the Find, Fix, Track, Target, Engage and Assess (F2T2EA) executive procedure. Key points in the F2T2EA executive procedure are TEWA, performed in real time, with efficient and precise estimation of aerial objects' capability and intent to engage Defended Assets (DAs). The algorithm is based on layered multi-criteria decision-making analyses (MCDMA), implemented and tested in a simulated environment, showing overall effectiveness. Compared to the Baseline algorithm, which simulates fast human response, the proposed algorithm shows a ~46% decrease in total scenario execution time and a ~28% decrease in total threat exposure of DA over time, demonstrating a significant increase in DA survivability.*

Keywords: *threat evaluation, weapon assignment, GBAD systems, MCDMA*

1. INTRODUCTION

Ground-Based Air Defence (GBAD) systems incorporate sensors, effectors, command and control (C2), and telecommunication systems to provide efficient short- to medium-range air defence. Unlike long-range air defence systems (LRAD), which primarily deal with medium- to high-altitude and high-speed targets (such as fighters, bombers, medium-range ballistic missiles, etc.), short-range air defence systems (SHORAD) deal with low-altitude, low radar cross-section and high-speed, or low/slow/small threats (such as loitering munitions, drone swarms, and sea-skimming cruise missiles). Thus, LRAD systems' reaction time is measured in minutes, and SHORAD systems' reaction times drop from minutes to seconds.

To enable efficient resource management of available effectors and ammunition vs. designated targets, the Find→ Fix→ Track→ Target→ Engage→ Assess (F2T2EA) executive procedure is applied. This paper focuses on the Target→ Engage→ Assess steps of F2T2EA, while the Find→ Fix→ Track steps are simulated and hypothetical. Another focus of this paper is the automation of the decision-making process in order to provide maximum efficiency and survivability of the Defended Asset (DA) while reducing the need for human-in-the-loop in the mentioned process [1]. In modern-day asymmetric warfare conditions, SHORAD systems must provide a high level of efficiency and automation in the decision-making process. Threat Evaluation and Weapon Assignment (TEWA) problem is a critical decision support process in air defence and military C2 platforms. It typically consists of two mutually independent but interrelated sub-problems:

1. TE: Quantifying and prioritising incoming aerial or missile threats based on factors like intent, velocity, trajectory, distance, and DA priority (criticality).
2. Weapon Assignment (WA): Dynamically allocating optimal weapon systems to neutralise previously prioritised threats in real-time, under defined operational constraints.

The proposed TEWA system uses an algorithm based on Multi-Criteria Decision-Making Analyses (MCDMA) to produce efficient engagement planning and target distribution [2].
Simulation is performed following the Stage-Based Weapon Target Assignment methodology [3]. The efficiency assessment criterion is based on a cross-reference evaluation framework by defining appropriate

DOI: 10.5937/OTEH26080P

Key Performance Indicators (KPI) [4]. Efficient TEWA reflects military proficiency and requires prompt decision-making while managing the available resources [2].

2. LITERATURE REVIEW AND METHODOLOGICAL FRAMEWORK

2.1. F2T2EA execution cycle (kill-chain)

F2T2EA execution cycle enables the entire end-to-end operational cycle to provide efficient resource management from target acquisition to engagement results assessment. The F2T2EA kill chain framework is the standard process used for dynamic targeting and time-sensitive threat response in modern joint military operations [5]. In SHORAD and GBAD operational environments, the F2T2EA kill chain undergoes fundamental structural changes. The F2T2EA execution cycle applies not just to kinetic means, but also to military capabilities that achieve lethal or nonlethal effects through non-kinetic means [6]. Due to limited resources available (number of available rockets/projectiles, number of available channels for engagement per Fire Unit (FU), jammer saturation, FU readiness level and engagement time, FU recovery time after engagement, etc.), the F2T2EA execution cycle is considered to operate in a strictly dynamic environment. For example, the US Air Force follows the F2T2EA kill chain for the Dynamic Targeting Process (DTP) [6]. F2T2EA DTP execution cycle is depicted in Figure 1.

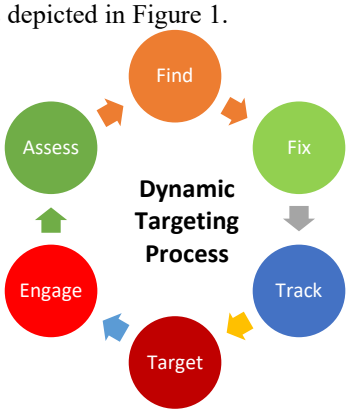

Figure 1 F2T2EA DTP Execution Cycle

Main characteristics of the F2T2EA DTP kill-chain application in SHORAD systems are the following:

- Linearity and dependency – each phase is directly dependent on results obtained from the previous phase [6];
- Time criticality – the cycle must be designed to meet requirements for dynamic target kinematics combined with short time for engagement [7];
- Iterative – direct output from the *assess* phase is taken into consideration for future FUs resource management [8].

Technically, if the *track* phase of F2T2EA fails, no target designation and engagement is possible. Also, if results of the *assess* phase are negative (e.g., target is missed), FU resources remain occupied for further engagement on the designated target. Thus, F2T2EA DTP practically provides a correct and efficient way for resource management over available FUs.

2.2. Threat Evaluation (TE)

In military operations, TE measures how dangerous an entity (aircraft, missile, drone, or other airborne vessel) is to DA at a given point in time. It converts raw tracking and sensor data into a continuous numerical threat score or a ranked priority list, updated in real time (often on every tracking data refresh). With respect to the object of TE, two base methods are known: DA-based TE and target-based TE. With respect to methodology applied, three classes of TE can be found in the literature [8],[9],[10]:

1. Analytical Methods: an approach using strict mathematical equation programming for TE execution – achieving global optimality and predictive system behaviour;
2. Heuristic & Metaheuristic Methods: an approach that skips guaranteed global optimality in exchange for calculating "fast and good enough" threat scores;
3. AI & Machine Learning Methods – an approach that focuses on handling uncertainty, incomplete radar tracking data, target deception, and non-linear intent inference.

2.3. Weapon Assignment (WA)

In SHORAD systems, Weapon Assignment (WA) – often designated as the Weapon-Target Assignment (WTA) problem – is the optimisation engine of the TEWA cycle. Its objective is to optimally allocate available defensive effectors (missiles, anti-aircraft guns, jammers, directed energy weapons) to incoming aerial threats and secure minimal DA damage, while strictly satisfying operational constraints (ammunition inventory, launcher slewing, fire channels). According to [11], WA refers to the reactive assignment of FUs to engage identified threats in a defined operational timeline, consistent with the related own force mission objectives and compliant with the Rules of Engagement (ROE) [8],[12]. The WA problem may be considered from a number of different perspectives [8],[12]. When investigating which FUs to assign, one of the following two perspectives is usually adopted:

- The single platform perspective – referring to a single platform protecting itself from threats, and the main problem is selecting the most suitable weapon system,
- The force coordination perspective – referring to a C2 platform providing TE against a predefined set of DAs, where assessment relates to the identification of the most suitable FUs to engage or counter a threat.

Furthermore, when investigating the approach by which FUs are assigned, two perspectives are prevalent [5],[8],[12]:

- The threat-by-threat perspective, which refers to the assignment of FUs sequentially, in such a way that the best FU is essentially assigned to each threat in turn (from the highest priority to the lowest priority),
- The multi-threat perspective, which refers to the assignment of FUs to the current set of threats concurrently, so that the assignment is best in some overall sense.

In terms of methodology used, major WTA method families in GBAD and SHORAD systems follow [8],[13],[14],[15]:

- Exact / Integer solvers - solving the FU allocation optimisation under fixed constraints,
- Heuristics and Greedy methods - rule-based heuristics immediately assign available FUs to the highest-ranked targets in real time, guaranteeing solution feasibility without iterative loops,
- Bi-level Pareto Evolutionary - minimises DA damage while minimising missile inventory depletion, producing a set of non-dominated Pareto-optimal trade-off solutions,
- Game-Theoretic and Multi-Agent - evaluates weapon assignment in electronic warfare environments or dynamic salvo scenarios, treating the engagement as a multi-stage game with uncertain target tracks,
- Machine learning – primarily supervised and reinforcement learning.

3. THE METHOD

3.1. Methodology selection

Due to the problem statement, the decision-making process in SHORAD and GBAD systems must reside on a methodology that is a compromise between computational complexity, the desired optimal solution, and the possibility for real-time application across multiple DAs and numerous potential threats, simultaneously. Therefore, the TE part, as an entry point, must correctly analyse potential threat behaviour with respect to a predefined set of DAs, and the WA part must provide efficient optimisation of target designation across a set of available FUs.

With respect to the short reaction time of SHORAD systems and reduced scope of targets for engagement, this paper focuses on DA-based TE, with an analytical methodology for kinematic threat analyses of potential targets. A standard DA-based analytical kinematic TE model evaluates three main dimensions [8],[11]:

1. Intent (Q: What can the target do?) – based on target type and kinematic capability for engagement;
2. Trajectory (Q: Where is it going?) – based on estimation of Closest Point of Approach (CPA) and Time to CPA;
3. DA Priority Value / Criticality (Q: What is at risk?) – not all DAs are equal, and it is mandatory to define a priority parameter for each DA.

To optimise available resources across critical/priority targets obtained by TE, while maintaining moderate computational complexity, choosing between heuristics and MCDMA is considered justified. This paper addresses applications of the heuristic “Greedy” model and MCDMA model for optimising the decision-making process. To perform a fair efficiency analysis of the obtained results, a suitable set of KPIs must be defined. Given the SHORAD and GBAD systems' operational objectives, ensuring the survivability of DA is an absolute priority. Therefore, a set of KPIs for cross-referencing and analysis can be defined as follows:

- Integral of Total Threat Exposure (ITTE) of DA over time – representing the area under the total threat score curve during Total Scenario Execution Time (TSET),
- TSET – representing the time period in which all high-intensity manoeuvring targets are neutralised/destroyed.

Using the proposed set of KPIs, maximising the survivability of DA is fairly depicted through measurable numeric indicators, which essentially represent processed outputs from the proposed TEWA system, indicating its efficiency.

3.2. TOPSIS

MCDMA remains a central theme in contemporary research due to its capacity to resolve complex challenges in various fields, so it is widely used for military purposes [2],[16]. One commonly used MCDMA method in TEWA is the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS). TOPSIS ranks alternatives based on their proximity to ideal and anti-ideal solutions [17]. Although the method accommodates both quantitative and qualitative data, its reliability can be affected by the weighting of criteria and the specific choice of reference points.

The criteria chosen for TOPSIS are listed and explained in Table 1.

Table 1 TOPSIS criteria

CRITERION	TYPE	OPERATIONAL IMPLICATION
Threat score (w_1)	Benefit	Prioritises engagement of the highest-threat targets to minimise exposure.
Time to destruction of target (w_2)	Cost	Favours pairs that minimise intercept duration.
Time to FU range (w_3)	Cost	Chooses targets that enter the range of FU faster.
Number of potential targets (w_4)	Cost	Favours FU with fewer potential targets.

3.3. Baseline algorithm

The Baseline algorithm serves as a reference point and counter-example to the advanced MCDMA model. It demonstrates the decision-making process based solely on one criterion: the distance from the target to the FU. Unlike the MCDMA approach, the Baseline algorithm uses a heuristic “Greedy” strategy and simulates a quick human reaction.

4. SIMULATION

To test the proposed algorithm, a realistic GBAD scenario is created. The scenario total duration is 120 seconds.

4.1. A realistic SHORAD scenario

The scenario intends to mimic a typical military exercise with a circular defence of a high-value DA. The scenario was created based on the work in [18]. In the scenario, there are three short-range FUs arranged in a triangle formation, as shown in Figure 2. Their maximum range of 8 km overlaps, and the DA is placed at the centre.

Five threats (T1-T5 in Figure 2), which represent high-intensity manoeuvring targets, enter the defended airspace. Threats approach from north-west, south-west, and south at initial ranges of ~9.5 km, and their trajectories consist of multi-segment waypoints with linear interpolation between nodes. Speeds range from 160 to 200 m/s, and altitudes vary from 2000 to 3400 m. Target T5 executes a sharp left U-turn above the DA to simulate a so-called toss bomb flight path attack technique. Ten additional targets (T6-T15 in Figure 2) organised into directional groups with staggered launch offsets simulate lower-priority background traffic. These targets follow linear paths toward the DA region. Three fixed flight profiles are used:

- High (altitude of 5000 m, speed of 250 m/s),
- Medium (altitude of 3500 m, speed of 120 m/s), and
- Low (altitude of 1700 m, speed of 40 m/s).

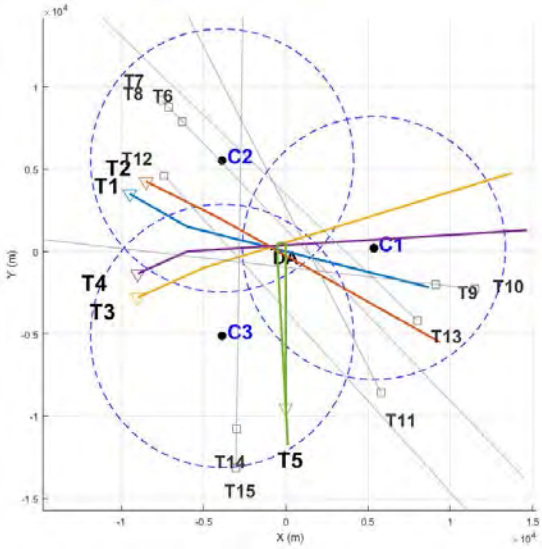

Figure 2 SHORAD/GBAD scenario

4.2. Radar data acquisition and threat score calculation

Radar data acquisition simulates a rotating air surveillance system with a fixed rotation period of 1,5 s. Additional radar parameters define the mean values and standard deviations for range, azimuth, and elevation measurements.

The threat scores quantify the immediate threat level for each detected track on a scale of 0% to 100%. The score of the represented DA is based on predefined thresholds; four threat properties are scored:

1. Direction – Smaller angular deviation yields higher scores (0°–3° with score 10, descending to score 2 for 70°–180°).
2. Speed – Prioritises fast interceptors (150–200 m/s with score 10), with reduced scores for extremely slow or hypersonic targets.
3. Distance – Closer proximity increases threat weight (0–2500 m with score 10, descending to score 4 for values greater than 5000).
4. Altitude – Lower altitudes receive higher scores (0–1500 m with score 10, descending to score 2 for values above 6000 m), aligning with the 8 km ceiling of the defence system.

As shown in Figure 3, the first five potential targets have a greater threat score.

4.3. Performance evaluation

Performance evaluation is conducted by testing and cross-referencing the results obtained using MCDMA TOPSIS model and the Baseline heuristic model. The weights of the TOPSIS algorithm are iterated from 0 to 1 (the sum of weights equals 1) to find the optimal parameters for the system in terms of the given criteria.

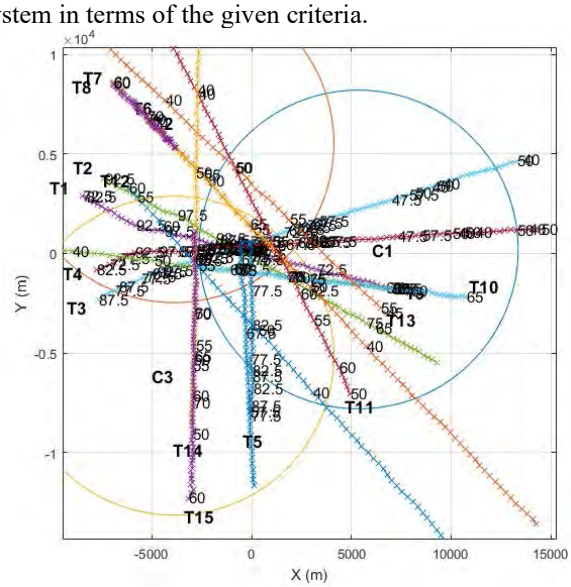

Figure 3 Tracks with calculated threat scores

The following cycle is the same for both algorithms:

1. The last update of tracks is used for simulation.
2. The engagement plan is calculated for all Track↔FU pairs.
3. The best pairs (depended of selected algorithm) are designated, and the destruction time is computed as:

$$t_e = t_c + (t_r + t_d) \times 1000 \qquad (1)$$

where:

t_e – total target engagement time
t_c – current scenario time
t_r – system reaction time
t_d – projectile-to-target flight (destruction) time

4. When the t_e time elapses, the track is destroyed, and the FU is freed for further use after its recovery time.
5. The test finishes when the condition is met - the most dangerous threats (T1-T5) have been destroyed.

The ITTE KPI for cross-referencing and performance assessment of both proposed algorithms is computed by following equation:

$$I_{te} = \int_{t_0}^{t_f} E_d(t)\, dt \qquad (2)$$

where:

I_{te} – ITTE
t_0 – scenario start time
t_f – scenario finish time
E_d – sum of threat scores of all remaining targets at moment t

Lower values indicate faster threat neutralisation and a reduced window of vulnerability.

5. RESULTS

The whole simulation is done using the Baseline algorithm first. As it considers only the distance between targets and FUs, it requires a long time to destroy high-intensity

manoeuvring targets (T1-T5).

For the TOPSIS-based MCDMA, extensive parameter sweeping is performed. Each of the four weights is varied from 0 to 1 with a step of 0.1, generating 10000 combinations. The complete simulation is executed for each combination.

Although the results for all 10000 combinations would be too extensive to present in full, three representative cases are selected and summarised in Table 2 to illustrate the impact of each criterion: one corresponding to the best performance, one to average performance, and one to the worst performance.

Based on the analysis of all simulated combinations, the following observations can be made:

1. Dominance of threat priority: Configurations emphasising calculated threat score ($w_1 \geq 0.4$) consistently yielded the lowest ITTE and fastest response times. The system successfully prioritised high-priority over low-priority targets.
2. Role of temporal criteria: A moderate weight on time to destruction ($w_2 = 0.1$) optimised kill timing without sacrificing threat prioritisation. The time-to-FU range criterion (w_3) showed negligible impact, as all targets entered engagement envelopes early in the scenario.
3. Degraded performance when threat is ignored: Configurations with $w_1 = 0$ produced the worst outcomes ($I_{te} > 31000$, $t_e \approx 69s$), confirming that distance-only or resource-balanced strategies fail under high-threat saturation.
4. Robustness and flexibility: Unlike the fixed Baseline algorithm, TOPSIS demonstrates adaptive behaviour. Suboptimal weight combinations gracefully degrade rather than fail, while optimal tuning delivers near-double the engagement speed and significantly reduced cumulative exposure.

Different combinations of weight factors, which demonstrate the impact of each factor, are given in Table 2.

Table 2 Results of different tuning

Algorithm	ITTE	TSET (s)
BASELINE	30307.5	61.5
TOPSIS (1)	21720	33
TOPSIS (2)	25627.5	42
TOPSIS (3)	31646.2	69

** TOPSIS (1) - $w_1 = 0.8$, $w_2 = 0.1$, $w_3 = 0$, $w_4 = 0.1$*
TOPSIS (2) - $w_1 = 0.3$, $w_2 = 0.2$, $w_3 = 0.2$, $w_4 = 0.3$
TOPSIS (3) - $w_1 = 0.1$, $w_2 = 0.7$, $w_3 = 0.1$, $w_4 = 0.1$

5.1. Comparative analysis

This section presents a quantitative and qualitative cross-referencing between the Baseline strategy and the proposed TOPSIS MCDMA. The analysis evaluates system performance based on the value of ITTE and TSET (in Table 3). The behaviour of each algorithm over the simulation duration is shown in Figure 4 and Figure 5.

Table 3 Comparative analysis summary

Metric	Baseline	TOPSIS (1)	Improvement
ITTE	30307.5	21720	28.33%
TSET	61.5 s	33 s	46.34 %

A review of the engagement logs reveals a fundamental difference in strategy between the two proposed models.

Baseline strategy: The Baseline algorithm engaged a total of 14 targets (T6, T9, T14, T13, T12, T3, T11, T1, T5, T10, T7, T15, T4, T2) as shown in Figure 4. While it neutralised a higher volume of targets, it required significantly more time to destroy the most critical targets, with the final engagement (T2) occurring at approximately 61.5 seconds.

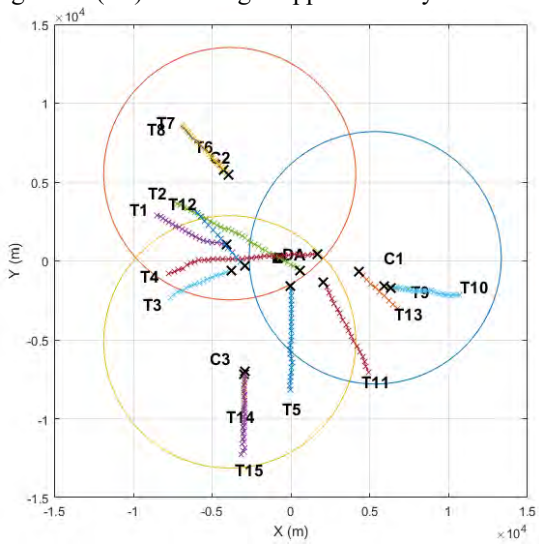

Figure 4 Baseline strategy results

TOPSIS strategy: The TOPSIS algorithm was configured to prioritise the most critical threats. It engaged a specific subset of 5 critical targets (T2, T3, T5, T4, T1) as shown in Figure 5.

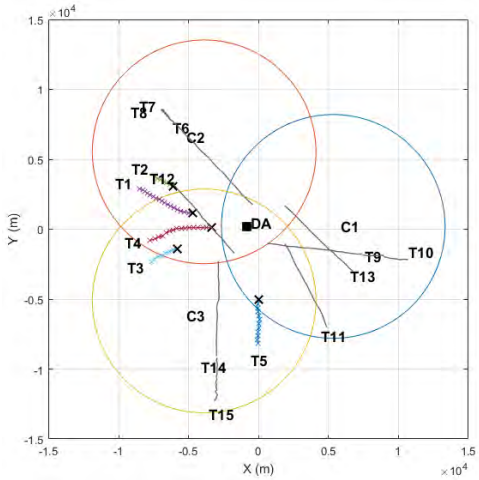

Figure 5 TOPSIS (1) strategy results

By focusing on high-priority targets first, the algorithm completed the engagement of the final critical target (T1) in approximately 33 seconds.

This demonstrates that while the Baseline approach is thorough, it is also inefficient regarding time criticality. The TOPSIS method provides a nearly 50% reduction in TSET. The second key observation illustrated in the figures is that the TOPSIS algorithm eliminates all high-priority threats at a considerable distance from the DA. In contrast, the Baseline algorithm failed to neutralise high-priority threats in time, allowing them to penetrate the DA's immediate vicinity.

Figure 6 illustrates the dynamic behaviour of the calculated threat score for both algorithms. Initially, the Baseline algorithm seems to lower the total threat score faster because it chooses the closest targets, even if they are not

the highest priority. In contrast, TOPSIS chooses the correct targets, but this process takes longer than simply destroying the nearest targets. This creates an illusion of efficiency in the Baseline algorithm, which masks a strategic failure.

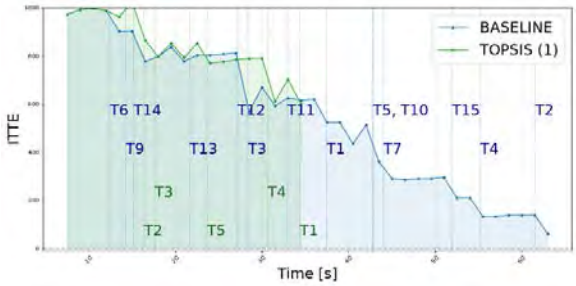

Figure 6 Threat score over time

6. CONCLUSION AND FUTURE WORK

In a modern warfare dynamic operational environment, automation of the decision-making process in GBAD and SHORAD systems is imperative. New threats such as loitering munitions, first-person view drones, and swarms provide means for the enemy to perform cheap and efficient strikes behind the first defensive line. The proposed approach enables efficient resource management of available FUs based on calculated threat score and MCDMA in a dynamic SHORAD operational environment. Results confirm the superiority of MCDMA-based TEWA against the heuristic "Greedy" strategy used to simulate quick human reaction. Considering FU constraints and ROE, as well as TOPSIS's dependency on a set of defined weighting factors for each individual criterion, further improvements toward Machine Learning and AI are possible. One possible improvement for future work is to define a large set of different scenarios and perform reinforcement learning based on finding an optimal set of weighting factors for MCDMA-based TEWA.

Abstract: *We present a software-defined radar digital back-end (DBE) applicable in fully coherent radars with a power amplifier (PA) transmitter. DBE includes a digital exciter (DEX), receiver digital front-end (DFE), and radar signal processor (RSP). DEX performs direct digital synthesis of the transmit waveform and the local oscillator signal, along with synchronization signals. DFE accepts the intermediate-frequency signal and performs digital down-conversion, filtering, and decimation. Pulse compression, Doppler filtering, and constant false alarm rate detection are performed in the RSP. We use a commercial off-the-shelf, high-performance embedded computing platform to implement the DBE, with DEX and DFE implemented on a field-programmable gate array, and RSP implemented on a general-purpose processor. To test the DBE, we connect it with an existing PA-based analog front-end (AFE), antenna sub-system, and radar data processor. Field tests show that DBE enables the function of a fully coherent pulsed air-surveillance radar, capable of continuously tracking a multitude of aircraft, on both short and long distances, while successfully mitigating both clutter and noise interference. Although the field tests are performed only with very high frequency (VHF) band radar hardware, if connected with an appropriate AFE, DBE could be used in radars operating at higher frequencies.*

Keywords: *radar, receiver, signal processing, software defined, waveform synthesis.*

1. INTRODUCTION

Software-defined radar (SDR), with exciter, receiver, and signal processor realized digitally on reconfigurable hardware, is an established design approach with numerous implementations on commercial off-the-shelf (COTS) hardware [1]. This paper concerns the digital back-end (DBE) of such a radar, comprising: (1) a digital exciter (DEX) for direct digital synthesis (DDS) of the transmit waveform, local-oscillator (LO) signal, and trigger signals; (2) a receiver digital front-end (DFE) that digitizes the intermediate frequency (IF) echo and performs digital down-conversion (DDC), filtering, and decimation; and (3) a radar signal processor (RSP) for pulse compression (PC), Doppler filtering (DF), and detection. In a complete radar, the DBE operates with an

DOI: 10.5937/OTEH26082J

analog front-end (AFE) encompassing a power amplifier (PA) transmitter, and a radar data processor (RDP) for plot extraction and tracking.

Radars of this class transmit through a solid-state PA, whose modest peak power (commercial units reach the order of kilowatts [2]) is compensated by long pulses with intrapulse modulation and PC [3], [4]. Practical operation requires interleaving short and long pulses, transmitting at several pulse repetition frequencies (PRF), and suppressing clutter by moving target indication (MTI) or moving target detector (MTD) processing [3].

Reported SDR systems largely fall into two categories. General-purpose frameworks like GNU Radio with USRP-class hardware are used to build experimental processing chains, but operate at low power and short range, e.g., detecting a 0.1 m² drone out to about 150 m [5]. At the other end, dedicated DBEs implementing the full pulse-Doppler chain (DDC, PC, MTD, and constant-false-alarm-rate (CFAR) detection) have been realized on custom field-programmable gate array (FPGA) boards for specific radars [6]. The DBE described here occupies a different point in the SDR space: it is built on a COTS high-performance embedded computing (HPEC) platform, partitioning the DEX and DFE onto an FPGA and the RSP onto a general-purpose processor (GPP), aiming at applicability in fully coherent PA-based radars.

The contributions of this paper are the following: (1) an integrated, COTS-based radar DBE that combines the DEX, DFE, and RSP; (2) a hardware/software partitioning that maps the DEX and DFE functions onto an FPGA and the RSP onto a GPP; (3) support for complex waveforms, including interleaved short and long pulses and multiple PRFs, together with MTI or MTD clutter suppression; (4) a demonstration that the DBE, combined with a PA-based AFE and an antenna, constitutes a functioning fully coherent very high frequency (VHF) air-surveillance radar, validated in the field against live air traffic, with applicability to higher frequency bands given a suitable AFE.

2. REQUIREMENTS AND CONSTRAINTS

The operating concept from Section 1 imposes the following requirements on the DBE:

- it shall provide fully coherent operation;
- it shall operate in real time;
- the transmit waveform shall support configurable intrapulse modulation;
- it shall support interleaving of two pulses, short and long, the short pulse restoring the short-range coverage lost to eclipsing during the long pulse [3];
- the carrier frequency, the pulse duration, and the pulse repetition interval (PRI) shall be configurable;
- it shall support pulse-to-pulse carrier-frequency and PRI agility;
- it shall mitigate clutter and noise interference, with multiple-PRF operation used to circumvent the effects of the blind Doppler intervals introduced by clutter suppression [3].

3. SYSTEM ARCHITECTURE

The DBE comprises three logically distinct subsystems: DEX, DFE, and RSP. The DEX and DFE execute as deterministic hardware pipelines on the FPGA, while the RSP runs as software on the GPP. Both processing domains are hosted on a single COTS HPEC platform, which provides the shared backplane, deterministic synchronization, and high-bandwidth data transport.

The block diagram of DBE is shown in Figure 1. The transmit signal flows from the DEX through a digital-to-analog (D/A) converter to the AFE for power amplification. The DEX generates triggers that coordinate the AFE transmit/receive switch and signal the start of reception. Echo returns are collected by the antenna sub-system, amplified and down-converted by the AFE to the analog IF (AIF), and presented to the DFE for digitization. The DFE extracts the complex envelope and applies decimation. The decimated complex envelope samples are organized into frames, together with the azimuth value at the moment of the originating pulse transmission and pulse metadata. Frames are transferred from the FPGA to GPP memory via direct memory access (DMA) and delivered to the RSP through a callback interface. After processing, the RSP produces a real-valued radar video signal, framed with azimuth, and passes it to an external RDP for downstream plot extraction and tracking [3, Fig. 1.2].

The DBE's COTS HPEC platform is based on the NI FlexRIO system. It comprises a transceiver module providing analog-to-digital (A/D) and D/A conversion, an FPGA module, a real-time controller based on a GPP, and a shared chassis. FlexRIO modules have been employed in radar applications before [7].

The partitioning of the DBE follows the principle: sample-synchronous processing on the FPGA, frame-based processing on the GPP. The DEX and DFE form streaming, sample-synchronous pipelines with strict latency bounds. The RSP's algorithms are compute-intensive but tolerate the latency of frame assembly, and benefit from the numerical precision and vectorization capabilities of a modern GPP, the flexibility of software reconfiguration and the easier integration with RDP.

4. SUBSYSTEM DESIGN

4.1. Digital Exciter (DEX)

The DEX is built on the DDS principle [4, Ch. 6]. Its block diagram is shown in Figure 2. The transmit waveform is defined as a pre-computed complex envelope of a pulse, stored in FPGA memory. The pulse duration and all intrapulse modulation parameters of the waveform are set from the configuration transferred from the GPP. The complex envelope is up-sampled by an interpolation chain comprising a multiplierless cascaded integrator-comb (CIC) filter, followed by a finite impulse response (FIR) filter that compensates the CIC amplitude response and provides precise anti-imaging filtering [8]. Then, the complex envelope is translated to the digital IF (DIF) by complex multiplication with a complex sinusoid from a

numerically controlled oscillator (NCO). The DIF is configurable, allowing the carrier frequency to be adjusted. The digital complex pulse at the DIF is interpolated to the output sampling rate by a digital interpolator inside the D/A converter on-board the transceiver module. The D/A converter then applies a digital complex modulator to up-convert the signal from the DIF to the carrier frequency. The I component of the resulting signal is D/A-converted, and the output is cleaned by on-board and external analog low-pass filters.

The LO signal is synthesized independently as a complex sinusoid at a fixed DIF value by a separate NCO on the FPGA. The output is interpolated, up-converted, and D/A-converted through a separate D/A channel on the transceiver module, producing the analog sinusoid that drives the AFE's analog down-conversion mixer. Both the waveform DIF mixer and the LO NCO operate within the same FPGA clock domain. The per-pulse phase reset of both NCOs ensures that each transmitted pulse has a well-defined, repeatable phase relationship with the LO, which is required for coherent reception and DF.

The trigger pulses that mark the instant of each pulse transmission are output from the FPGA through the transceiver's digital I/O lines. Triggers are derived from the same FPGA clock that drives waveform synthesis. Trigger timing and DIF are configurable per-pulse from a preset sequence transferred from the GPP.

4.2. Receiver Digital Front-End (DFE)

The DFE (Figure 3) comprises three stages: (1) A/D conversion of the AIF echo signal; (2) DDC from the AIF to the complex baseband; and (3) a filtering and decimation chain that reduces the sampling rate while providing spectral selectivity. The A/D conversion is performed on the transceiver module, while the DDC and decimation execute on the FPGA.

The AIF signal is digitized by the A/D converter of the transceiver module. Collection of the converted samples is synchronized with the trigger routed from the DEX.

The complex envelope of the digitized real-valued AIF signal is extracted by complex mixing with a digital complex sinusoid [8]. The sinusoid is generated by an NCO set to the AIF, with its initial phase reset on each trigger edge (essential for coherence across pulses).

The complex envelope is decimated using a cascaded pair of FIR decimators, each performing low-pass filtering followed by down-sampling by an integer factor [8].

Assembled complex envelope frames are written to a first-in-first-out buffer on the FPGA, from which they are read by the GPP via DMA and delivered to the RSP.

4.3. Radar Signal Processor (RSP)

The RSP processing chain (Figure 4) comprises five stages: (1) PC; (2) DF; (3) envelope detection; (4) CFAR detection; and (5) frame combining. These stages are applied sequentially, with the DF stage being the only point of branching between MTI and MTD modes.

PC resolves targets in range by matched filtering the received echo against the transmitted pulse template. It is implemented via multiplication in the discrete Fourier transform (DFT) domain [3]. A Taylor window is applied to the matched-filter coefficients for sidelobe control.

To suppress clutter, DF is performed along the slow-time axis (across successive pulses at each range gate), with two modes available. The first mode is MTI [3], implemented as a FIR filter, with configurable order, applied only within a configurable range window.

As an alternative, MTD processor [3], [9] is available. It transforms a coherent processing interval (CPI)-length sequence of complex input frames into a Doppler-resolved output via two parallel channels. The zero-velocity channel retains near-DC returns: a low-pass integrator accumulates energy across the CPI, followed by magnitude computation and an adaptive range-azimuth clutter map update via exponential averaging. The clutter map based detector compares the magnitudes against the learned clutter levels to produce a detection mask for the zero-Doppler bin. The non-zero Doppler channels begin with a high-pass FIR filter. A Taylor-windowed DFT bank then resolves returns across Doppler frequency for all range gates simultaneously. After magnitude computation per Doppler channel, a sliding-window cell-averaging CFAR (CA-CFAR) [3] detector is applied in the range domain. The outputs of all channels pass through a pulse-width discriminator and a primitive observation extractor, followed by binary M-of-N integration across successive CPIs. The video synthesizer constructs complex output frames from the observations, making MTD a drop-in replacement for MTI.

After DF, envelope detection converts the complex-valued signal to a real-valued magnitude.

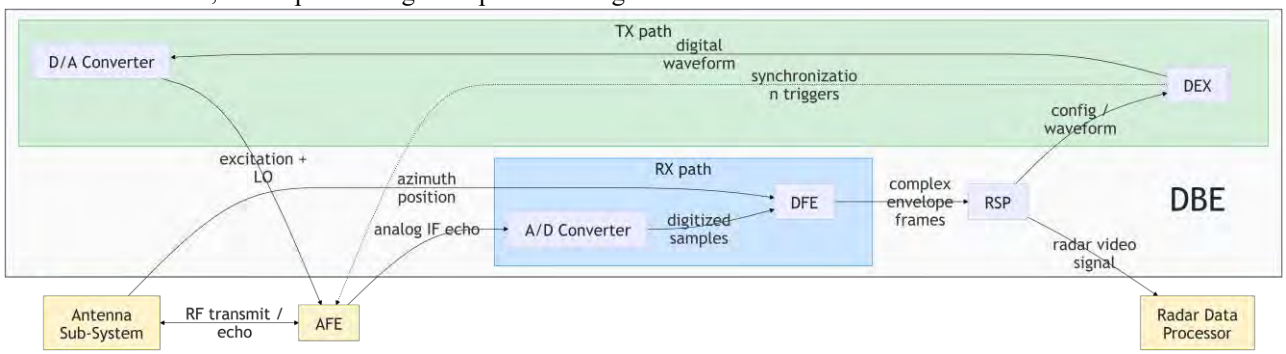

Figure 1. Top-level block diagram: antenna sub-system — AFE — DBE (DEX / DFE / RSP) — RDP.

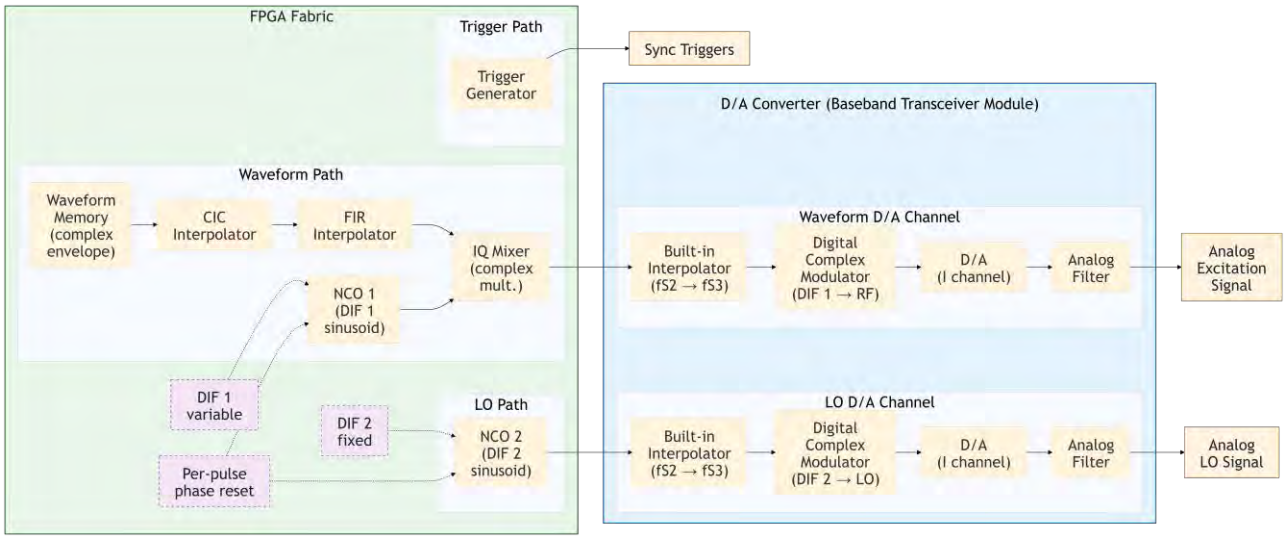

Figure 2. Block diagram of the digital exciter (DEX).

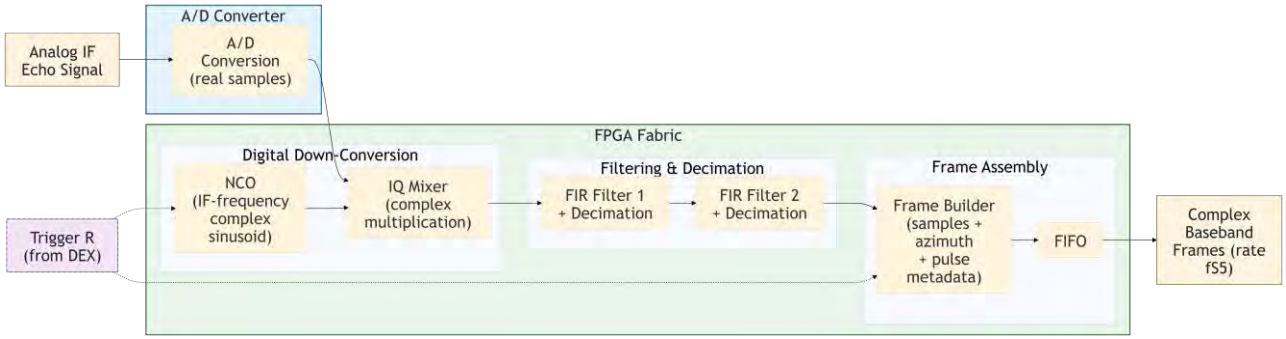

Figure 3. Signal chain of the receiver digital front-end (DFE).

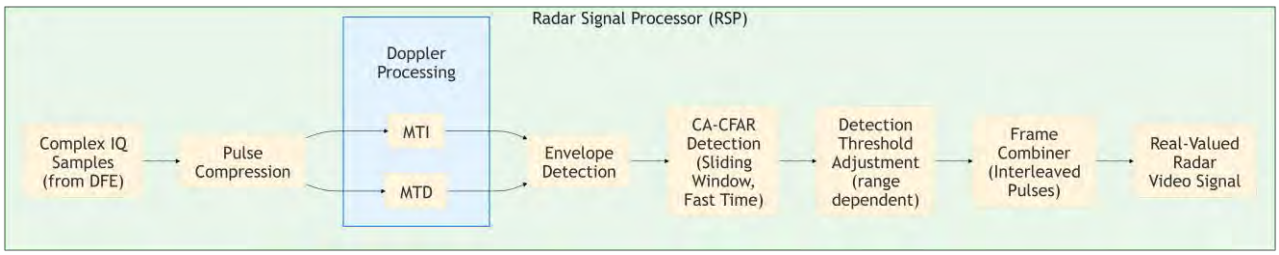

Figure 4. Radar signal processor (RSP) processing chain.

The CFAR detector computes an adaptive threshold from the local noise-plus-clutter environment using a sliding window along the fast-time (range) axis. When the MTI path is active, the detector uses CA-CFAR, with configurable window width, guard-cell count, CFAR constant, and bias. When the MTD path is active, the outer detection stage is bypassed, since the MTD already performs CFAR detection. An optional detection threshold adjustment provides range-dependent scaling of the threshold.

The frame combiner is active only in the interleaved short-and-long-pulse mode. It concatenates the near-range samples from the short-pulse output and the far-range samples from the long-pulse output. The final output is a real-valued radar video signal, accompanied by the azimuth value at transmission time.

5. FIELD TEST AND RESULTS

The DBE was integrated with an existing PA-based AFE, a rotating antenna subsystem designed for VHF-band operation, and a RDP running on a GPP. The RDP comprises a plot extractor [10], a tracker [11], and a radar display application that visualizes radar video, tracks, and annotation overlays [12].

Evaluation was carried out using two complementary operational modes. In live field mode, the DBE was connected directly to the AFE and antenna, with echo signals from real airborne targets digitized and processed in real time. The complex envelope data entering the RSP was recorded digitally by the RSP. In replay mode, recorded data is injected into the same data entry path used by live hardware, ensuring the same input signal and processing pipeline as in the live field mode.

From the available field recordings, four situational windows were selected for evaluation. These “scenarios” were opportunistic observations captured from live air traffic during the recording sessions. After preliminary analysis, stationary clutter fields were mapped by correlating radar returns with terrain data. To prevent the

formation of tracks on dense clutter returns, a circular forbidden track-initiation zone was configured around the radar site. The four scenarios are described below.

The objective of scenario 1 was to demonstrate sustained tracking of a large number of simultaneous airborne targets. Figure 5 shows the result. Continuous tracks are maintained across the surveillance volume, confirming that the DBE's processing pipeline supports simultaneous tracking of multiple targets under realistic clutter conditions. The result demonstrates that the DBE, when combined with the antenna sub-system, the AFE and the RDP, satisfies the requirement for air-surveillance operation over a wide coverage area.

Scenario 2 compared MTI and MTD processing in the context of tracking far-range targets. The recorded signal was re-processed with two different configurations: MTI and MTD, both evaluated against the same set of targets. Figure 6 presents the two processing variants side by side. In both MTI (top) and MTD (bottom) configurations, the far-range target at ~245 km is tracked successfully. Both processing variants are capable of tracking targets at long range on this dataset, demonstrating operational flexibility in the choice of DF strategy.

The 3rd scenario evaluated tracking performance at short range, where the eclipsing caused by long-pulse transmission can leave a blind zone if not compensated. As shown in Figure 7, targets at 9 km (blue) and 15 km (yellow) are tracked consistently. Critically, the interleaved short pulse restores coverage in the near-range zone that would otherwise be eclipsed [13].

The 4th scenario quantified the impact of DF on track quality when targets traverse a clutter field originating from a known mountain. The tracks of three targets passing through the clutter field were evaluated under three processing configurations: no DF, MTI, and MTD (Figure 8). In the left panel (no DF), strong clutter returns generate numerous false detections. Multiple spurious tracks appear in the clutter field, and the legitimate track histories for two of the three targets are corrupted by clutter-induced detections. In the center panel (MTI), the stationary clutter is suppressed, and the target tracks are clean and continuous. In the right panel (MTD), the target tracks are similarly clean and continuous. The before-and-after comparison shows that both MTI and MTD achieve an adequate level of clutter suppression on this dataset.

6. CONCLUSION

This paper presented a SDR DBE that integrates a DEX, a DFE, and a RSP on a COTS HPEC platform. The DEX and DFE were mapped to a FPGA as deterministic, sample-synchronous hardware pipelines, while the RSP runs as software on a GPP. This FPGA/GPP partitioning exploits the complementary strengths of each domain.

The DEX employs DDS with CIC + FIR interpolation and per-pulse NCO phase reset to guarantee full coherence across the pulse train. The DFE performs DDC and two-stage FIR decimation. The RSP chains frequency-domain PC, DF (either MTI or MTD), envelope detection, and CFAR detection into a single configurable pipeline.

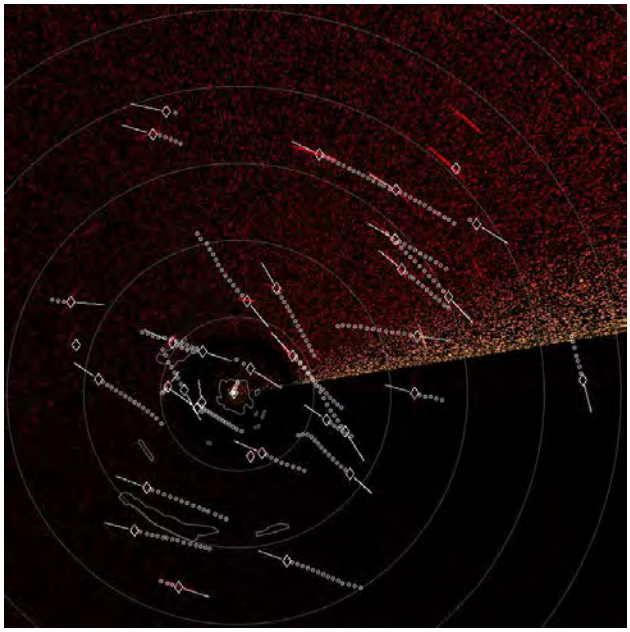

Figure 5. Multi-target tracking. Radar video (red), tracks (white), clutter fields (gray polygons).

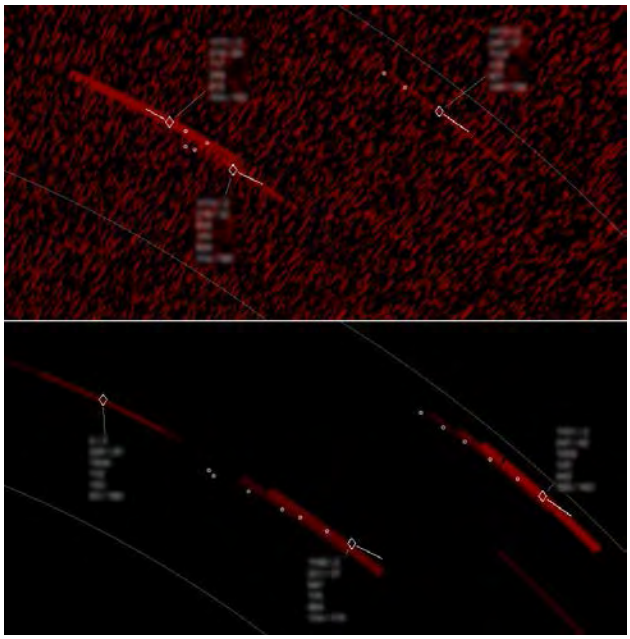

Figure 6. Far-range tracking — MTI (top) versus MTD (bottom). Radar video (red), tracks (white).

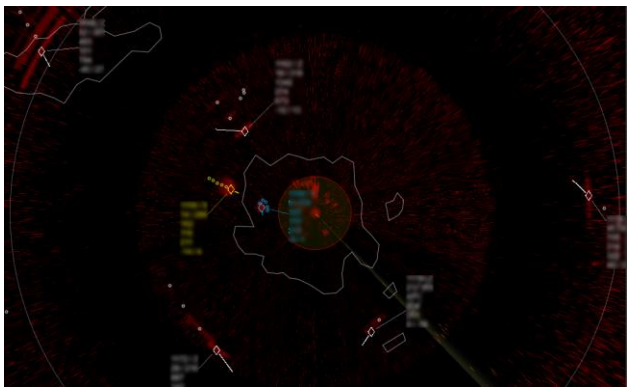

Figure 7. Near-range tracking. Radar video (red), tracks (color-coded), clutter fields (gray polygons).

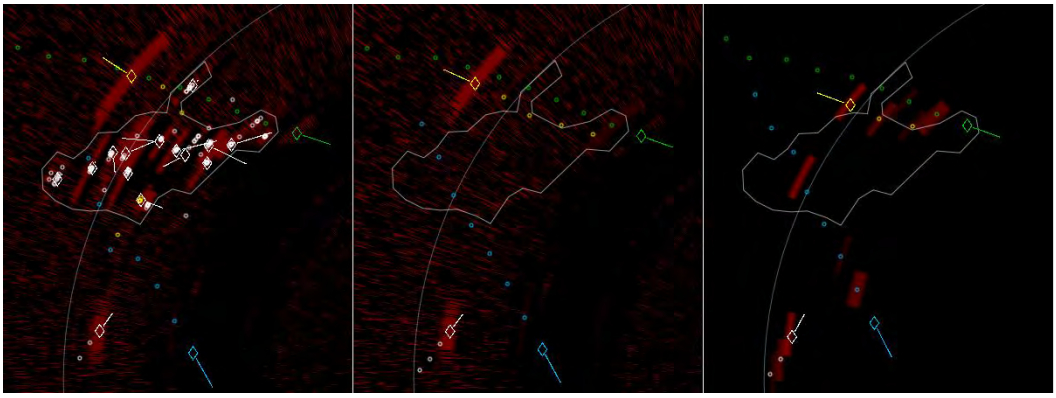

Figure 8. Clutter-field tracking — Doppler filtering disabled (left), MTI (center), MTD (right). Radar video (red), tracks (color-coded), clutter field (gray polygon).

The DBE supports complex waveforms including interleaved short and long pulses, and pulse-to-pulse carrier-frequency and PRI agility.

Field tests against live air traffic, carried out with the DBE integrated into a proof-of-concept PA-based VHF air-surveillance radar, demonstrated continuous tracking of multiple simultaneous airborne targets across the wide area, including far-range target at ~245 km and near-range target at ~9 km. Both MTI and MTD processors were shown to provide effective clutter mitigation.

Although validated with VHF-band hardware, the DBE's signal-processing architecture is frequency-agnostic. Given an appropriate AFE and antenna sub-system, the same DEX, DFE, and RSP pipeline can be applied to radars operating at higher frequency bands, consistent with the system's software-defined design philosophy.

Future work could include deploying the DBE in higher frequency bands to validate its scalability, extending the RSP with additional CFAR and Doppler-processing algorithms, and extending the RSP's interface to RDP.

Abstract: *Emerging TEMPEST threats are gaining relevance due to increasing availablity of open platforms and publicly software that facilitate electromagnetic (EM) side-channel experimentation. Most commercial off-the-shelf and industrial-grade devices, as potential targets, do not address these vulnerabilities, while awareness of associated risks remains limited. Conversely, procurement of TEMPEST resistant devices, structures and facilities often requires heavy budget strains. Preventive EM measurements of protected entities are therefore essential for assesing exposure and identifying vulnerabilities. However, such measurements can be costly and resource-intensive, and unlike electromagnetic compatibility testing, where pre-compliance frameworks exist to reduce risk and cost, TEMPEST evaluation currently lacks formal intermediate assesment stages. As a result, organizations face significant uncertainty and potential expense if measurement processes are not properly structured. This paper proposes a hybrid methodology that integrates engineering-level pre-compliance EMSEC measurements with physical security measures, including shielding effectiveness (SE) assesment and EM security zoning. The approach leverages publicly available ITU-T Recommendations K.81, K.84, and K.87 to provide a systematic, repeatable and extensible framework for early-stage risk assesment and mitigation. By combining measurement-driven evaluation with spatially structured protective measures, the methodology bridges the gap between open-standard practices and classified TEMPEST requirements.*

Keywords: *side-channels, EMSEC, TEMPEST, zoning, shielding, profiling.*

1. INTRODUCTION

In an era where spectrum dominance dictates cross-domain security, mitigating data leakage via compromising electromagnetic emanations (CE) has become a critical priority at the convergence of cyber and physical warfare, Figure 1. Traditionally, exploiting such vulnerabilities required highly specialized equipment and expertise, limiting practical attacks to well-funded state actors or advanced laboratories. However, the threat landscape is rapidly evolving due to the increasing availability of open platforms and publicly accessible software tools that facilitate EM side-channel experimentation [1]. Recent comprehensive research surveys on EM information leakage [2] is followed by an on-line available tool to conduct some tests. Beyond phreaking video signals from monitors, recently published report describes similar leakage from cameras as well, including free tools for signal reconstruction [3]. Other give more general degrees of freedom creating more specific reconstruction templates [4]. Other closed-tool publications report on succsessfull recovering of other classes of emanations such as from touchscreens, smartphones [5], serial cables and broad list of other physical asserts. Furthermore, novel class of available threats is usage of sending informations over unintended emissions from electronic devices with activity of simple unprivileged code [6], showing increased risk that CE carry. However, in order to procure TEMPEST resistant devices, structures and facilities, expose high costs if not structured properly. Finally, to challenge the common assumption that compromising emanations are confined to short-range effects, recent studies on so-called *"screaming channels"* have demonstrated that sensitive information can couple onto RF carriers and propagate over significantly longer distances [7].

In this context, the paper proposes a hybrid EMSEC pre-compliance framework derived from publicly available ITU-T recommendations and extended through analytical propagation and probabilistic compromise models.

The proposed approach combines intrusion-zone-oriented assessment, shielding evaluation, and receiver-oriented measurement interpretation to support systematic early-stage EMSEC evaluation. The objective of proposed framework is not to replace formal TEMPEST evaluation, but to provide a structured engineering methodology for preliminary EMSEC assestment and mitigation planning.

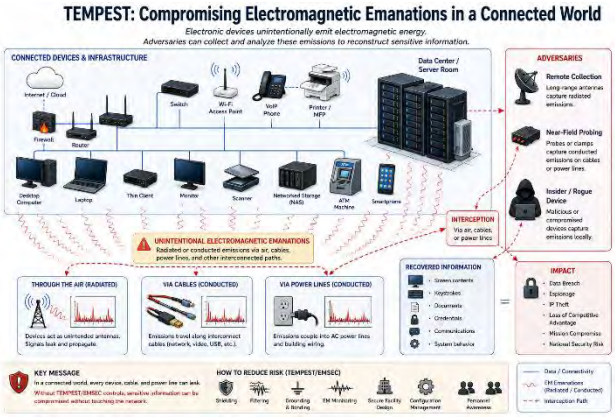

Figure 1. Overall description of CE threats

The paper contributions are:

- Interpretation of ITU-T K.84 through a propagation-oriented EMSEC threat model.
- Introduction of an engineering-level EMSEC pre-compliance workflow inspired by EMC pre-compliance practices.
- Development of a probabilistic compromise model linking emanation level, shielding, propagation distance and receiver capability.
- Extension of intrusion zones from geometric boundaries into probability-based exposure regions.
- Demonstration of measurement-driven mitigation optimization through illustrative examples.

2. EMSEC THREAT MODEL

2.1. Compromising Emanation Threat Landscape

Electromagnetic security assessment defined in ITU-T K.84 is fundamentally based on the relationship between the spatial intrusion threat model and the measurable compromising emanations generated by information processing equipment, Figure 2. Unlike conventional EMC testing, the purpose of EMSEC measurements is not regulatory compliance but evaluation of information reconstruction feasibility at different intrusion zones. The recommendation implicitly defines a spatially dependent threat model where the electromagnetic field strength at the attacker location depends on the original emanation level, equipment countermeasures, building shielding, propagation distance and receiver sensitivity.

Consequently, the measurement methodology must be adapted to the assumed intrusion zone and attacker capabilities.

The measurement methodology is directly linked to the assumed intrusion zone, table 1. Lower intrusion zones correspond to shorter attacker distances and therefore require evaluation of higher received field strengths and wider receiver capabilities.

Conversely, higher intrusion zones are dominated by propagation attenuation and shielding effects, making narrow-band spectral detection more suitable for evaluating residual leakage components.

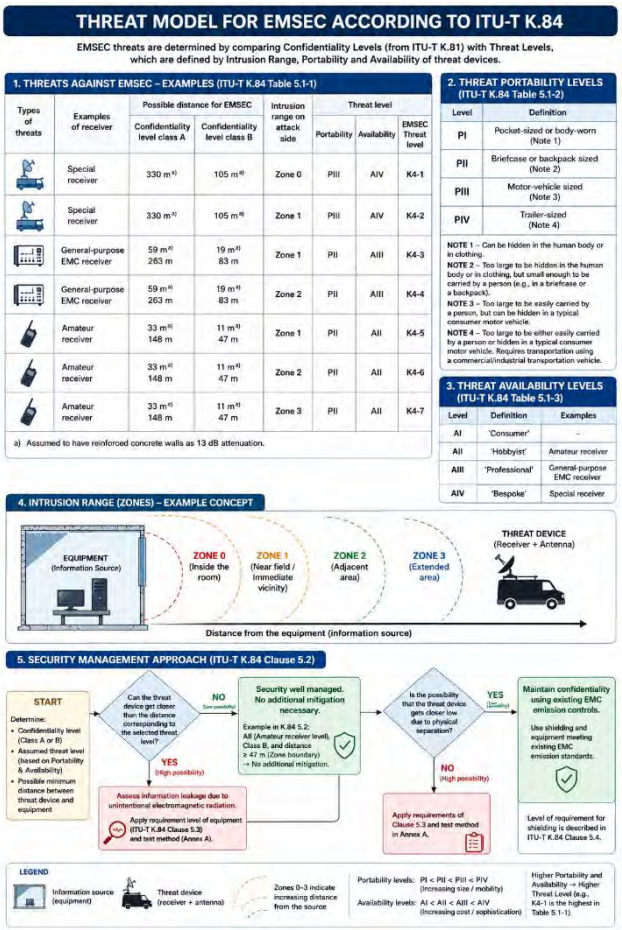

Figure 2. Modeling threats acording to ITU-T K.84

ITU-T K.84 implicitly separates EMSEC evaluation into two complementary dimensions:

1. Spatial threat evaluation through intrusion zones and propagation attenuation;
2. Spectral leakage evaluation through wideband and narrow-band measurement techniques.

Table 1. Intrusion EMSEC zones

Intrusion Zone	Dominant threat	Preferred measurement meth.	Objective
Zone 0	Direct reconstruction	*Wideband*	*Image reconstruction capability*
Zone 1	Adjacent room leakage	*Wideband + Narrowband*	*Reconstruction + spectral analysis*
Zone 2	Boundary leakage	*Narrowband*	*Leakage frequency identification*
Zone 3	Extended perimeter	*Narrowband*	*Residual spectral detectability*

The combination of these approaches forms a practical framework for estimating the feasibility of electromagnetic information compromise under realistic operational conditions.

Recommendation identifies several possible mechanisms for compromising electromagnetic emanation acquisition, including free-space radiated interception using antennas, conductive coupling through metallic structures and

leakage acquisition through power-supply lines.

2.2 Wideband and Narrow-Band EMSEC Measurements

ITU-T K.84 practically introduces two different measurement paradigms, table 2.

Table 2. EMSEC measurement approaches

Method	Purpose	Security interpretation
Wideband	Reconstruction capability	*Can attacker reconstruct information?*
Narrowband	Spectral leakage detection	*Which frequencies carry compromising information?*

The wideband method attempts to emulate the operational conditions of a realistic compromising emanation receiver capable of reconstructing video information. The measurement process approximates the operational capability of advanced EMSEC threat receivers described in higher threat classes. The wideband method preserves the energy distribution of compromising emanations over a broad frequency interval, enabling estimation of reconstructed information quality rather than isolated spectral components.

The narrow-band method focuses on identification of discrete spectral components correlated with assumed information patterns. Frequencies exhibiting significant amplitude differences between static and time-varying patterns are identified as potential compromising emanation carriers. Consequently, the narrow-band method represents a frequency-domain leakage localization technique rather than a direct reconstruction method.

The minimum electromagnetic field level [dBμV/m], necessary for successful information reconstruction is expressed as:

$$E_{min} = V_{min} + SN + A_f \quad (1)$$

where: V_{min} [dBμV] denotes minimum detectable receiver voltage, SN [dB] denotes the signal-to-noise ratio required for reconstruction, and $A_f[dB]$ denotes the antenna factor. This formulation directly links electromagnetic propagation to information reconstruction feasibility. Consequently, successful EMSEC interception requires careful optimization between receiver bandwidth, amplifier gain, noise figure and spectral filtering.

The recommendation categorizes interception receivers into three operational classes: amateur receivers, professional EMC receivers and specialized EMSEC receivers. These categories correspond to progressively improved sensitivity, signal processing capability, bandwidth and reconstruction performance. The interception problem may therefore be interpreted as a competition between propagation attenuation, shielding attenuation and receiver sensitivity enhancement. This interpretation directly motivates the use of probabilistic compromise models, described later in section 4.2.

3. EMSEC PRE-COMPLIANCE FRAMEWORK

3.1 Cost-Effective Measurement-Driven EMSEC Assessment

EMSEC protection mechanisms such as facility shielding, filtered infrastructure, protected zoning, and TEMPEST-certified equipment may introduce substantial financial and operational costs if implemented without prior leakage characterization. Unlike conventional EMC mitigation, where compliance limits are standardized and well understood, EMSEC protection depends strongly on equipment-specific compromising emanation profiles, installation geometry, building materials, cable routing and attacker positioning relative to the protected asset. Consequently, the effectiveness of countermeasures cannot be reliably estimated without measurement-driven assessment.

In practical environments, compromising emanations are rarely uniformly distributed across the spectrum or spatial environment. Certain frequency bands may exhibit significantly elevated leakage levels due to internal clock harmonics, display synchronization frequencies, cable resonances, power conversion stages or unintended antenna structures formed by connected conductors.
Similarly, electromagnetic leakage paths are highly dependent on physical installation conditions. Openings, windows, ventilation structures, cable penetrations, and conductive building elements may create localized reductions in shielding effectiveness (SE), enabling disproportionate propagation toward specific intrusion zones.

As a result, implementation of generalized shielding measures without prior measurements may produce excessive shielding costs, unnecessary infrastructure modifications, overestimation of threat exposure, or insufficient protection against dominant leakage mechanisms.

The measurement methodology defined in ITU-T K.84 therefore serves not only as a security evaluation procedure, but also as an engineering optimization mechanism for determining dominant leakage frequencies, effective propagation directions, critical intrusion zones and required attenuation margins. Wideband measurements enable estimation of practical information reconstruction feasibility, while narrow-band measurements identify dominant spectral leakage components. Their combined application supports prioritization of mitigation measures according to measurable compromise potential rather than purely theoretical assumptions.

3.2 Facility-Oriented Workflow

The proposed analytical propagation framework further extends this concept by enabling preliminary estimation of compromise distance, shielding requirements and intrusion-zone exposure before deployment of expensive TEMPEST-oriented infrastructure modifications.
The conceptual facility-oriented assessment shown in Figure 3 illustrates how EMSEC pre-compliance

evaluation may be integrated into realistic operational environments. Instead of treating compromising emanations as purely device-level phenomena, the proposed approach considers the combined influence of equipment leakage characteristics, building geometry, SE, intrusion-zone proximity and propagation-oriented measurement positioning.

Wideband and narrow-band measurements are strategically positioned according to expected attacker locations and dominant propagation paths. The resulting measurements are then incorporated into the proposed analytical propagation framework to estimate residual compromise probability across the protected facility. This interpretation enables targeted deployment of shielding and filtering countermeasures only where measurements indicate elevated compromise potential, thereby reducing unnecessary infrastructure hardening and minimizing over-engineering costs.

3.3 Proposed Pre-Compliance Methodology

The proposed framework may be interpreted as a staged EMSEC pre-compliance methodology intended to reduce uncertainty prior to expensive TEMPEST-oriented mitigation deployment.

Unlike conventional TEMPEST evaluation procedures, which are typically performed only after infrastructure deployment or during formal certification stages, the proposed methodology introduces intermediate engineering-level assessment phases derived from publicly available ITU-T recommendations.

The workflow consists of five sequential stages:

1. **Initial Threat Profiling**. Identification of critical assets, expected attacker capabilities, operational frequencies, and applicable intrusion zones according to ITU-T K.84.
2. **Preliminary Spectral Leakage Assessment.** Narrow-band measurements are performed to identify dominant compromising frequencies, harmonics, cable resonances, and propagation-sensitive spectral regions.
3. **Reconstruction-Oriented Evaluation.** Wideband measurements are performed for selected high-risk frequencies and operational modes to evaluate practical information reconstruction feasibility.
4. **Spatial Propagation and Intrusion-Zone Analysis.** Measured emanation levels are incorporated into the proposed propagation model to estimate compromise probability across intrusion zones while considering shielding attenuation, building geometry, and receiver sensitivity.
5. **Targeted Mitigation Optimization.** Shielding reinforcement, zoning adaptation, filtering deployment, and equipment hardening are prioritized according to the measured compromise contribution of individual leakage paths.

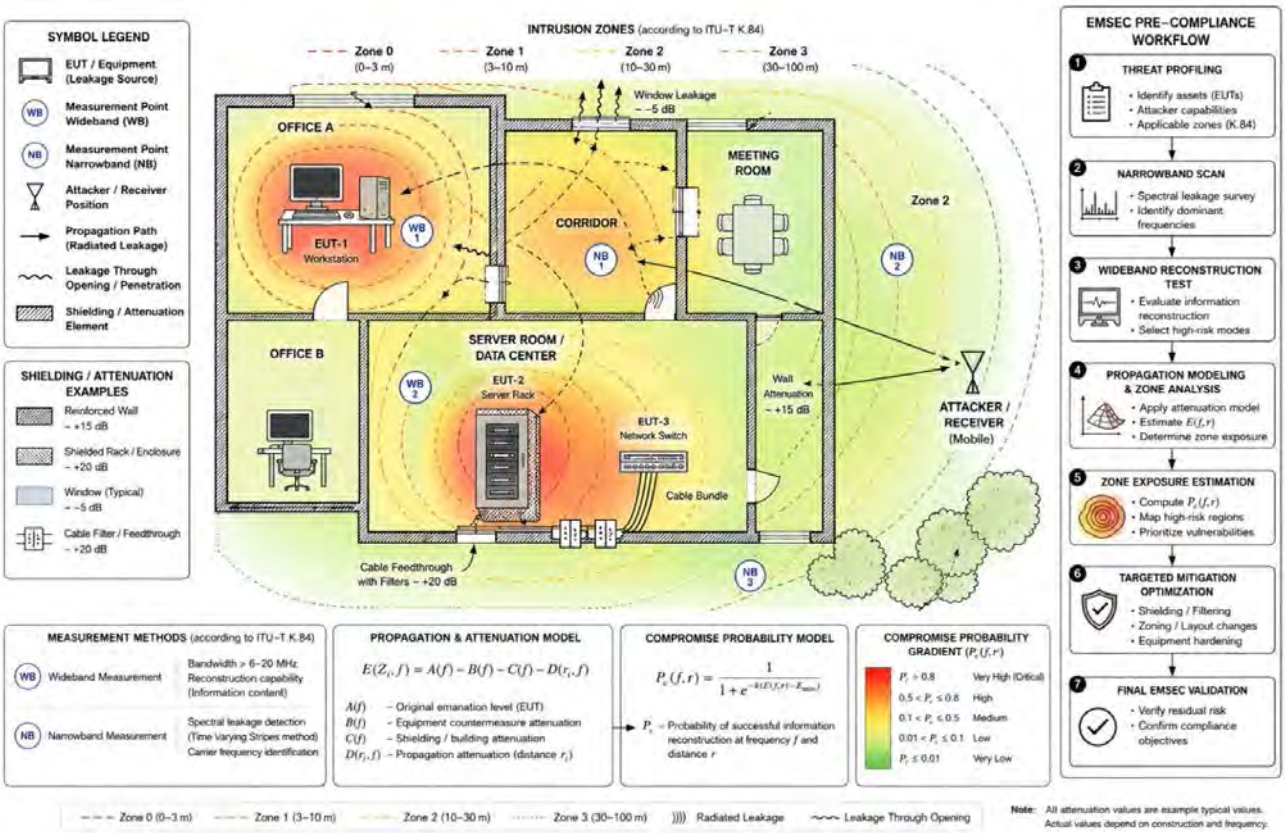

Figure 3. Example facility-oriented EMSEC pre-compliance assessment workflow integrating intrusion-zone analysis, propagation-oriented leakage measurements, shielding evaluation, and targeted mitigation optimization derived from ITU-T K.84 and related recommendations.

The proposed staged approach enables iterative EMSEC hardening where mitigation measures are guided by measurable compromise potential rather than worst-case assumptions alone. Consequently, the methodology supports cost-effective deployment of EMSEC protections while preserving compatibility with formal TEMPEST-oriented evaluation procedures.

4. ANALYTICAL PROPAGATION AND COMPROMISE MODEL

The intrusion zones defined in ITU-T K.84 directly determine the required measurement configuration. As the intrusion distance increases from Zone 0 toward Zone 3, the received field strength decreases due to propagation attenuation and shielding effects.

4.1 Spatial propagation model

For each intrusion zone Z_i, the measurable threat level can be expressed as:

$$E(Z_i, f) = A(f) - B(f) - C(f) - D(r_i, f) \quad (2)$$

where: $E(Z_i, f)$ is the received electric field strength at intrusion zone Z_i and frequency f, $A(f)$ denotes the original compromising emanation spectrum generated by the EUT, $B(f)$ denotes equipment countermeasure attenuation, $C(f)$ represents shielding attenuation, $D(r_i, f)$ represents propagation attenuation associated with attacker distance r_i.

The security criterion becomes:

$$E(Z_i, f) \leq E_{th}(f) \quad (3)$$

which establishes $E_{th}(f)$ the maximum acceptable emanation level for each intrusion zone - the minimum detectable electromagnetic field required for information reconstruction.

Substituting the propagation model yields:

$$A(f) - B(f) - C(f) - D(r_i, f) \leq E_{th}(f) \quad (4)$$

which can be rearranged into:

$$B(f) + C(f) + D(r_i, f) \geq A(f) - E_{th}(f) \quad (5)$$

This expression defines the total required attenuation budget necessary to preserve confidentiality at intrusion zone Z_i. The maximum compromise distance can be derived from the security condition. Solving for distance yields:

$$r_{max}(f) = 10^{\frac{A(f)-B(f)-C(f)-E_{th}(f)}{20}} \quad (6)$$

The obtained value represents the maximum intrusion radius at which compromising information remains detectable.

4.2 Probabilistic Reconstruction Model

Because information reconstruction quality improves gradually rather than instantaneously, EMSEC compromise may be represented using a probabilistic model. The probability of successful information reconstruction is approximated as:

$$P_c(f, r) = \frac{1}{1+e^{-k(E(f,r)-E_{min})}} \quad (7)$$

where: P_c denotes compromise probability, k controls transition sharpness, $E(f, r)$ represents received field strength, E_{min} represents the minimum reconstruction threshold.

This formulation enables continuous estimation of EMSEC exposure rather than binary secure/insecure classification. The wideband and narrow-band measurement methods defined in ITU-T K.84 may now be interpreted within the proposed propagation framework.

The wideband method evaluates practical information reconstruction capability, temporal signal integrity and real compromise feasibility. Conversely, the narrow-band method evaluates spectral leakage localization, carrier frequency identification and frequency-selective propagation characteristics.

5. ILLUSTRATIVE APPICATIONS

5.1 Protection Optimization Concept

The conceptual model shown in Figure 4 illustrates that mitigation strategies implemented without prior leakage characterization may result in excessive shielding complexity and unnecessary infrastructure modifications. In contrast, measurement-driven assessment enables prioritization of dominant leakage paths and frequency components, thereby reducing overall protection cost while maintaining acceptable EMSEC risk levels. The residual compromise probability illustrated in Figure 4 conceptually corresponds to the probabilistic compromise function defined in Equation (7), where mitigation measures progressively reduce the received field strength below the reconstruction threshold. The “Potential Over-Engineering” region illustrates that EMSEC countermeasures implemented without prior leakage characterization may produce disproportionately high shielding and infrastructure costs while yielding only marginal reductions in residual compromise probability. This directly emphasizes the necessity of measurement-driven assessment, since realistic propagation analysis and intrusion-zone evaluation enable optimization of protection measures according to actual electromagnetic exposure rather than worst-case assumptions.

5.2 Spatial-Frequency Exposure Surface

The probabilistic compromise model introduced in Equation (7) can be further extended into a spatial-frequency exposure metric representing the residual EMSEC risk over the operational bandwidth of the compromising emanation. Instead of evaluating information reconstruction feasibility at a single frequency component, practical EMSEC compromise depends on the cumulative contribution of multiple spectral components propagating through the environment.

Accordingly, the average residual compromise probability at distance r may be expressed as:

$$P_{avg}(r) = \frac{1}{BW}\int_{f_1}^{f_2} P_c(f, r)df \quad (8)$$

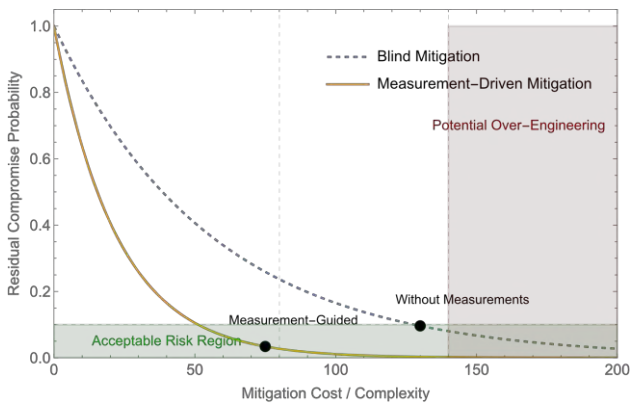

Figure 4. Conceptual comparison between blind EMSEC mitigation and measurement-driven protection optimization.

where: $BW = f_2 - f_1$ denotes the observed frequency bandwidth,

$P_c(f, r)$ represents the probabilistic compromise function,

and $P_{avg}(r)$ expresses the cumulative reconstruction feasibility across the measured spectral interval.

This formulation enables interpretation of EMSEC exposure as a continuous spatial-frequency risk distribution rather than a discrete threshold phenomenon. Consequently, the compromise probability becomes dependent not only on distance and shielding attenuation, but also on the spectral distribution of the emanation source and receiver sensitivity over the operational bandwidth. The proposed model is particularly suitable for visualization through three-dimensional propagation surfaces and intrusion-zone probability maps, Figure 5.
Such visualization enables measurement-driven optimization of shielding deployment, intrusion-zone geometry, receiver-oriented threat assessment and pre-compliance EMSEC mitigation strategies.
The probabilistic compromise surface may additionally be interpreted through intrusion-zone thresholds derived from ITU-T K.84. Instead of representing intrusion zones solely as fixed physical distances, the proposed framework associates each zone with a compromise probability interval over the spatial-frequency propagation surface, Figure 6. Instead of defining intrusion zones only through physical separation distances, the proposed framework associates each zone with a characteristic compromise probability interval derived from the propagation model.

Accordingly, intrusion zones may be represented as:

$$Z_i \equiv \{(f, r) | P_c(f, r) \in \Omega_i\}$$

where: Ω_i denotes the compromise probability interval associated with intrusion zone Z_i and $P_c(f, r)$ represents the probability of successful information reconstruction at frequency f and distance r.

An example interpretation may be expressed as:

– Zone 0: high-confidence reconstruction region ($P_c > 0.8$),

– Zone 1: partial reconstruction region ($0.5 < P_c \leq 0.8$),

– Zone 2: detectable spectral leakage region ($0.1 < P_c \leq 0.5$),

– Zone 3: residual detectability region ($P_c \leq 0.1$).

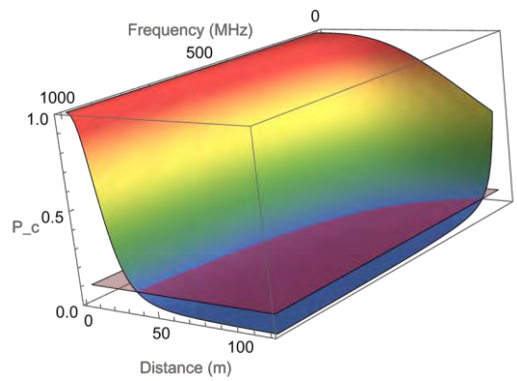

Figure 5. Three-dimensional spatial-frequency representation of probabilistic EMSEC exposure derived from the proposed propagation and reconstruction model. The red plane represents an acceptable residual compromise probability threshold.

This interpretation transforms intrusion zones into measurable propagation-dependent security regions whose boundaries vary according to SE, receiver sensitivity, propagation attenuation and emanation spectral distribution. Consequently, intrusion-zone boundaries are no longer fixed architectural distances, but dynamically depend on the electromagnetic characteristics of the protected environment and attacker capabilities.

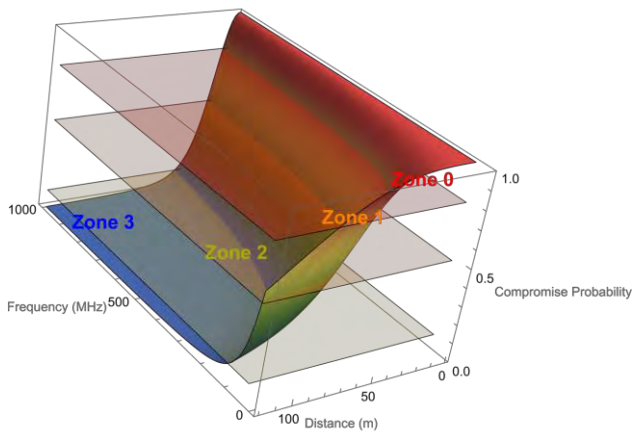

Figure 6. Spatial-frequency EMSEC Exposure with Intrusion Zone thresholds derived from the proposed compromise model.

This representation transforms the intrusion-zone concept into a dynamic propagation-oriented EMSEC assessment model suitable for measurement-driven pre-compliance analysis.

5.3 Intrusion-Zone Exposure versus Shielding

Figure 7 illustrates the relationship between intrusion distance, SE, and the probability of successful electromagnetic information reconstruction. The model assumes an emanation level of 62.2 dBμV/m at the reference distance and a reconstruction threshold of 15 dBμV/m representing the minimum field strength required by the adversary's receiving system. The probability curves are generated using the proposed logistic compromise model, where the parameter k=0.166 controls the transition

between successful and unsuccessful reconstruction regions.

The results demonstrate that increasing shielding attenuation shifts the compromise-probability curves downward and compresses the effective interception range. Without shielding, the probability of successful reconstruction remains relatively high even within extended intrusion zones, whereas shielding levels of 20–30 dB substantially reduce the compromise probability before the Zone 2 and Zone 3 boundaries are reached. This observation supports the central premise of measurement-driven EMSEC assessment: the required protection level is strongly dependent on the actual emanation characteristics and intrusion-zone geometry rather than on generic worst-case assumptions.

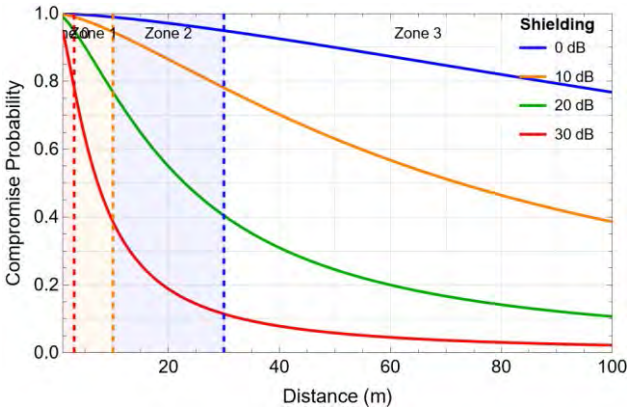

Figure 7. Intrusion-Zone EMSEC Exposure versus Shielding

The selected emanation level (62.2 dBµV/m) approximately corresponds to a leakage source that already satisfies conventional EMC emission requirements, illustrating that EMC compliance alone does not necessarily imply electromagnetic security. The reconstruction threshold (15 dBµV/m) represents the minimum electromagnetic field strength required for meaningful signal recovery by the assumed receiver class, hile the probability sharpness parameter (k = 0.166) models the gradual degradation of reconstruction quality observed in practical EMSEC scenarios. Rather than producing a strict secure/insecure boundary, the model reflects the realistic transition from reliable reconstruction to partial recovery and finally to residual detectability.

The figure highlights that intrusion-zone boundaries alone are insufficient for EMSEC assessment; identical facilities may exhibit substantially different exposure profiles depending on the measured emanation level and SE, thereby justifying the need for pre-compliance EMSEC measurements prior to implementation of costly countermeasures.

5.4 Frequency-Selective Leakage Characterization

In contrast to the spatial propagation analysis presented previously, narrow-band EMSEC measurements focus on identification of spectral components that carry compromising information. As described in ITU-T K.84, specific frequencies may exhibit significantly higher leakage levels due to deterministic electronic processes occurring inside the equipment under test.

The conceptual spectrum shown in Figure 8 models three representative leakage mechanisms frequently encountered in practical systems: clock harmonic, cable resonance and switching noise. Each mechanism contributes differently to the overall compromising emanation profile and therefore requires different mitigation strategies.

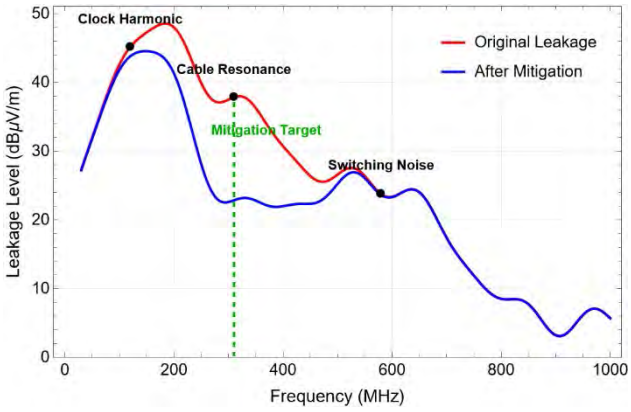

Figure 8. Frequency-Selective EMSEC Leakage Analysis

The resulting leakage spectrum may be approximated as:

$$S(f) = S_{clk}(f) + S_{cab}(f) + S_{sw}(f) \tag{9}$$

where, $S_{clk}(f)$ represents leakage generated by internal clock harmonics, $S_{cab}(f)$ represents resonant amplification caused by connected cables or conductive structures, and $S_{sw}(f)$ represents broadband emissions produced by switching power electronics and digital circuitry. A mitigation function $M(t)$ is then applied around a selected dominant leakage frequency, producing a residual spectrum

$$S_{mit}(f) = S(f) + M(f) \tag{10}$$

which models the effect of shielding, filtering, cable treatment, or redesign actions.

Figure 8 illustrates a representative narrow-band EMSEC measurement scenario derived from the concepts described in ITU-T K.84. The red curve represents the original leakage spectrum measured from an information-processing device, while the blue curve illustrates the residual leakage after application of a targeted mitigation measure. Three dominant leakage components can be observed. The first peak at approximately 120 MHz corresponds to a clock harmonic generated by internal digital timing circuits. The second peak at approximately 310 MHz is associated with cable resonance effects, where connected conductors behave as unintended radiating structures. The third peak at approximately 580 MHz represents switching-noise emissions originating from power conversion circuitry. The dashed line indicates a mitigation target frequency identified through spectral analysis. Application of a frequency-selective countermeasure reduces the leakage level around the dominant resonance, resulting in the mitigated spectrum shown in blue. The figure illustrates how narrow-band measurements can be used to identify dominant compromising frequencies and guide targeted EMSEC mitigation efforts. Instead of applying generalized

shielding measures over the entire spectrum, the proposed methodology uses measurement results to identify dominant leakage frequencies and prioritize mitigation efforts where they produce the greatest reduction in compromise potential. Examples of such mitigation techniques include selective shielding reinforcement, cable rerouting, ferrite suppression, filtering, grounding improvements, or equipment relocation.

Within the context of the proposed analytical framework, the mitigated spectrum corresponds to a reduction of the emanation term $A(f)$ in Equation (5), which directly decreases the maximum compromise distance and lowers the compromise probability defined by Equation (7). The figure therefore provides a practical interpretation of how narrow-band measurements can be translated into measurable reductions of EMSEC exposure and intrusion-zone risk.

6 CONCLUSION

The proposed analytical framework represents a simplified propagation-oriented approximation of practical EMSEC environments. Real electromagnetic leakage scenarios may additionally depend on multipath propagation, polarization mismatch, near-field coupling effects, non-linear leakage mechanisms and receiver-specific reconstruction algorithms. Consequently, the proposed framework should be interpreted primarily as an engineering-oriented pre-compliance assessment methodology intended to support early-stage EMSEC risk evaluation and mitigation prioritization rather than a replacement for formal TEMPEST certification procedures.

To be concluded, the proposed framework demonstrates how publicly available ITU-T recommendations can be combined with propagation-oriented analysis, intrusion-zone assessment, and measurement-driven mitigation planning to establish an engineering-level EMSEC pre-compliance methodology. Unlike traditional TEMPEST evaluation procedures, which are typically performed during certification stages, the proposed approach enables early identification of dominant leakage paths, estimation of compromise probability, and optimization of shielding and zoning strategies prior to expensive infrastructure modifications. However, it is not substitution for formal TEMPEST evaluation. The illustrative examples demonstrate how propagation modeling and spectral leakage characterization can support targeted mitigation while reducing the risk of over-engineered countermeasures.

Abstract: *Orthogonal Frequency Division Multiplexing (OFDM) is a widely used multi-carrier modulation technique in modern high-speed wireless and mobile communication systems due to its robustness against multipath fading channels. This paper presents the design, simulation, and hardware implementation of an OFDM transmitter based on Quadrature Amplitude Modulation (QAM) using the STM32F407 microcontroller. The system was fully developed in the MATLAB/Simulink environment, where extensive algorithm validation was performed. Using Simulink Coder, C code was automatically generated and deployed onto the STM32F4DISCOVERY board. This proof-of-concept demonstrates the effectiveness of the model-based design approach for rapid development and validation of communication algorithms on a resource-constrained Cortex-M4-based platform. Spectral measurements of the transmitted signal on a spectrum analyzer showed strong agreement with the simulation results. A receiver has also been implemented, including necessary synchronization blocks; however, due to its complexity, it is not described in detail in this work.*

Keywords: *OFDM, QAM, STM32F407, MATLAB, Simulink, model-based design, embedded communications, proof-of-concept*

1. INTRODUCTION

Orthogonal Frequency Division Multiplexing (OFDM) has become the dominant modulation technique in modern high-speed wireless communication systems due to its high spectral efficiency and robustness against multipath fading channels [1], [2]. Traditionally, OFDM transceivers are implemented on high-performance platforms such as Field-Programmable Gate Arrays (FPGAs), Digital Signal Processors (DSPs), or Software-Defined Radios (SDRs). However, there is a growing demand for deploying communication algorithms on low-cost, resource-constrained embedded microcontrollers for specialized telemetry, Internet of Things (IoT) applications, and educational purposes.

The primary motivation for this work stems from the modernization of legacy telemetry systems operating over the analog FM audio subcarrier of PAL television standard. The objective is to replace traditional Frequency-Shift Keying (FSK) tone-based signaling with a high-throughput 16-Quadrature Amplitude Modulation (16-QAM) OFDM data transmission scheme. To achieve this in a cost-effective manner, the STM32F407 microcontroller (based on the ARM Cortex-M4 architecture), paired with the onboard audio codec of the STM32F4DISCOVERY board, presents an attractive hardware solution. Nevertheless, implementing complex multicarrier modulation on such a platform introduces significant challenges, particularly regarding computational limits, memory constraints, and the critical transition from floating-point simulation to integer arithmetic for hardware interfacing [3].

To address these challenges, this paper adopts a Model-Based Design (MBD) methodology using the MATLAB/Simulink environment. MBD bridges the gap between theoretical algorithm design and embedded deployment by enabling extensive simulation-based verification and automatic generation of optimized C code [4]. This work demonstrates the feasibility of a complete 16-QAM OFDM transmitter operating in real-time on a low-cost microcontroller, detailing the practical MBD workflow from frame-based processing to Inter-IC Sound (I^2S) audio codec interfacing.

2. THEORETICAL BACKGROUND OF OFDM SYSTEMS

The fundamental concept of OFDM lies in dividing a wideband channel into multiple narrowband orthogonal subcarriers, thereby significantly reducing the impact of frequency-selective fading.

Corresponding author: S. Gundelj;
E-mail: gundelj@yahoo.com

DOI: 10.5937/OTEH26083G

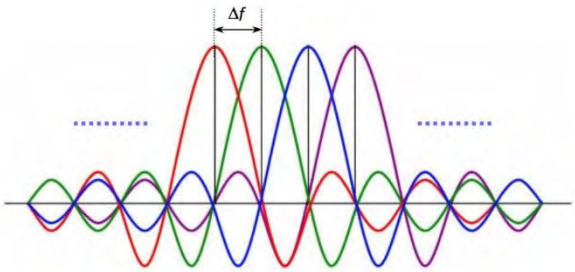

Figure 1. Orthogonal subcarrier spectra in OFDM

The OFDM signal is generated using the Inverse Fast Fourier Transform (IFFT). Let $X[k]$ denote the complex data symbols on the k-th subcarrier ($k = 0, 1, \ldots, N-1$), where N is the total number of subcarriers. The discrete-time OFDM symbol is then expressed as:

$$x[n] = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} X[k] \cdot e^{j2\pi kn/N},$$

$$n = 0, 1, \ldots, N-1 \qquad (1)$$

After the IFFT operation, a Cyclic Prefix (CP) of length N_{CP} is prepended to the symbol by copying the last N_{CP} samples to the beginning. This mechanism converts linear convolution with the channel impulse response into circular convolution, enabling simple one-tap frequency-domain equalization [5]. In this work, 16-QAM is employed for bit-to-symbol mapping. The 16-QAM constellation allows the transmission of 4 bits per symbol, providing a good agreement between spectral efficiency and noise resilience [6]. The constellation is typically normalized to unit average symbol energy, and Gray coding is applied to minimize bit errors between adjacent symbols.

The main advantages of OFDM over single-carrier modulation schemes include high robustness to multipath propagation, simple frequency-domain equalization, and flexible subcarrier allocation [1]. However, OFDM systems suffer from two notable drawbacks: a high Peak-to-Average Power Ratio (PAPR) and sensitivity to carrier frequency offset and phase noise [7]. These issues require careful system design, particularly when implementing on resource-constrained embedded platforms.

The following sections describe the model-based design of a 16-QAM OFDM transmitter using MATLAB/Simulink, with emphasis on automatic code generation and deployment onto the STM32F407 hardware.

3. MODEL-BASED DESIGN IN MATLAB/SIMULINK

The complete 16-QAM OFDM transmitter was developed using the Model-Based Design methodology within the MATLAB/Simulink environment. This approach enables rapid algorithm development, extensive simulation-based verification, and automatic generation of optimized embedded code [4].

Within the MATLAB/Simulink environment, signal processing can be executed using either sample-based or frame-based processing paradigms. While sample-based processing handles a single scalar value per simulation step, frame-based processing operates on vectors or matrices of data (frames) simultaneously [4]. For the proposed OFDM transmitter, frame-based processing is highly advantageous, as core operations such as the Inverse Fast Fourier Transform (IFFT) and Cyclic Prefix (CP) insertion inherently require block-level data manipulation. Furthermore, adopting a frame-based approach significantly accelerates simulation execution speed and seamlessly maps to the generated embedded C code, effectively mirroring the buffer-oriented data handling utilized by the STM32F407 microcontroller during real-time operation.

Figure 2 presents the complete Simulink model of the 16-QAM OFDM transmitter developed within the MATLAB/Simulink environment. The architecture follows a systematic signal processing chain, beginning with the **Bernoulli Binary Generator** block, which produces a random binary data sequence represented as a column vector of dimension [192×1]. This block serves as the information source for the transmission system.

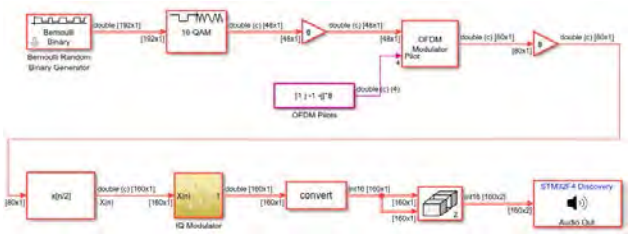

Figure 2. Simulink model of the 16-QAM OFDM transmitter

The binary sequence is subsequently processed by the **Rectangular QAM Modulator Baseband** block, which performs 16-QAM symbol mapping according to Gray coding principles. Each group of 4 bits is mapped to a complex constellation point, resulting in a symbol vector of dimension [48×1]. The 16-QAM constellation is normalized to unit average energy.

Parallel to the main data path, the **OFDM Pilots** block generates known reference symbols of dimension [4×1], which are inserted at predetermined subcarrier positions. These pilot symbols facilitate future channel estimation and frequency offset correction at the receiver side.

The complex symbols are then fed into the **OFDM Modulator** block, which performs the core OFDM processing. This block executes the Inverse Fast Fourier Transform (IFFT) operation, converting frequency-domain symbols into a time-domain signal according to Equation (1). Subsequently, a Cyclic Prefix (CP) is prepended to each OFDM symbol by copying the last N_{CP} samples to the beginning, yielding the final time-discrete OFDM signal:

$$x_{CP}[n] = \begin{cases} x[n + N - N_{CP}], & n = -N_{CP}, \ldots, -1 \\ x[n], & n = 0, 1, \ldots, N-1 \end{cases}, \qquad (2)$$

where N represents the IFFT size and N_{CP} denotes the CP length. The OFDM Modulator block was configured with FFT length N=64, following the subcarrier allocation structure of the IEEE 802.11a/g standard [8], guard bands of 6 lower and 5 upper subcarriers, DC null insertion, and

four pilot subcarriers at indices 7, 21, 43, and 57.

Following OFDM modulation, the signal undergoes amplitude scaling through gain blocks to optimize the dynamic range. The **upsampling block** ($x[n/2]$) then increases the sampling rate by a factor of 2, preparing the signal for digital-to-analog conversion and subsequent IQ modulation.

The processed signal is routed to the **IQ Modulator** subsystem (detailed in Figure 3), where quadrature upconversion to the 8 kHz carrier frequency is performed, with cosine and sine references generated as 160-sample discrete frames at the 32 kHz sampling rate.

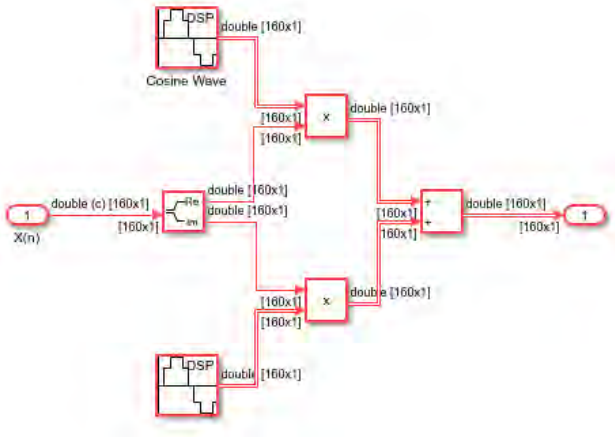

Figure 3. IQ Modulator

Following the IQ modulation stage, the passband signal exists in double-precision floating-point format, which must be converted to 16-bit signed integers to interface with the audio codec connected to the STM32F407. The signal is scaled to utilize the full dynamic range and then quantized to *int16* format, introducing minimal degradation while maintaining sufficient resolution for algorithm validation on the target hardware.

All system parameters, including FFT size (N), CP length (N_{CP}), modulation order ($M = 16$), and sampling frequency (f_s), are defined as tunable workspace variables, enabling rapid exploration of different system configurations during the design phase.

PAPR analysis was not performed in this work, as the primary objective was algorithm validation rather than RF power efficiency optimization.

Channel coding (scrambling, BCH, and convolutional encoding) was omitted from the presented transmitter to prioritize core OFDM signal processing validation. A complementary OFDM receiver has been developed in the same MATLAB/Simulink environment, comprising IQ demodulation, FFT-based OFDM demodulation with pilot extraction, frame and carrier synchronization via PI control loops and pilot-based channel estimation with linear interpolation. Due to space constraints, its detailed description is deferred to future work.

Table 1. System Parameters

Parameter	Value
FFT Size (N)	64
Cyclic Prefix (N_{CP})	16 samples
Guard Bands	6 lower, 5 upper
Pilot subcarriers	4 (indices: 7, 21, 43, 57)
Modulation	16-QAM (Gray code)
Data Subcarriers	48
Sampling Frequency (f_s)	32 kHz
CP Overhead	25%
Interpolation Factor	2
Carrier Frequency (f_c)	8 kHz
Raw Data Rate	38.4 kbps

The specific system parameters used in this implementation are summarized in Table 1. An FFT size of $N = 64$ subcarriers was selected to balance spectral efficiency with the computational constraints of the Cortex-M4 processor. This follows a structure similar to the IEEE 802.11a/g standard [8], where 48 subcarriers are used for data transmission, 4 for pilot symbols, and the remaining are null subcarriers for DC and guard bands. The cyclic prefix length was set to $N_{CP} = 16$ samples (25% overhead), providing sufficient protection against multipath delay spread while maintaining acceptable spectral efficiency. After interpolation the system operates at a sampling frequency of $f_s = 32\ kHz$, which is fully compatible with standard audio codec interfaces. The OFDM modulator itself runs at a base rate of $f_{s,base} = 16\ kHz$. The 16-QAM modulation with Gray coding yields a raw data rate of approximately 38.4 kbps. These parameters were carefully chosen to ensure real-time operation on the STM32F407 while demonstrating the fundamental principles of OFDM transmission.

One of the key benefits of this methodology is the direct path from a verified Simulink model to deployable C code using Simulink Coder and Embedded Coder. After successful simulation, the model was configured for code generation targeting the ARM Cortex-M4 processor, with appropriate optimization settings for execution speed and memory footprint.

4. HARDWARE IMPLEMENTATION AND RESULTS

The generated C code was deployed onto the STM32F4DISCOVERY board featuring the STM32F407VG microcontroller (ARM Cortex-M4, 168 MHz, 192 KB SRAM, 1 MB Flash). The onboard CS43L22 audio codec, interfaced via I²S at 32 kHz, served as the digital-to-analog converter for the passband OFDM signal. No external RF frontend was used; the signal was observed directly at the codec's line output.

Table 2. Memory Footprint

Resource	Used	Available	Percentage
Flash(program)	21.2 KB	1,024 KB	2.1%
SRAM (data)	22.9 KB	192 KB	11.9%

Automatic code generation via Simulink Coder and Embedded Coder produced an executable of approximately 21 KB Flash and 23 KB SRAM footprint, corresponding to 2.1% and 11.9% of the STM32F407VG resources, respectively. The build leverages the ARM Cortex-M4 FPU with hard-float ABI and -O3 optimization, targeting single-precision hardware-accelerated arithmetic. Deployment was performed directly from the MATLAB environment via ST-Link/OpenOCD. Based on the symbol rate of 200 Hz and the observed real-time stability, the CPU utilization is estimated to be well below 5%, leaving substantial headroom for receiver processing.

Figure 4 presents the power spectral density of the transmitted signal obtained from the Simulink simulation, while Figure 5 shows the corresponding measurement captured on the HP 3582A spectrum analyzer at the STM32F4DISCOVERY line output. Both spectra exhibit the expected 64-subcarrier OFDM structure with 250 Hz subcarrier spacing ($\Delta f = f_{s,base} / N = 16000/64$), centered at the 8 kHz carrier frequency. The measured spectrum closely matches the simulation, confirming the fidelity of the implementation and the correctness of the automatic code generation process. Minor deviations in the sidelobe levels are attributed to the finite resolution bandwidth of the analog spectrum analyzer and the reconstruction filter characteristics of the CS43L22 audio codec.

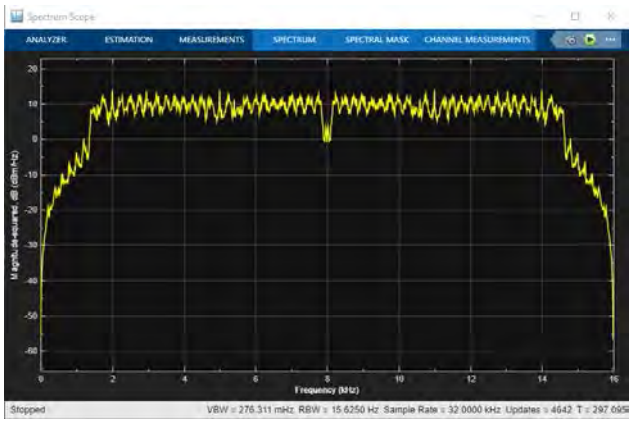

Figure 4. Simulated power spectral density

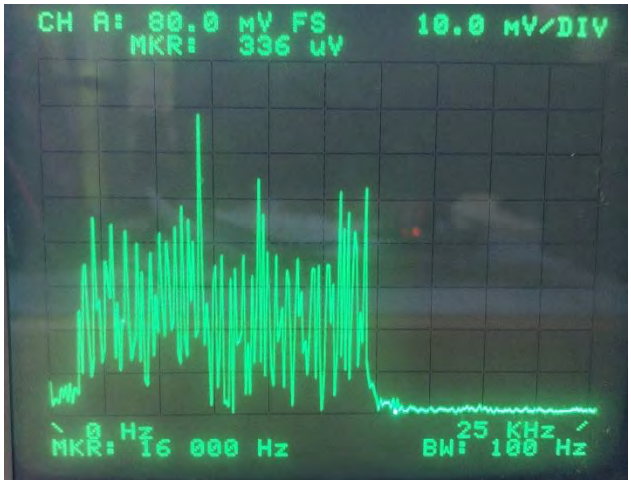

Figure 5. Measured power spectral density

The experimental results validate the model-based design approach: the floating-point implementation preserves the spectral characteristics of the reference simulation, while operating well within the real-time constraints of the Cortex-M4 platform. The primary limitation is the audio codec's 32 kHz sampling rate, which constrains the passband carrier to the audible range — acceptable for wired or near-field telemetry applications, but requiring an external upconverter for true wireless transmission.

5. CONCLUSION

This paper presented a complete model-based design and implementation of a 16-QAM OFDM transmitter on the STM32F407 microcontroller. The system was fully developed and validated in the MATLAB/Simulink environment, with automatic C code generation and deployment onto the STM32F4DISCOVERY board via Simulink Coder and Embedded Coder. Spectral measurements on the HP 3582A spectrum analyzer confirmed strong agreement with simulation results, demonstrating the feasibility of multicarrier modulation on a resource-constrained Cortex-M4 platform. The achieved raw data rate of 38.4 kbps, with minimal CPU and memory utilization, leaves substantial headroom for system expansion. A complementary OFDM receiver with synchronization and channel estimation has also been developed, as has a channel-coded transmitter variant; both are omitted here for brevity. Future work will fully characterize the receiver performance, integrate channel coding, and address fixed-point optimization for enhanced efficiency.

TELECOMMUNICATION AND INFORMATION SYSTEMS INFORMATION-PSYCHOLOGICAL ACTIVITIES IN MODERN CONFLICTS

JELENA BAJIC
College of vocational studies for Security and criminalistics KIB, Bulevar Cara Konstantina 82-86,NIS,
prof.drjelenabajic@gmail.com

Abstract: *Modern society is founded on both information and disinformation. The Internet and global networking have enabled rapid access to information, but also, in communication terms, introduced significant "noise" within it. Communication is of crucial importance, as those who possess timely information effectively control the situation—a principle that has always held true. Within the military-security operational environment, military communications, radio communications, satellite links, and cyber communication are gaining increasing importance under contemporary conditions, particularly in modern conflicts. In the context of ongoing modern conflicts, the significance of communication is most evident in crisis management and communication during emergency situations. This is especially relevant in defensive military operations, counterterrorism efforts, and responses to hybrid threats, as well as in psychological operations, information warfare, and the corresponding communication strategies employed in military crisis situations. The human factor in defense systems, including the psychological aspects of communication under stress and in military conditions, can significantly contribute to, but also undermine, the effectiveness of operations. All of the above, with particular emphasis on information-psychological operations in modern conflicts, will be discussed in greater detail in the paper.*

Keywords: *information, communication, modern conflicts, psychological operations*

1. INTRODUCTION

The contemporary security environment is characterized by rapid technological transformations that have significantly influenced the planning, execution, and assessment of military and security operations. In addition to the land, maritime, air, space, and cyber domains, the information environment has emerged as one of the key arenas for achieving strategic objectives. Within such an environment, information represents a strategic resource, while the capability to collect, process, protect, and disseminate information has become one of the fundamental elements of modern operations (NATO, 2025).

The development of telecommunication and information systems has enabled near real-time transmission of data, coordination among various levels of command, and decision-making processes based on timely and accurate information. At the same time, digital platforms and social media have created a new information environment in which, alongside reliable information, disinformation, propaganda, and other forms of information influence spread rapidly (NATO, 2023).

A particular challenge stems from the advancement of generative artificial intelligence, which enables the creation of highly convincing textual, audio, and video content. These technologies possess significant potential for improving data analysis processes and supporting decision-making; however, they simultaneously increase the risk of sophisticated disinformation campaigns and manipulation of public opinion (Shoaib et al., 2023).

In this paper, the term *information-psychological activities* is employed as a broader concept encompassing information operations, psychological operations (PSYOPS), strategic communications, and other activities aimed at shaping the perceptions, attitudes, and behavior of target audiences within the information environment. This approach is consistent with contemporary NATO doctrinal documents emphasizing the integration of information-related activities into operational planning and execution (NATO, 2015).

The subject of this study is the analysis of the role of telecommunication and information systems in information-psychological activities during modern conflicts, with particular emphasis on the application of digital technologies and artificial intelligence. The objective of the paper is to examine the importance of these systems in achieving information superiority and to propose a conceptual model linking technological, informational, and psychological dimensions of contemporary information operations.

2. THEORETICAL FRAMEWORK OF INFORMATION-PSYCHOLOGICAL ACTIVITIES

Modern conflicts are characterized by the extensive application of information and communication technologies and an increasing dependence of military and

Corresponding author: J. Bajic
E-mail: prof.drjelenabajic@gmail.com

DOI: 10.5937/OTEH26084B

security systems on the reliable functioning of telecommunication infrastructure. Within contemporary NATO doctrine, information operations are defined as a planning function integrating various information-related activities in order to achieve effects within the information environment (Joint Chiefs of Staff, 2022; NATO, 2015).

In this study, information-psychological activities are conceptualized as an interdisciplinary framework encompassing information operations, psychological operations (PSYOPS), strategic communications, counter-disinformation activities, and other forms of communication-based influence directed toward target audiences. Such an approach facilitates a comprehensive understanding of the technological, informational, and psychological dimensions of modern conflicts.

The foundation of information-psychological activities lies in information superiority, understood as the ability to collect, process, protect, and disseminate relevant information in a timely and effective manner. Information superiority depends not only on the technological sophistication of systems but also on the quality of data analysis, the speed of decision-making processes, and the efficiency of communication among different command levels (NATO, 2015).

Telecommunication systems play a particularly significant role by enabling reliable data transmission among participants involved in operations. Satellite communications, radio systems, optical networks, mobile communications, and digital platforms constitute the basis of modern information activities. Their security and resilience against electronic interference and cyberattacks have a direct impact on the effectiveness of military and security operations (NATO, 2020).

The emergence of social media and digital platforms has further transformed the nature of the information environment. Information now spreads almost instantaneously, while every user can simultaneously act as both a consumer and producer of content. This environment facilitates coordinated disinformation campaigns, propaganda efforts, and other forms of information influence capable of generating substantial psychological and societal consequences (Singer & Brooking, 2018).

An additional challenge arises from the application of generative artificial intelligence, which enables the automated production of highly persuasive textual, audio, and video content. While these technologies offer numerous advantages in data analysis and decision support, they also increase the risk of misuse through the creation of deepfake materials and sophisticated disinformation campaigns (Shoaib et al., 2023).

Contemporary literature suggests that information-psychological activities constitute an interdisciplinary field where telecommunications, information technologies, psychology, communication studies, and security sciences intersect. Understanding the interrelationships among these domains provides the foundation for developing effective mechanisms for protecting the information environment and enhancing societal resilience against modern information threats.

3. INTEGRATED MODEL OF INFORMATION-PSYCHOLOGICAL ACTIVITIES

Contemporary developments in information and communication technologies indicate that the effectiveness of information-psychological activities no longer depends solely on the technical capabilities of systems but increasingly on their integration with information processes and psychological mechanisms influencing perception and decision-making.

An analysis of recent literature demonstrates that these three dimensions are frequently examined separately, whereas their interconnections remain considerably underexplored (NATO, 2015; Joint Chiefs of Staff, 2022). Accordingly, this paper proposes a conceptual model of information-psychological activities integrating three interrelated components: the technological, informational, and psychological dimensions.

The technological component comprises telecommunication and information systems that enable the collection, processing, protection, and dissemination of data. This category includes communication networks, satellite systems, computer networks, command-and-control systems (C4ISR), and artificial intelligence-based platforms. Their primary function is to provide a reliable information environment that serves as the foundation for planning and implementing information-related activities.

The informational component encompasses the collection, analysis, processing, and distribution of information, as well as strategic communications, information operations, and information content management activities. The purpose of this component is to ensure timely, reliable, and coordinated information supporting the achievement of operational and strategic objectives (NATO, 2023).

The psychological component focuses on understanding how individuals and social groups perceive, interpret, and accept information. Emotions, motivation, previous experiences, trust in information sources, and cognitive biases constitute important factors affecting the effectiveness of information-psychological activities (Singer & Brooking, 2018).

Artificial intelligence plays a central role in connecting all three components. Its application facilitates the processing of large volumes of data, identification of behavioral patterns, assessment of information risks, and support for decision-making processes. At the same time, generative artificial intelligence may be exploited for the automated production of disinformation, deepfake content, and other

forms of information manipulation, further emphasizing the necessity of developing effective mechanisms for protecting the information environment (Shoaib et al., 2023).

The proposed model indicates that the full potential of information-psychological activities can only be achieved through the coordinated interaction of all three components. In this regard, the model may serve as a conceptual framework for future research and the development of modern national security systems.

(izvor: autor)

4. TELECOMMUNICATION AND INFORMATION SYSTEMS IN INFORMATION-PSYCHOLOGICAL ACTIVITIES

Telecommunication and information systems constitute the foundation for planning, implementing, and coordinating information-psychological activities in modern conflicts. Their role extends beyond the traditional transmission of data, as they enable the collection, processing, protection, and dissemination of information that forms the basis for timely decision-making and the achievement of information superiority (NATO, 2015).

The development of digital communication technologies has enabled near-instantaneous information exchange among different levels of command and control. Satellite communications, radio communication systems, optical networks, mobile communications, and Internet infrastructure currently represent the technological backbone of contemporary military and security systems. Their reliability, availability, and resilience against electronic interference and cyberattacks constitute essential prerequisites for the successful conduct of information operations (NATO, 2020).

Particular importance is attributed to integrated Command, Control, Communications, Computers, Intelligence, Surveillance, and Reconnaissance (C4ISR) systems. By integrating data from multiple sources, these systems facilitate a more accurate understanding of the operational environment and enable more efficient management of available resources. The integration of sensor systems, unmanned platforms, satellite reconnaissance capabilities, and information networks significantly enhances the quality of decision-making under complex operational conditions.

Contemporary information systems increasingly employ artificial intelligence algorithms and big data analytics to identify patterns, assess risks, and support decision-making processes. Their application enables faster information processing, more effective operational planning, and improved forecasting of potential scenarios. However, the same technologies can also be exploited for the automated creation and dissemination of disinformation, thereby further complicating the contemporary information environment (Singer & Brooking, 2018).

In addition to technological advancement, the protection of communication and information infrastructure is of paramount importance. Cyberattacks directed against communication networks, databases, or command-and-control systems may seriously disrupt the functioning of defense and national security institutions. Consequently, the implementation of encryption mechanisms, multifactor authentication, continuous network monitoring, and other cybersecurity measures has become an integral component of modern telecommunication system development (Libicki, 2009).

Based on the analysis presented, it can be concluded that telecommunication and information systems represent a crucial pillar of information-psychological activities, as they enable the attainment of information superiority and significantly influence the planning and execution of activities in modern conflicts.

5. INFORMATION-PSYCHOLOGICAL ACTIVITIES IN MODERN CONFLICTS

Modern conflicts increasingly depend less on the application of conventional military force and more on the ability to manage information and influence the perceptions of target audiences. Information-psychological activities have become an integral element of contemporary military and security practices, utilizing various communication, informational, and psychological instruments to achieve political and strategic objectives (Joint Chiefs of Staff, 2022).

One of the most significant forms of information-psychological activities is represented by strategic communications and psychological operations (PSYOPS), aimed at shaping the attitudes, emotions, and behavior of diverse target groups. Their effectiveness depends on the quality of collected information, knowledge of the psychological characteristics of target populations, and the selection of appropriate communication channels (NATO, 2023).

A major challenge within the contemporary information environment is posed by organized disinformation campaigns conducted through digital media and social networking platforms. Due to the rapid dissemination of content and the possibility of algorithmically targeting specific user groups, disinformation may substantially influence public opinion formation, undermine trust in institutions, and affect political and security-related decision-making processes (Singer & Brooking, 2018).

The development of generative artificial intelligence has further enhanced the capabilities of information-psychological activities. The automated generation of texts, images, audio recordings, and video materials, including deepfake technology, makes it possible to create content that is difficult to distinguish from authentic sources. As a result, assessing the credibility and authenticity of information has become one of the greatest challenges facing contemporary societies (Shoaib et al., 2023).

From a psychological perspective, the effectiveness of information influence largely depends on how individuals perceive and process information. Emotions, previous experiences, cognitive biases, trust in information sources, and perceptions of threat all influence the acceptance or rejection of particular messages. For this reason, contemporary information activities increasingly combine technological capabilities with insights derived from psychology and communication sciences in order to maximize their impact on targeted populations.

It may therefore be concluded that information-psychological activities constitute one of the defining features of modern conflicts and that their importance will continue to increase alongside the further advancement of digital technologies and artificial intelligence.

6. CHALLENGES AND FUTURE DEVELOPMENT PERSPECTIVES

The development of telecommunication and information technologies, digital platforms, and artificial intelligence has significantly expanded the capabilities of information-psychological activities while simultaneously creating new security challenges. Particular threats arise from coordinated disinformation campaigns, the misuse of social media platforms, deepfake content, and sophisticated cyberattacks directed against communication and information infrastructures.

In addition to technological considerations, the human factor remains highly significant. Limited media literacy, insufficient information literacy, and pronounced cognitive biases increase susceptibility to manipulative content. Consequently, strengthening societal resilience requires simultaneous improvements in technological capacities, cybersecurity measures, and continuous user education.

An effective response to contemporary information threats necessitates an integrated approach that combines telecommunication and information systems, strategic communications, psychological resilience, and international cooperation. Under conditions of accelerated artificial intelligence development, it is reasonable to expect that information-psychological activities will assume an increasingly prominent role in the planning and implementation of operations in modern conflicts.

CONCLUSION

Modern conflicts demonstrate that information has become one of the most valuable strategic resources, while telecommunication and information systems play a central role in its collection, processing, protection, and dissemination. At the same time, information-psychological activities are emerging as an indispensable component of contemporary military and security practices, aimed at shaping perceptions, attitudes, and decision-making processes.

The analysis presented in this paper indicates that the effectiveness of information-psychological activities depends on the interaction among technological, informational, and psychological factors. The proposed conceptual model highlights the necessity of considering these dimensions in an integrated manner and may provide a useful framework for future research and the enhancement of information operations.

The continuing development of digital communications, cyber technologies, and artificial intelligence will further increase the significance of information-psychological activities in modern conflicts. Therefore, it is essential to continuously improve telecommunication and information systems, strengthen cybersecurity capabilities, and promote media and information literacy as critical elements of national security.

JOVAN RADIVOJEVIĆ
Iritel a.d, Belgrade, jovan.radivojevic@iritel.com

Abstract: *Unmanned aerial vehicles (UAVs) pose a growing threat to airspace security, critical infrastructure protection and privacy enforcement. Reliable identification, detection and tracking of small, fast-paced drones in various visual scenes remains an open problem, particularly under varying lighting conditions and sensing modalities. This paper investigates a multi-UAV detection and tracking pipeline from video in special conditions, using a combination of single-stage anchor-free detection with multi-object tracking based on Kalman prediction and hierarchical data association. The proposed pipeline is designed with real-time applicability in mind, balancing inference speed with detection and tracking quality. One of the tasks is to leverage both low-confidence and high-confidence detections during the association stage in order to maintain track continuity under low-contrast conditions and occlusion. The system is evaluated on established benchmarks for UAVs with provided thermal infrared sequences in dense multi-UAV scenarios where UAVs are relatively small in comparison to frame size. Performance assessment is done using standard multi-object tracking metrics, with comparative analysis between alternative tracking strategies. Furthermore, we explore potential improvements on the detection phase targeting small-target recall. The paper discusses the trade-offs between detection accuracy, tracking robustness and computational complexity. The paper is intended for Telecommunications and Information Systems topic.*

Keywords: *UAV detection, multi-object tracking, deep learning, real-time.*

1. INTRODUCTION

Unmanned aerial vehicles (UAVs) over time have become cheaper, more accessible and easier to fly, which has turned them in one of the primary threats to airspace security, both in military and civil environment. Detection and tracking of UAVs emerged as one of leading security problems. Thermal infrared (IR) cameras are widely used in solving this problem due to their performance in complex scenarios such as operating in night or in poor visibility. However, with IR cameras, there is trade-off with UAVs occupying relatively small number of pixels. For example, in Anti-UAV Track 3 [1], dataset used for this research, targets have average width of around 11 pixels in 640×512 frame. Also, IR images carry very little useful information in terms of object texture. Tracking multiple UAVs (or swarm drones) can simply be described as tracking by detection – each frame detector feeds detections to the tracker where these detections are linked to appropriate trajectories. Due to specific nature of the dataset, there are couple of problems that were addressed in this paper. With objects width of average 11 pixels, and no significant texture information, appearance of the object is uninformative. This issue raises a question which motivates this paper: how to achieve good multiple object tracking (MOT) performance with challenging conditions for detection?

To answer this question, we paired anchor-free two detectors YOLOv8s [2] and YOLOX-S [3] with several trackers. Trackers are implemented with following algorithms:

- DeepSORT [4] – algorithm which is based on appearance embeddings
- ByteTrack [5] – run across a range of confidence threshold values
- ByteTrack with camera motion compensation (CMC) – overhead which calculates camera motion, is added to ByteTrack

Each combination of detectors and trackers is evaluated on the same validation split with the HOTA [6] metrics. Higher Order Tracking Accuracy (HOTA) is used because it can be factored to a detection accuracy (DetA) and an association accuracy (AssA), so it lets us evaluate gains and losses in each stage of the pipeline.

This analysis showed that, for this particular problem, detection accuracy is saturated, as DetA score is around 68 for both YOLOv8s and YOLOX-S detectors. Also, association turned out to be binding constrain in obtaining higher HOTA score. However, what stood out the most is increasing AssA by 16 to 20 points when CMC is applied, which consequently raises HOTA by 10 to 12 points, all while keeping pipeline efficiency at a real-time level.

2. METHOD

In this paper we implement tracking by detection paradigm. In each frame independently detector localizes UAVs and tracker links those detections to trajectories while maintaining identity of each UAV. Due to the

E-mail: lazar.velinov@iritel.com

DOI: 10.5937/OTEH26085V

nature of dataset (small objects), we choose anchor-free detectors, which are more suitable for this task.

2.1. Detectors

For detection stage we have chosen two comparable iterations of algorithms from YOLO series: YOLOv8-s and YOLOX-S. Both algorithms are chosen due to their anchor-free design, because anchors could yield worse Intersection-over-Union (IoU) scores for small absolute misalignment (couple of pixels), which could suppress recall. The YOLOX is selected as it is the detector used in the original ByteTrack implementation, and YOLOv8 is selected as an official Ultralytics distribution for comparison. Both detectors are initialized from COCO pretrained weights [7] and fine-tuned once on a training split from the dataset as a single class model. Weights are than frozen so that every tracker uses the same detection front-end for inference. At inference, low-scoring detections are needed for ByteTrack second stage association, therefore confidence threshold is held deliberately low.

2.2. Tracking

In this paper, we evaluate three trackers with per-frame detections from detector inference.

ByteTrack uses constant-velocity Kalman filter [8] to model each track. Detections are associated with each predicted track using IoU metric. A distinguish feature of ByteTrack is its two-stage association. In the first stage, high-confidence detections are matched to tracks. In the second stage, low-confidence detections are used to recover objects so that they are not discarded. Because of small objects nature of the dataset, we expect relatively lower detection confidence in some cases, so we sweep single track initialization confidence threshold τ over values {0.3, 0.4, 0.5}. That parameter controls which detections may be associated with a new track (new track threshold set to $\tau + 0.1$).

DeepSORT uses the same model and augments it with appearance embedding of the object, which is used for re-identifying (Re-ID) temporarily lost tracks. Appearance embeddings are included to test whether appearance is relevant at thermal camera with this resolution and small object scale.

2.3. Camera Motion Compensation

Some thermal video sequences from the dataset are captured with a panning, non-stationary camera. For constant-velocity Kalman filter, that poses a problem, as it cannot differentiate true object motion from global camera motion. While camera is moving, between two frames each track's predicted position shifts away relative to the detection causing low IoU score and breaking the association, which inflates identity switches. To tackle this problem, following the idea of global-motion-compensation (GMC) used in BoT-SORT [9] we insert camera-motion-compensation after motion prediction step. Frame-to-frame camera movement is estimated and each predicted box is warped in new frame's coordinates before matching in association stage.

Transformation is calculated using features from the image. First, we need to detect ORB (Oriented FAST and Rotated BRIEF) [10] keypoints in consecutive frames. Detected keypoints are then matched by descriptor distance and ratio, and fitted to partial-affine transform using RANSAC (Random Sample Consensus) [11] to reject outliers. Resulting affine is applied to Kalman state of each track. Full affine transformation is used for the bounding box centre, an isotropic scale is applied to the height, and linear component is applied to the velocities. Aspect ratio is left invariant.

Due to thermal infrared nature of videos in the dataset, default ORB settings provide insufficient results. The frames are low contrast and untextured, so stable points are either not found or clustered around UAVs (objects whose motion need to be excluded when calculating CMC). Three parameter adaptations are made in order to make ORB engage on the static background. First, Contrast Limited Adaptive Histogram Equalization (CLAHE) [12] is applied before feature detection to expose local structure. Secondly, the FAST (Features from Accelerated Segment Test) [13] corner threshold is lowered from 20 to 7 so that sufficient number of keypoints are yielded from muted background. Finally, we mask out detected UAVs with certain level of confidence (confidence threshold ≥ 0.3) before feature extraction, making sure that keypoints are drawn from the static background rather than moving objects. Confidence threshold needs to be chosen carefully, because low threshold could erase important background features, while high threshold could allow moving objects to be extracted as keypoints. When threshold is optimally set, even if some moving objects aren't masked, RANSAC will remove them as outliers. Implementation of CMC with ByteTrack leaves baseline tracker unchanged as it is implemented additively.

3. IMPLEMENTATION

Experimental setup consists of three parts. First is preparing dataset and creating train and validation splits. Second part is training and inference of detectors. Third and final part consists of evaluation for each combination of detectors and trackers.

3.1. Dataset and split

Dataset used for training and validation consists of 200 thermal infrared videos with resolution of 640×512 at 25 frames per second from Anti-UAV Track 3 training set. Official test set from Anti-UAV Track 3 does not provide annotations for full sequences, but only for the first frame, so it can't be used for tracking evaluation. Therefore, we are using 200 annotated sequences to create splits. Sequences are partitioned into 161 training and 39 validation sequences using density-stratified sampling, so that distribution of UAV density per frame (ranging from 0 to more than 40) is preserved across the splits. Targets are labelled with single class – "uav", and mean target area spans around 11×11 pixels.

3.2. Detector training and inference

Both detectors used in this paper are initialized from COCO pretrained weights and fine-tuned on the training split. Training for both detectors was scheduled for 50 epochs, but halted early once mAP@50 plateaued. YOLOv8 stopped after 15 epochs with best scores at epoch 4, and YOLOX stopped after 12 epochs with best scores at epoch 6. Both detectors were trained on native input resolution (640×512), with SGD optimizer and batch size of 16. Early convergence of mAP@50 for both detectors is an indication that detection accuracy saturates on small sized targets on thermal infrared images. Both detectors exhibit comparable accuracy on validation split. The mAP@50 score is approximately 0.95 for YOLOv8 and 0.94 for YOLOX, while the mAP@50-95 is approximately 0.501 for YOLOv8 and 0.511 for YOLOX. At inference, confidence threshold is held deliberately low at 0.1 and non-maximum suppression IoU of 0.45, retaining the low-scoring detections for ByteTrack's second stage association. Detections per sequence are exported and converted in MOT format, and all tracker share the same detection input so that tracking differences can be attributed to association alone. Training and inference are run on single NVIDIA T4 GPU.

3.3. Evaluation

We evaluate tracking performance with HOTA metrics family using TrackEval [14]. Along with HOTA, we report its factorization as detection part score (DetA) and association part score (AssA). We complement these with MOTA (Multi-Object Tracking Accuracy) [15], IDF1 [16], and count of identity switches made (IDSW). HOTA decomposition is important part of our analysis, as it lets us attribute each gain or loss to a specific stage in tracking pipeline, rather than just reporting aggregate score. All metrics are reported based on evaluation on 39 sequences from validation split.

Since we also evaluate real-time applicability, we also report inference speed and frames per second to measure throughput. We measure entire detection and tracking pipeline end to end, reporting detection and tracking speed separately as well as combined. First, we run a warm up of 20 frames in order to discard CUDA initialization and disk I/O. Speed and frame rate are averaged on 500 frames. As sequences in dataset are 25 frames per second, we take that number as real-time threshold. Benchmark, same as inference, is run on single NVIDIA T4 GPU.

4. EXPERIMENTS AND RESULTS

The performance of each detector-tracker combination on the 39-sequence validation split, evaluated using the metrics described in the previous chapter, is reported in the Table 1. When reading by column, table shows asymmetry in DetA and AssA scores. DetA score is nearly constant, corroborating the claim that detection is saturated in small object thermal infrared regime. However, identity metrics, and AssA which depends on identity, vary significantly across configurations.

For each configuration but one, DetA is nearly identical and lands between 65.89 and 69.46. When comparing two detectors at their best, they are almost indistinguishable, with YOLOv8 scoring 69.23 and YOLOX scoring 69.4. With two different detectors reaching same level of accuracy, and the fact that their training lasted only few epochs due to mAP@50 convergence, we can say that DetA saturation is product of small thermal infrared targets rather than detector capacity.

One configuration that stands out is YOLOv8 with $\tau = 0.5$ (track threshold). Raising τ from 0.3 to 0.5 lowers HOTA from 53.72 to 50.63, which is a result of DetA decline from 67.35 to 56.08, while rise of AssA is insignificant. This is the effect of starving sequences with low-confidence detections – tracker fails to assign new track as $\tau + 0.1$ threshold is too high. YOLOX, whose detector is better calibrated and native to ByteTrack, is less sensitive to τ change (HOTA stays around 57 – there is no substantial gain or loss). For all subsequent comparisons τ is fixed to 0.3.

HOTA variance is almost entirely governed by AssA, which ranges from 43.3 (YOLOv8 + ByteTrack) to 65.0 (YOLOX + ByteTrack + CMC). There is also variance in IDF1 and IDSW metrics, which are implicated by AssA and move along with it.

DeepSORT adds Appearance Re-ID – a learned appearance embedding used in association process. However, at this resolution and undefined texture due to thermal infrared images, appearance Re-ID does not improve association. On YOLOv8, DeepSORT and ByteTrack have identical AssA at 43.3, but DeepSORT has more identity switches (4368 compared to ByteTrack's 3389). On YOLOX, DeepSORT is worse both on HOTA (54.68 vs 57.32) and on AssA (44.92 vs 48.57).

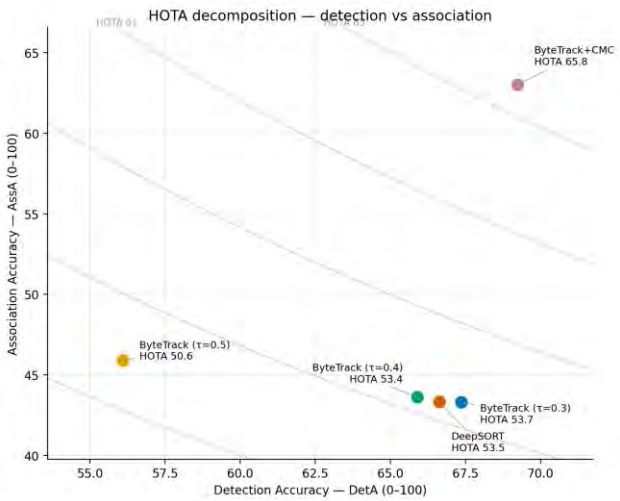

Figure 1. HOTA decomposition for YOLOv8 trackers

Most significant AssA gain is achieved by inserting camera motion compensation before association stage of the pipeline. It raises AssA by 19.68 points on YOLOv8 and 16.44 points on YOLOX, which results in the rise of HOTA by 10-12 points reaching the best results recorded in this experiment (YOLOX + ByteTrack + CMC has

Table 1. Performance of each detector-tracker combination

Detector	Tracker	HOTA	DetA	AssA	MOTA	IDF1	IDSW
YOLOv8	ByteTrack (τ=0.3)	53.72	67.35	43.3	84.92	61.29	3389
YOLOv8	ByteTrack (τ=0.4)	53.35	65.89	43.62	83.19	61.51	3137
YOLOv8	ByteTrack (τ=0.5)	50.63	56.08	45.92	70.63	58.52	2240
YOLOv8	ByteTrack+CMC	65.82	69.23	63.02	87.66	82.05	1134
YOLOv8	DeepSORT	53.49	66.63	43.33	83.16	61.62	4368
YOLOX	ByteTrack (τ=0.3)	57.32	68.22	48.57	85.68	66.97	2620
YOLOX	ByteTrack (τ=0.4)	57.40	68.30	48.66	85.83	67.16	2561
YOLOX	ByteTrack (τ=0.5)	57.02	67.36	48.66	84.74	66.90	2478
YOLOX	ByteTrack+CMC	66.97	69.46	65.01	87.80	83.47	993
YOLOX	DeepSORT	54.68	67.18	44.92	83.89	62.97	3824

HOTA score of 66.97). IDF1 has gains of 21 and 16 points, and identity switches are cut by around two-thirds (3389→1134 on YOLOv8 and 2620→993 on YOLOX). Figure 1 shows HOTA score breakdown in DetA-AssA space for YOLOv8 trackers. Each tracker sits at roughly the same DetA (except ByteTrack with τ = 0.5 which exhibits lower DetA). ByteTrack + CMC advances significantly on AssA axis while maintaining position on DetA axis, placing it in the top-right corner of the plot as the best performing tracker.

Figure 2 shows real-time throughput of each detector-tracker combination. The ones that have the best HOTA score run just above real-time threshold (25 FPS); YOLOv8 + ByteTrack + CMC pipeline runs at around 27 FPS, and YOLOX + ByteTrack + CMC around 28 FPS. CMC adds 15 ms per frame compared to plain ByteTrack, because global motion estimation runs once per frame. DeepSORT throughput collapses to around 3-4 FPS due to adding appearance embedding, which is significantly slower than other trackers, making appearance Re-ID both ineffective and impractical. Most efficient tracker is plain ByteTrack (76.8 FPS on YOLOv8 and 59.6 on YOLOX), but these gains come at the cost of worse association score.

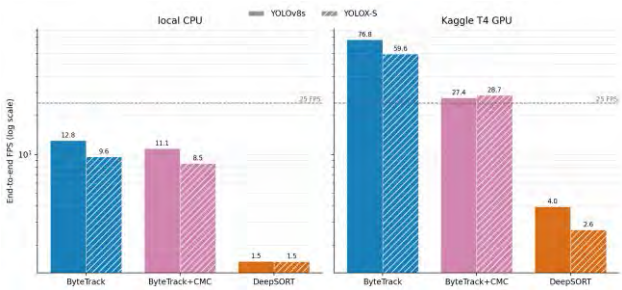

Figure 2. Real-time throughput on different hardware

5. ANALYSIS

In this section, we present key findings and discuss the conclusions drawn. We also explain the rationale behind each intervention and parameter change, as well as the reason behind its success or failure.

Two different detectors used in this research reached similar DetA score (69.23 and 69.46) and converged towards these values after only couple of epochs. Reason for this behaviour of detectors is attributed to the dataset. At box size 11×11 pixels, UAVs are represented with a few warm pixels against cool background. Due to thermal image nature, those bright pixels that represent UAV carry almost no internal structure which would normally be exploited by convolutional layers. Converging in small number of epochs indicate that COCO pretrained weights already scored relatively good, and needed just few epochs to converge. By combining the YOLOv8 detector with ByteTrack and comparing the results with those obtained using YOLOX + ByteTrack (YOLOX is native detector for ByteTrack) we achieved only slightly worse results, which supports the conclusion that detector choice is second-order factor.

This low contrast feature limits not only detection, but also appearance Re-ID feature in DeepSORT. The feature vectors carry little to no useful information. Consequently, consulting appearance cues before motion in the DeepSORT pipeline causes tracker to rely on noisy appearance embeddings, which not only fails to improve association, but also performs slightly worse in terms of AssA and the number of identity switches.

Another consequence of small-sized low-contrast targets is low detection confidence. That directly affects the ByteTrack's initialization of new tracks. Gate for initialization of new tracks is τ + 0.1, which for ByteTrack's default track threshold of τ = 0.5 requires detection confidence to be more than 0.6 to initialize a track. Default threshold was proven to be too high on this dataset, as some sequences contributed almost no true positives, collapsing DetA, MOTA and HOTA on YOLOv8. Lowering the τ to 0.4 and 0.3 is enough to recover scores on those sequences starved by high threshold, while not harming the healthy ones. Better-

calibrated detector YOLOX was proven to be insensitive on changing τ values from 0.3 to 0.5.

Addition of CMC is decisive intervention in this research. The constant-velocity Kalman filter is used to model motion in image coordinates and it doesn't take camera movement into consideration when modelling motion. If camera pans, entire frame of reference is shifted. As a result, camera displacement introduces a discrepancy between the predicted and detected bounding boxes. Consequently, IoU-based association fails, and new identity is assigned to the same object. Adding CMC to detection and tracking pipeline removes that discrepancy by estimating global inter-frame transform. It warps predicted states into the new frame, so that association stage has true object-only motion, not object and camera motion. Since CMC intervention only repairs coordinate frame when warping predicted states, almost all the gain is achieved in association stage (Figure 1).

6. CONCLUSION

In this research, we studied detection and tracking of multiple UAVs from thermal infrared videos in extreme small object regime. We used HOTA decomposition to attribute gains and losses to detection versus association. HOTA decomposition proved that, across combinations of two anchor-free detectors and several trackers, detection saturates regardless of the architecture, while association is the binding constraint. We found that, within small object thermal regime, appearance embeddings (appearance-based re-identification) do not improve over motion-only baseline, while sacrificing performance resulting in approximately 20 × lower throughput. Decisive intervention is adding camera motion compensation to baseline ByteTrack. Global motion estimator applied before association stage raises AssA by up to 20 points, cuts number of identity switches by roughly two-thirds, while maintaining a frame rate above the real-time threshold (YOLOv8 + ByteTrack + CMC run at 27.4 FPS, while video capture rate is 25 FPS), making this system deployable for real-time applications.

The conclusions drawn in this paper should not be considered applicable on UAV detection and tracking in a broader context. Rather, they should be interpreted in light of the specific characteristics of the dataset – thermal infrared low resolution pictures and small objects as targets. The motion model uses partial-affine global transformation. It ignores 3D motion and parallax, and only assumes planar camera motion as dominant. As these sequences mainly consist of distant aerial targets, this motion model is an adequate approximation, although it limits generality of our approach.

Abstract: *This paper presents an extended version of the XTTS model, a multilingual open source Text-to-Speech (TTS) model, with Serbian language Text-to-Speech Generation. This is achieved by fine-tuning the original XTTS model using open source CoquiTTS framework with a transcribed speech dataset of Serbian speakers. Apart from that, the tokenizer of the CoquiTTS framework is extended to support the Serbian language. The dataset used for fine-tuning in this paper is created using YouTube videos in the Serbian language with Creative Commons (CC) licenses. YouTube videos are transcribed with the Sagicc/faster-whisper-medium-sr model from Hugging Face, which is a fine-tuned version of the Faster Whisper Medium, Automatic Speech Recognition (ASR) model, for the Serbian language. Transcript generation is performed on a GPU with 6 GB of VRAM. Generated transcripts are checked and corrected manually. The dataset creation process resulted in about 140 hours of Serbian audio-transcribed data. The fine-tuning process is performed using the described dataset on a Kaggle notebook, using a session with a GPU P100 with 16 GB of VRAM, and it took around 25 hours for the whole training process. The final result is open source model capable of generating natural-sounding speech in the Serbian language.*

Keywords: *XTTS model, Text-to-Speech (TTS), Serbian language, dataset, fine-tuning*

1. INTRODUCTION

Text-to-speech (TTS), as an important field in Natural Language Processing (NLP) and generative AI, has witnessed an amazing revolution in the last five years following advancements in the sphere of deep learning. However, despite the presence of some truly wonderful and expressive synthetic voices in high-resource languages that are almost indistinguishable from humans, low-resource languages such as Serbian simply fails to keep that pace. It becomes even more evident when taking into account the fact that there is absolutely no good open-source TTS system available for Serbian. The main goal of this paper is creation of open-source TTS system that will bring closer Serbian TTS to TTS of high-resource languages.

Considering the fact that most modern TTS model's architectures has no corelation with its languages learning capabilities and that model capabilities in certain language solely depend on quality of training data, everything boils down to the fact that the main bottleneck is scarcity of data. Also, existing open source models used for other languages can be used for Serbian language as well. Main missing part of the puzzle for Serbian open-source TTS system is not model, its scarcity of open source Serbian audio datasets. That is secondary goal of this paper, creation of Serbian audio transcribed dataset. The main goal of the paper is achieved using created dataset in fine-tuning process on existing open source TTS model.

2. TTS MODEL

Following expansion of generative AI, researches applied new principles in the field of TTS. Most of the modern TTS models use LLM based architecture with adaptations for working with audio data. In recent years many different approaches and improvements of TTS model architecture emerged [1]. First and important step in building Serbian TTS system is selection of open-source TTS model that we used for fine-tuning training process.

2.1. TTS model selection

Models are searched on Hugging Face platform and following specifications are taken into account: size of the model, resource requirements, speed and quality of generated speech, multilinguality, usage amount, popularity and its documentation for fine-tuning process. XTTS v2 model is picked for this work which is also part

Corresponding author: S. Ivanović
E-mail: stefanivanovic1012@gmail.com
DOI: 10.5937/OTEH26086I

of CoquiTTS framework. Main reason for that is its multilinguality and support for 16 languages [2], which is displayed in Table 1 with data amount used for original XTTS training. This is important feature because in the original training process of the model, model learnt common patterns and rules for all languages, especially similar Slavic languages (Polish, Russian and Czech), which can be reused for Serbian language which leads to smaller dataset required for fine-tuning the model with Serbian data. Other reasons for picking XTTS v2 are its good documentation [3] for fine-tuning process and finaly capabilities to resource requirements ratio.

Table 1. Number of hours for each language in XTTS original training dataset [2]

Language	Hours
English	14513.1
German	3584.4
Spanish	1514.3
French	2215.5
Italian	1296.6
Portuguese	2386.8
Russian	147.1
Dutch	74.1
Czech	52.4
Korean	539.1
Hungarian	62.0
Japanese	57.3
Turkish	165.3
Arabic	240.9
Chinese	233.9
Polish	198.8
Total	27281.6

2.2. XTTS Architecture

The XTTS model is based on the TorToise model, with specific modifications to improve performance in multilingual training and zero-shot TTS (ZS-TTS), as well as to enhance training and speech generation speeds.

During the training process, the XTTS model is fed with text and the corresponding audio recording of that text, serving as the desired output for learning, along with a reference audio recording of the speaker, which allows the model to learn that specific speaker's voice characteristics. Upon entering the model, both audio recordings are converted into Mel spectrograms, which are subsequently processed through the model's blocks. Figure 5 shows a diagram of the XTTS model, illustrating the components of the XTTS architecture itself [2].

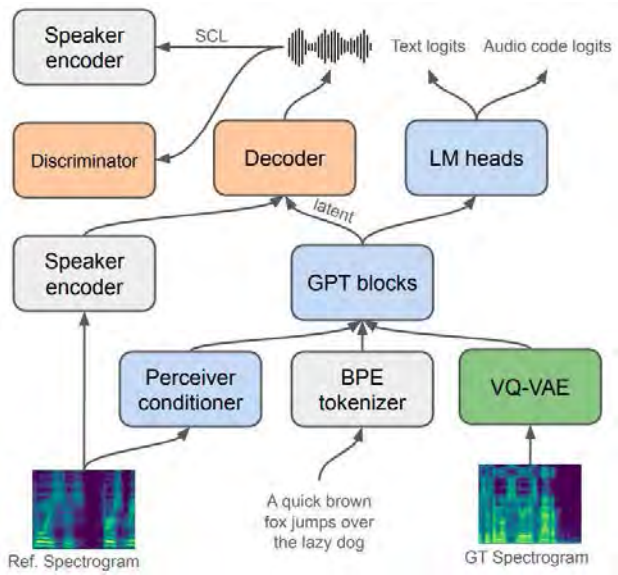

Figure 1. XTTS training architecture [2]

During the training process, the Mel-spectrogram corresponding to the audio associated with the input text is passed through a VQ-VAE (Vector Quantized-Variational AutoEncoder) block. The function of this block is to encode the input Mel-spectrogram into a more compressed form by encoding each spectrogram frame using a codebook containing 8,192 codes. The codebook is filtered to retain only the 1,024 most frequent codes; this represents one of the changes compared to the TorToise model. The authors state that this process has increased the model's expressiveness.

The input text is tokenized using a BPE (Byte Pair Encoding) tokenizer, the same one employed in GPT models. At the core of the model lies a GPT-2 block tasked with generating corresponding VQ-VAE codes from the text tokens. A reference Mel-spectrogram is processed through a conditional encoder block, yielding a vector representation of the speaker's voice characteristics extracted from that spectrogram. This vector representation is also fed into the GPT-2 block, thereby conditioning the generation of VQ-VAE codes on the specific speaker's characteristics. Finally, the model's output stage features a decoder based on the HiFi-GAN vocoder.

The authors state that, instead of VQ-VAE codes, they used the latent space of the GPT-2 model as input to the decoder, similar to the approach taken with the TorToise model. The reason for this is that VQ-VAE codes are highly compressed, and their direct use results in speech generation containing pronunciation errors. Decoder audio generation is also conditioned on the vector representation of a specific speaker's voice characteristics, obtained using the H/ASP model [2].

3. DATASET CREATION

As it is stated at the beggining of the paper, dataset for fine-tuning process should consists of transcribed audio data of Serbian speakers. The amount of that type of data for low resource languages in the open-source community

is even smaller than that of the plain textual data which is also lacking.

3.1. Challenges of Serbian language

Regarding the impact of the Serbian language's complexity on the development of TTS systems, pitch accents pose the greatest challenge among all its characteristics. In Serbian, words with the same written form can carry different meanings depending on their accentuation. From the perspective of a TTS system, there must be a mechanism to convert a word with a specific written form into the appropriate audio output with the correct accent. The system itself requires a mechanism to differentiate words, not merely based on their written form but also on context, in order to distinguish between words based on meaning and generate an accurately accented audio output. This was the reason for picking XTTS model, which is LLM based TTS system which has proven to have the best architecture for data with complex context inter relation.

3.2. Data preparation

In contrast to ASR models, which perform better when trained on noisy audio data, TTS models require audio recordings with minimal noise. This factor complicates the creation of a suitable dataset for this task. Given the scarcity of existing datasets that meet the necessary criteria, a suitable dataset was created specifically for this study. The crated dataset is named SLYIVA-D1 (Serbian Language YouTube Integrated Verbal Audio Dataset v1) and process of its creation is described in the following paragraphs.

Such a dataset can be created by recording audio content and transcribing it, or by collecting data from the Internet under licenses that permit the use of content for training artificial intelligence models without infringing on copyright. Inspired with YODAS (Youtube-Oriented Dataset for Audio and Speech) dataset [4], a second approach was used to create the necessary dataset. When dealing with dataset creation, especialy when data is collected from the Internet in various types and formats, data should be preprocessed in several steps (Figure 2), which are described in details in the following paragraphs.

Content from the YouTube platform bearing a Creative Commons (CC) license served as the source of raw data. Videos in Serbian with a Creative Commons (CC) license were selected [4]. The chosen videos consisted of lectures, speeches, or audiobooks to ensure the required audio quality and speaker voice consistency throughout the recording. The videos were downloaded in .webm format, and the filenames included speaker pseudonyms that were subsequently used to label the speakers for the training audio samples.

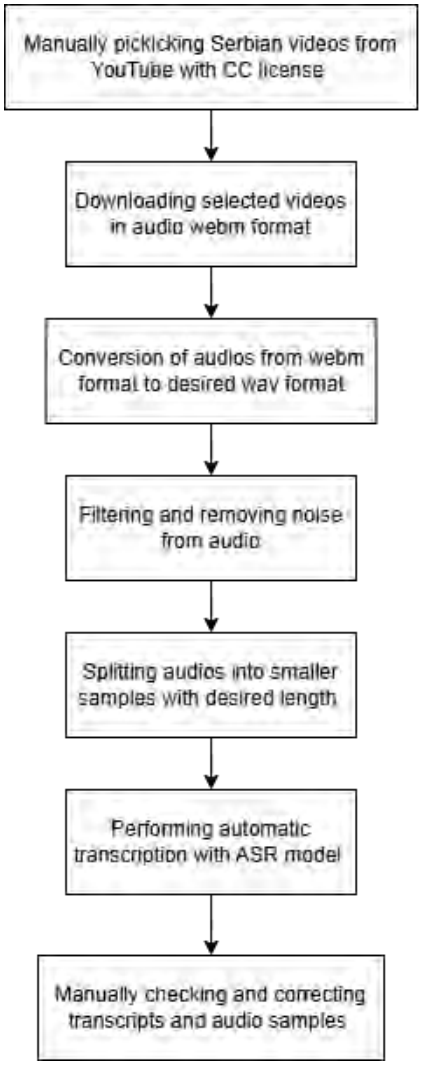

Figure 2. Diagram of steps applied in process of SLYIVA-D1 creation

As specified in the CoquiTTS documentation for the XTTS model, training audio recordings must be in .wav format with a sampling rate of 22,050 Hz, single-channel (mono), and a 16-bit sample depth. The training data format itself matches the format used in the LJSpeech public dataset for English (example in Figure 3 and Table 2). Regarding the characteristics of the data itself, achieving better results requires the data to possess the following attributes:

– Normal distribution of audio recording lengths (3-11s)
– Absence of noise and errors
– Speaker consistency across all audio recordings
– Good phoneme coverage for the specific language
– Naturalness of speech in the audio recordings [3]

wavs/audio_0002.wav	It's purpose is to synthesize speech from text data.	Milan
wavs/audio_0003.wav	Modern models are based on transformer architecture.	Marko

Conversion from .webm format to the required format was performed using the ffmpeg tool. Due to the presence of noise in the audio recordings, stemming from background noise, microphone self-noise, and the quality of the recording itself, noise reduction was performed. The first step in this process involved passing the audio recordings through a high-pass filter to eliminate low-frequency noise falling outside the human voice's frequency spectrum. A fifth-order Butterworth filter with a cutoff frequency of 80 Hz was used for this purpose. The Python library "noisereduction" was used to remove noise from the frequency spectrum overlapping with the speech spectrum. At the very end of this process, Root Mean Square (RMS) normalization was performed to eliminate any amplitudes exceeding 1.0 that might occur after using the "noisereduction" library.

After converting to the desired format and filtering out noise, the next step is to split large audio recordings into smaller segments to meet the duration requirements for the dataset samples (Figure 4). It is important that the segmentation process does not disrupt the speaker's flow of speech, specifically that the original audio is not cut off in the middle of a word. Ideally, the split points should coincide with longer pauses in the speech. Data regarding the timestamps of video segments containing speech were extracted using the Silero Voice Activity Detection (VAD) model via the `silero_vad` Python library. The resulting segments varied in length, since the XTTS fine-tuning process requires audio samples between 3 and 11 seconds long, shorter segments were merged to meet this requirement. Conversely, longer segments were subjected to further processing to shorten them. Such long segments typically occurred when the speaker had a prolonged speaking turn or when the Silero VAD model failed to detect the end of speech. In these instances, an alternative method was employed to further subdivide the segments. The Sagicc/faster-whisper-medium-sr Automatic Speech Recognition (ASR) model was used for transcription, a topic to be discussed further later on. This model was also employed to further segment longer audio clips. In addition to the transcript itself, the model generates corresponding timestamps for each word. These timestamps were used to identify longer pauses and select suitable cut points. This method is less reliable than using a VAD model because the generated timestamps are often offset by several tens or hundreds of milliseconds, which can result in a cut point being selected in the middle of a word. This is also the reason why this method was used as a secondary option. For this reason, the newly segmented parts were specially marked so that particular attention could be paid to them during the manual review and correction process.

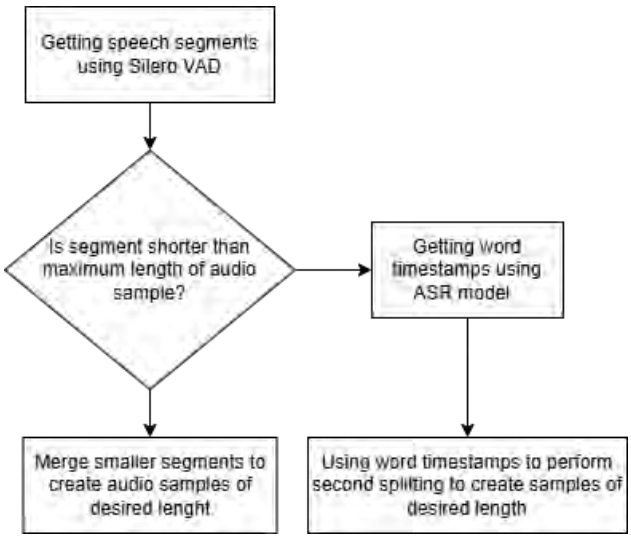

Figure 4. Flowchart of audio splitting process

Finally, once the audio recordings of the desired length were obtained, they needed to be transcribed. It is important to note that there is no open-source Automatic Speech Recognition (ASR) model capable of producing a perfectly accurate transcription of the Serbian language and that such accuracy can only be achieved through human effort. To accelerate the transcription process and minimize the amount of manual work required, a semi-automated approach was adopted. Initial transcription was performed using an ASR model, followed by a final manual review and error correction. For this purpose, the Sagicc/faster-whisper-medium-sr, model from the Hugging Face platform, was selected. This model is a fine-tuned version of Faster Whisper Medium, an ASR model with enhanced capabilities for the Serbian language achieved through fine-tuning [5]. Whisper models were developed by OpenAI and are based on the encoder-decoder Transformer architecture. Since this model architecture supports parallelization, efficient operation requires running it on a machine that supports the CUDA platform [6]. Transcript generation was performed on an NVIDIA GeForce RTX 4050 Laptop GPU with 6 GB of video memory and CUDA installed. The resulting transcript, paired with a pseudo-speaker name and the audio recording, constitutes a single dataset sample. The data was packaged in the expected LJSpeech format, as specified in the XTTS model documentation.

As it is mentioned in previous paragraph Sagicc/faster-whisper-medium-sr model is not perfect, it exhibits a Word Error Rate (WER) of 7.38% during transcription, as noted by its author [5]. Because of that, the audio samples were manually verified and corrected. Normalization of the transcripts was also required. To facilitate this, a simple GUI application was created using the gradio

Python library. The application allows for browsing the dataset samples and making any necessary modifications to them. A semi-automated approach was used for number normalization, the application suggests a normalized text to the user, though errors in grammatical case forms may occur and require user correction (Figure 5). Users also have the option to trim superfluous segments of the audio recording (such as stammers, background voices or sounds) that would otherwise compromise training quality (Figure 6). This marks the final step in the dataset creation process for this task, resulting in an audio dataset (in LJSpeech format) comprising approximately 140 hours of audio, complete with corresponding transcripts and speaker labels, which was subsequently used for fine-tuning.

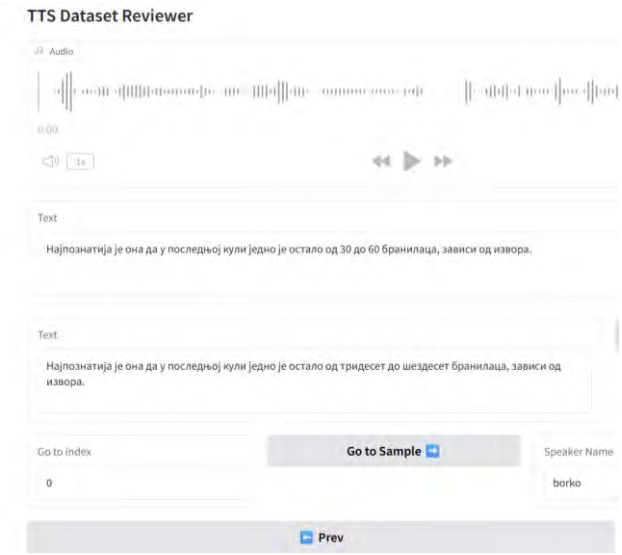

Figure 5. Part of the app screenshot showing its audio playing, transcript editing and number normalization suggestion functionalities

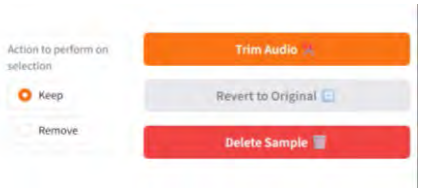

Figure 6. Part of the app screenshot showing its audio crop functionality

4. FINE-TUNING PROCESS

Since the core of the XTTS model is a GPT-2 model based on the Transformer architecture, its efficient use requires running the model on a GPU [2]. Fine-tuning the XTTS model requires a minimum of 16 GB of video memory. For this reason, the fine-tuning process for the Serbian language was carried out in a Kaggle notebook using a session with a P100 GPU featuring 16 GB of video memory. The example for extending the model used in this work was found on GitHub project anhnh2002/XTTSv2-Finetuning-for-New-Languages [7].

The project creator used this example to extend the XTTS model to the Vietnamese language [7]. As the project is no longer actively maintained, modifications were made to the project's scripts for the purposes of this study and to ensure compatibility with newer versions of Python and its libraries. Since the tokenizer rules within the CoquiTTS project are statically defined, the tokenizer itself was modified to support sentence tokenization in Serbian.

Subsequently, a script was executed to expand the XTTS model's vocabulary. Using a tokenizer, this script iterates through the entire text in the dataset and adds new tokens to the vocabulary. Finally, the training script was run with the following parameters:

– Number of epochs – 5
– Number of samples per training step – 4
– Gradient accumulation – 4
– L2 regularization – 0.01
– Learning rate – 0.000005

The fine-tuning process took approximately 25 hours, resulting in an XTTS model capable of generating natural speech in Serbian.

5. CONCLUSION

The primary product of this paper is fine-tuned XTTS capable of syntesizing Serbian speech. This version of model is not evaluated or compared with other Serbian open source or commercial TTS solutions. That can be done using subjective and objective methods which are not well established and standardized for Serbian language. Also every other model has its usage documentation which makes this task more time consuming and complex. This impose some future directions of development and research. Firstly, making standardized objective and subjective evaluation methods for Serbian TTS model, which than can be used to evaluate this as well as other TTS models.

Secondary product is SLYIVA-D1 dataset, which can be used for any other training or fine-tuning process of TTS or ASR models. For future work methodology applied for SLYIVA-D1 can be combined with YODAS methodologies [4] which can be used to create larger variant of this dataset.

PASSIVE TIME OF ARRIVAL BASED TARGET LOCALIZATION FOR RADAR SYSTEMS USING HYBRID METAHEURISTIC OPTIMIZATION ALGORITHMS

MAJA ROSIĆ

Abstract: *Accurate target localization of passive target remains a fundamental challenge in modern telecommunications and defense systems. Passive target localization based on time of arrival (TOA) measurements represents a critical capability in modern radar and military surveillance systems, enabling accurate position estimation without active signal emission by the target. Under line of sight (LOS) conditions, TOA measurements collected at spatially distributed receivers form a set of nonlinear equations whose solution defines the target position. The inherent nonlinearity and non-convexity of this problem make classical gradient-based solvers susceptible to local minima, motivating the use of hybrid metaheuristic optimization approaches. This paper investigates the application of hybrid optimization algorithms combining genetic algorithm (GA) with local search refinement for solving the passive TOA localization problem. Performance of considered algorithms is evaluated using root mean square error (RMSE) and compared against the Cramer-Rao lower bound (CRLB) as a theoretical benchmark. Results demonstrate that the hybrid approach consistently outperforms classical nonlinear least squares methods and conventional optimization algorithms in both accuracy and robustness, with hybrid optimization algorithm showing superior convergence in high-noise scenarios.*

Keywords: *passive localization, TOA, Genetic Algorithm, Hybrid optimization*

1. INTRODUCTION

The problem of determining the unknown position of a target from measurements collected at a set of spatially distributed receivers with known locations is a fundamental task in numerous military and civilian applications, including radar and sonar surveillance, electronic warfare, target tracking, navigation and wireless sensor networks [1], [2] .In passive localization the target does not cooperate with the localization system, and its position has to be inferred solely from the signals intercepted by the receivers, which makes the problem particularly relevant for modern defense and surveillance systems. The key requirement common to all of these applications is to estimate the target location as accurately as possible from a set of noisy measurements.

Depending on the available hardware, localization systems exploit different measurement types, such as the time of arrival (TOA), the time difference of arrival (TDOA), the received signal strength (RSS) or the angle of arrival (AOA) [3], [4]. This paper focuses on TOA-based localization, in which the position of the target is determined from the propagation times of the emitted signal to the receivers. Assuming synchronized receivers, each TOA measurement is converted into a range between the target and the corresponding receiver, defining a circle on which the target lies. TOA measurements are attractive because of their high ranging accuracy and the relatively simple required hardware [5].

Because the measured ranges are corrupted by noise, the localization task is naturally formulated as an optimization problem based on the least squares (LS) method, in which the sum of squared differences between the measured and the modelled ranges is minimized. LS estimators are commonly divided into linear least squares (LLS), which provide a closed-form solution after a suitable linearization, and nonlinear least squares (NLS), which operate directly on the original nonlinear model [6]. The weighted least squares (WLS) variant assigns to each residual a weight inversely proportional to its variance and yields an efficient closed-form estimate. However, the objective function of the NLS estimator is highly nonlinear and multimodal, so that conventional gradient-based optimization algorithms strongly depend on the initial solution and may converge to a local rather than to the global minimum.

To overcome this difficulty, researchers have proposed different hybrid variations of evolutionary algorithms [7]. Therefore, this paper proposes a hybrid metaheuristic optimization approach that combines a Genetic Algorithm (GA) with the Nelder-Mead (NM) local search method. The GA is a population-based stochastic optimizer inspired by natural selection [8] that explores the search space globally and is able to escape local minima, whereas the NM simplex method [9] efficiently refines a candidate solution without requiring derivative

Corresponding author: M. Rosić;
E-mail: mrosic@mas.bg.ac.rs

DOI: 10.5937/OTEH26087R

information. By hybridizing the two algorithms, the global exploration capability of the GA and the local exploitation efficiency of the NM method are combined into a single robust estimator, denoted GA-NM. The Cramer-Rao lower bound (CRLB) [10] is derived for the considered TOA model and used as a theoretical benchmark, while the root mean square error (RMSE) is adopted as the accuracy measure. The performance of the proposed GA-NM method is compared with the closed-form WLS estimator and with the standalone GA.

The remainder of the paper is organized as follows. Section 2 formulates the passive TOA localization problem. Section 3 presents the NLS and WLS formulations. Section 4 describes the proposed hybrid GA-NM method. Section 5 derives the CRLB for TOA measurements. Section 6 reports and discusses the simulation results, and Section 7 concludes the paper.

2. PROBLEM FORMULATION

Consider the two-dimensional (2D) passive localization of a single target under line-of-sight (LOS) conditions. The considered problem is consisting of a set of receivers $\mathbf{x}_i^r = \begin{bmatrix} x_i^r & y_i^r \end{bmatrix}^T \in \mathbb{R}^2, \forall i \in \{1,2,...,N\}$ with known coordinates, one transmitter $\mathbf{x}_t = \begin{bmatrix} x_t & y_t \end{bmatrix}^T$, and one passive target at unknown position $\mathbf{x} = \begin{bmatrix} x & y \end{bmatrix}^T \in \mathbb{R}^2$. Without the loss of generality, the transmitter is placed in the origin, i.e., $\mathbf{x}_t = \begin{bmatrix} 0 & 0 \end{bmatrix}^T$, as illustrated in Fig. 1. To determine the target position from passive TOA measurements, at least three receivers (N ≥ 3) are required.

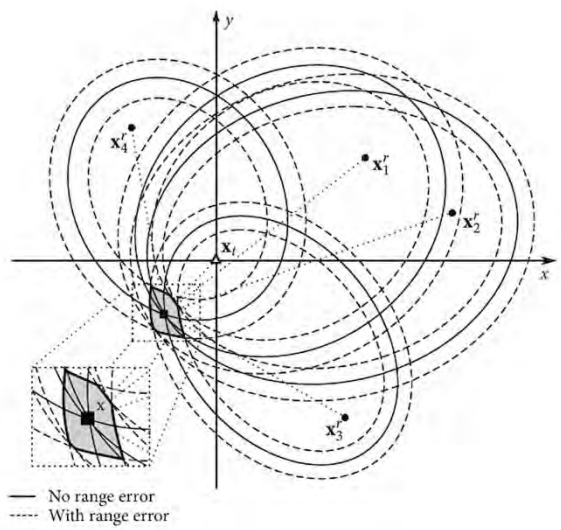

Figure 1. Geometrical model based on TOA.

In a passive target localization system, a signal is first transmitted and then reflected by the target upon arrival. The Time of Arrival (TOA) method considered in this work determines range measurements by exploiting the absolute travel time of the signal between the transmitter and the receivers. Assuming synchronized receivers, the range between the target and the i-th receiver is obtained by multiplying the measured propagation time by the speed of light c, as given in Eq. (1).

$$r_i = \frac{1}{c}\left(\|\mathbf{x}\|_2 + \|\mathbf{x} - \mathbf{x}_i^r\|_2\right) + \tilde{n}_i, \quad i = 1,2,...,N \tag{1}$$

where $\|\square\|_2$ denotes the Euclidian distance. In the absence of noise, this range equals the Euclidean distance between the target and the receiver, Eq. (2).

$$d_i = \sqrt{x^2 + y^2} + \sqrt{\left(x - x_i^r\right)^2 + \left(y - y_i^r\right)^2} \tag{2}$$

In practice the measurements are corrupted by noise, which is modelled as a set of independent zero-mean Gaussian random variables $\tilde{n}_i$ with variance σ^2. The measured range is therefore expressed by Eq. (3).

$$r_i = d_i + \tilde{n}_i \tag{3}$$

Each noiseless TOA measurement constrains the target to lie on a ellipse with foci at the corresponding receiver and transmitter. As shown in Fig. 1, in the absence of noise the target position is uniquely determined by the intersection of at least three such ellipses. When noise is present, the ellipses no longer intersect at a single point, and an appropriate optimization technique has to be employed in order to minimize the localization error.

3. LEAST SQUARE METHODS

Following the TOA measurement model, the localization problem is formulated as an NLS problem. The objective function $J_{NLS}(\mathbf{x})$ is defined as the sum of squared residuals between the measured and the modelled ranges, Eq. (4).

$$J_{NLS}(\mathbf{x}) = \sum_{i=1}^{N}\left(d_i - \|\mathbf{x} - \mathbf{x}_i^r\|\right)^2 \tag{4}$$

The optimal estimate of the target position is then obtained as the minimizer of this objective function over the feasible region, Eq. (5). Because the modelled range is a nonlinear function of the target coordinates, the objective function is non-convex and may exhibit multiple local minima.

$$\hat{x} = \arg\min_{\mathbf{x} \in \mathbb{R}^2} J_{NLS}(\mathbf{x}) \tag{5}$$

In order to obtain a closed-form estimate, the nonlinear model is linearized. Squaring the range equation yields the following

$$d_i^2 = \|\mathbf{x}\|^2 - 2\mathbf{x}_i^{rT}\mathbf{x} + \|\mathbf{x}_i^r\|^2 \tag{6}$$

Subtracting the equation of the reference receiver ($i = 1$) eliminates this common term and results in the linear relation given by Eq. (7).

$$\begin{aligned} 2x_i^r x + 2y_i^r y - 2r_i R^t = \left(x_i^r\right)^2 + \left(y_i^r\right)^2 - r_i^2 \\ -2n_i R^t + 2r_i n_i \end{aligned} \tag{7}$$

where $R^t = \|\mathbf{x}\|_2$. Collecting the equations for i = 2, ..., N leads to the matrix form of Eq. (8), where the matrix $\mathbf{A}$ and the vector $\mathbf{b}$ are defined in Eq. (9) and Eq. (11), respectively.

$$\mathbf{A}\boldsymbol{\theta} = \mathbf{b} + \mathbf{m}, \tag{8}$$

$$\mathbf{A} = 2\begin{bmatrix} x_1^r & y_1^r & -r_1 \\ \vdots & \vdots & \vdots \\ x_N^r & y_N^r & -r_N \end{bmatrix}, \tag{9}$$

$$\boldsymbol{\theta} = \begin{bmatrix} x & y & R^t \end{bmatrix}^T, \tag{10}$$

$$\mathbf{b} = \begin{bmatrix} (x_1^r)^2 + (y_1^r)^2 - r_1^2 \\ \vdots \\ (x_N^r)^2 + (y_N^r)^2 - r_N^2 \end{bmatrix}, \tag{11}$$

$$\mathbf{m} = 2\begin{bmatrix} (r_1 - R^t)n_1 & \cdots & (r_N - R^t)n_N \end{bmatrix}^T. \tag{12}$$

Based on the linear model, the WLS objective function is defined in Eq. (13), where $\mathbf{W}$ is a weighting matrix chosen as the inverse of the covariance matrix of the linearized measurement errors.

$$J_{WLS}(\mathbf{x}) = (\mathbf{A}\mathbf{x} - \mathbf{b})^T \mathbf{W} (\mathbf{A}\mathbf{x} - \mathbf{b}) \tag{13}$$

The corresponding closed-form WLS estimate is given by Eq. (14). The main advantages of the WLS estimator are its low computational cost and the absence of an initialization requirement. Nevertheless, the linearization introduces a bias, and the estimator does not attain sufficient accuracy in highly nonlinear, low-SNR scenarios, which motivates the use of the nonlinear formulation solved by metaheuristic optimization.

$$\hat{\mathbf{x}}_{WLS} = (\mathbf{A}^T\mathbf{W}\mathbf{A})^{-1}\mathbf{A}^T\mathbf{W}\mathbf{b} \tag{14}$$

4. HYBRID GA-NM METHOD

The proposed hybrid GA-NM method is described in this section in the context of passive TOA localization. The main idea behind hybridizing two optimization algorithms is to combine the advantages of each while mitigating their drawbacks. The GA is a powerful global optimizer that explores the search space by evolving a population of candidate solutions, whereas the NM method is an efficient local search technique that rapidly refines a given solution. In the proposed approach, the GA first identifies the region of the global optimum, after which the NM method fine-tunes the corresponding solution.

4.1. Genetic algorithm

The GA is a metaheuristic optimization method based on the mechanisms of natural selection and genetics [8]. To apply the GA to the NLS problem, the minimization in Eq. (4) is augmented with bound constraints, Eq. (15), where $\mathbf{x}^l$ and $\mathbf{x}^h$ denote the lower and upper bounds of the search region. The bound constraints prevent the objective function from being evaluated at infeasible points.

$$\min_{\mathbf{x}^l \le \mathbf{x} \le \mathbf{x}^h} J_{NLS}(\mathbf{x}) \tag{15}$$

The algorithm starts from a population of N_P individuals randomly generated within the feasible region, each representing a candidate target position, and evolves it through three genetic operators: selection, crossover and mutation. In the selection step, individuals are chosen for reproduction according to their fitness. Using roulette-wheel selection, the probability of selecting the i-th individual is proportional to its fitness, Eq. (16), so that individuals associated with lower objective-function values are more likely to be selected.

$$P_i = \frac{F_i}{\sum_{j=1}^{N_p} F_j}, \quad i = 1, \ldots, N_p \tag{16}$$

The crossover operator combines the information of two selected parents to produce offspring that inherit favorable traits from both, thereby driving the search towards promising regions. The mutation operator introduces small random perturbations into a limited number of individuals, maintaining population diversity and preventing premature convergence to local minima. The evolutionary process is repeated until a termination criterion is satisfied, for example a maximum number of generations or a sufficiently small relative change of the average population fitness between two consecutive generations, Eq. (17).

$$\left| \frac{f_{avg}^{(k)} - f_{avg}^{(k-1)}}{f_{avg}^{(k)}} \right| \le \varepsilon \tag{17}$$

4.2. Nelder-Mead method

The NM simplex method is a derivative-free local search technique for minimizing a function in an n-dimensional space [9]. It operates on a simplex of $n+1$ vertices, which for the considered 2D problem is a triangle. At each iteration the vertices are ordered according to their objective-function values, and the simplex is modified by means of four geometric operations: reflection, expansion, contraction and shrinkage. The reflection of the worst vertex through the centroid of the remaining vertices is computed by Eq. (18).

$$\mathbf{x}_r = \bar{\mathbf{x}} + \rho\left(\bar{\mathbf{x}} - \mathbf{x}_{n+1}\right) \tag{18}$$

If the reflected point improves the best value, the simplex is expanded according to Eq. (19); if the reflection does not yield an improvement, the simplex is contracted, Eq. (20); and if contraction fails, the simplex is shrunk towards the best vertex, Eq. (21). Here ρ, χ, γ and δ denote the reflection, expansion, contraction and shrinkage coefficients, respectively.

$$\mathbf{x}_e = \bar{\mathbf{x}} + \chi\left(\mathbf{x}_r - \bar{\mathbf{x}}\right) \tag{19}$$

$$\mathbf{x}_c = \bar{\mathbf{x}} + \gamma\left(\mathbf{x}_{n-1} - \bar{\mathbf{x}}\right) \tag{20}$$

$$\mathbf{x}_i = \mathbf{x}_1 + \delta(\mathbf{x}_i - \mathbf{x}_1), \quad i = 2,\ldots,n+1 \tag{21}$$

The process is repeated until the size of the simplex falls below a prescribed tolerance. The geometric illustration on 2D problem of different operations of the NM algorithm are shown in Figure 2.

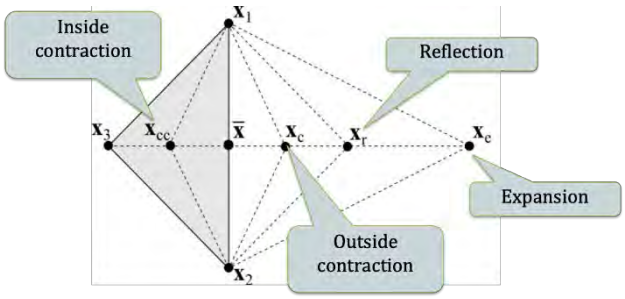

Figure 2. Geometrical illustration of NM method

4.3. Proposed hybrid GA-NM procedure

The proposed hybrid GA-NM method operates in two phases. In the global search phase, the GA evolves an initial population within the bound-constrained search region and, after a predefined number of generations, returns the best individual as an estimate of the region containing the global optimum. In the local refinement phase, this best individual is used to construct the initial simplex of the NM method, which then refines the solution through the geometric operations described above. If the refined solution does not satisfy the prescribed accuracy, a new GA cycle is initiated; otherwise the algorithm terminates and returns the final target-position estimate. By alternating between global exploration and local exploitation, the hybrid GA-NM method avoids the local minima that hamper purely local solvers and overcomes the limited final accuracy of the standalone GA, providing precise and robust localization even in noisy conditions. The pseudocode of the proposed hybrid GA-NM algorithm is shown in Figure 3.

5. CRAMER-RAO LOWER BOUND

The CRLB provides a theoretical lower bound on the variance of any unbiased estimator and is widely used to assess the efficiency of localization algorithms [10]. It is obtained from the inverse of the Fisher information matrix (FIM), and the position RMSE bound is given by the square root of the trace of the inverse FIM, Eq. (22).

$$\mathrm{CRLB}(\mathbf{x}) = \mathrm{trace}\left\{\mathbf{I}^{-1}(\mathbf{x})\right\} \tag{22}$$

For the considered passive TOA model with independent Gaussian range errors of variance σ^2, the FIM reduces to

$$\mathbf{I}(\mathbf{x}) = \begin{bmatrix} I_{xx} & I_{xy} \\ I_{yx} & I_{yy} \end{bmatrix}, \tag{23}$$

where the appropriate components are

$$\begin{aligned} I_{xx} &= \sum_{i=1}^{N} \frac{1}{\sigma_{ni}^2}\left(\frac{x - x_i^r}{\|\mathbf{x}-\mathbf{x}_i^r\|_2} + \frac{x}{\|\mathbf{x}\|_2}\right)^2, \\ I_{xy} = I_{yx} &= \sum_{i=1}^{N} \frac{1}{\sigma_{ni}^2}\left(\frac{x - x_i^r}{\|\mathbf{x}-\mathbf{x}_i^r\|_2} + \frac{x}{\|\mathbf{x}\|_2}\right) \\ &\quad \times\left(\frac{y - y_i^r}{\|\mathbf{x}-\mathbf{x}_i^r\|_2} + \frac{y}{\|\mathbf{x}\|_2}\right), \\ I_{yy} &= \sum_{i=1}^{N} \frac{1}{\sigma_{ni}^2}\left(\frac{y - y_i^r}{\|\mathbf{x}-\mathbf{x}_i^r\|_2} + \frac{y}{\|\mathbf{x}\|_2}\right)^2. \end{aligned} \tag{24}$$

The CRLB therefore depends both on the measurement noise level and on the geometric configuration of the receivers relative to the target.

Algorithm 1 Hybrid GA–NM Method for Target Localization

Require: Search bounds $[\mathbf{x}^l, \mathbf{x}^h]$, population size N_p, max generations $G_{\max}$, NM coefficients $\rho, \chi, \gamma, \delta$, accuracy threshold ε, max restarts $K_{\max}$
Ensure: Target position estimate $\hat{\mathbf{x}}$
Initialize restart counter $k \leftarrow 0$
Initialize best solution $\hat{\mathbf{x}} \leftarrow \emptyset$
repeat
  $k \leftarrow k + 1$ ▷ *Phase 1: Global Search via GA*
  Initialize population $\mathcal{P} = \{\mathbf{x}_1, \ldots, \mathbf{x}_{N_p}\}$ uniformly within $[\mathbf{x}^l, \mathbf{x}^h]$
  for $g = 1$ **to** $G_{\max}$ **do**
    Evaluate objective $J_{NLS}(\mathbf{x}_i)$ for all $\mathbf{x}_i \in \mathcal{P}$
    Select parents via roulette-wheel selection ▷ Eq. (14)
    Apply crossover and mutation operators to generate offspring
    Replace population $\mathcal{P}$ with new generation
  end for
  $\mathbf{x}^* \leftarrow \arg\min_{\mathbf{x}_i \in \mathcal{P}} J_{NLS}(\mathbf{x}_i)$
  ▷ *Phase 2: Local Refinement via Nelder–Mead*
  Construct initial simplex $\mathcal{S}$ centered at $\mathbf{x}^*$
  repeat
    Order simplex vertices:
    $J_{NLS}(\mathbf{x}_1) \leq \cdots \leq J_{NLS}(\mathbf{x}_{n+1})$
    Compute centroid $\bar{\mathbf{x}}$ of all vertices except $\mathbf{x}_{n+1}$
    Attempt **reflection**: $\mathbf{x}_r$

6. SIMULATION RESULTS

This section presents the results of numerical simulations carried out to evaluate the localization performance of the proposed hybrid GA-NM method against the closed-form WLS estimator, the standalone GA, and the derived CRLB. The considered scenario comprises five receivers placed at the known coordinates [200, 300], [1500, 100], [120, 1500], [1510, 1500] and [700, 900] m, while the true target position is set to [300, 500] m. The GA uses a population of 40 individuals, a crossover probability of 0.9 and a mutation probability of 0.12, while the relative measurement-noise level is controlled through the signal-to-noise ratio (SNR), with the noise standard deviation given by $\sigma = \sigma_0 \cdot 10^{(-SNR/20)}$. The localization accuracy is quantified by the RMSE, Eq. (25), evaluated over M = 1000 independent Monte Carlo runs, where $\hat{x}(n)$ denotes the estimate obtained in the n-th run.

$$\mathrm{RMSE} = \sqrt{\frac{1}{M}\sum_{n=1}^{M}\|\hat{\mathbf{x}}(n) - \mathbf{x}\|^2} \tag{25}$$

Fig. 4 illustrates the convergence behaviour of the GA for a representative noisy realization, showing the best objective-function value as a function of the generation number. The objective value decreases rapidly during the first generations, as the population concentrates around the global optimum, and subsequently flattens. This confirms that the GA quickly locates the region of the global minimum but exhibits a slow final convergence, which motivates the local refinement performed by the NM method in the proposed hybrid scheme.

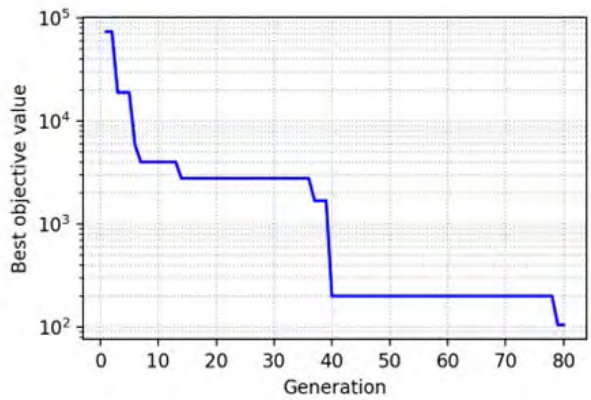

Figure 4. Convergence of the genetic algorithm for a representative noisy realization.

Fig. 5 shows the RMSE of the considered algorithms, expressed as 10 log(RMSE), as a function of the SNR. The proposed hybrid GA-NM method attains the CRLB over the entire range of SNR values, demonstrating its accuracy and robustness in different noise conditions. The closed-form WLS estimator follows the CRLB closely but remains slightly above it, particularly in the low-SNR region, where the linearization bias is more pronounced. In contrast, the standalone GA reaches the global region but is unable to refine the solution to the required precision, exhibiting an error floor at moderate and high SNR. This clearly demonstrates that the local refinement provided by the NM method is essential for achieving CRLB-level accuracy.

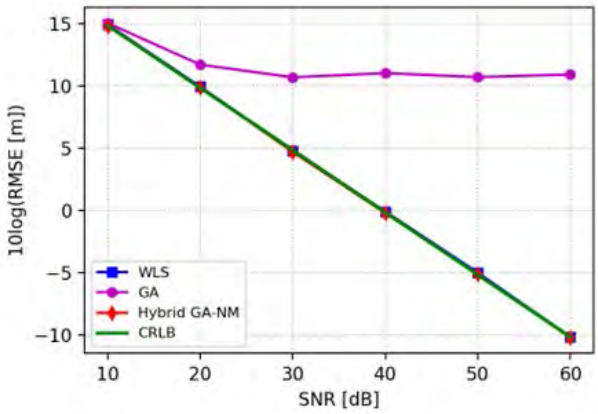

Figure 5. Comparison of RMSE versus SNR levels for the considered algorithms.

To further assess the localization performance, the cumulative distribution functions (CDFs) of the localization error are compared at two SNR levels, 10 dB and 50 dB, in Figs. 6 and 7, respectively. At SNR = 10 dB (Fig. 4), the hybrid GA-NM method achieves the highest CDF values across the whole error range, indicating that it produces small localization errors more frequently than the other methods, while the WLS estimator performs only marginally worse and the standalone GA exhibits a slightly heavier tail.

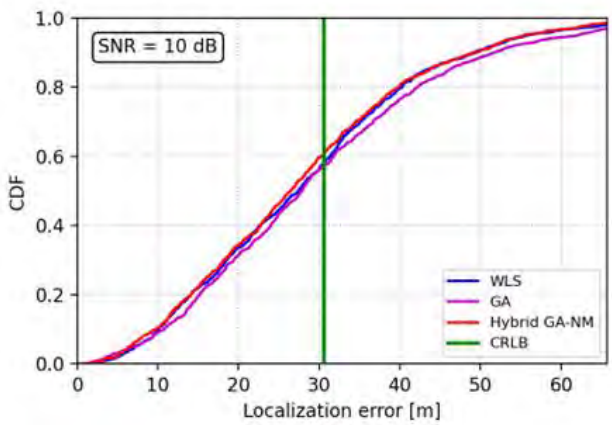

Figure 6. CDFs of the localization error of different algorithms for SNR = 10 dB.

At SNR = 50 dB (Fig. 7), both the hybrid GA-NM and the WLS estimators yield sub-meter localization errors that cluster around the CRLB, whereas the error of the standalone GA lies well outside the displayed sub-meter range, in agreement with the error floor observed in Fig. 5. These results confirm that the proposed hybrid GA-NM method offers superior accuracy and robustness compared with the conventional WLS estimator and the standalone GA.

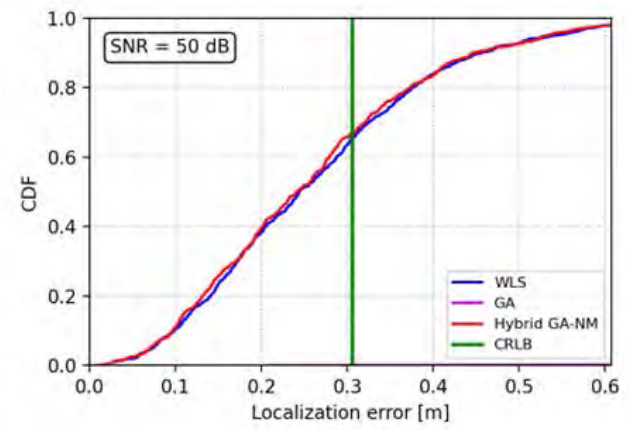

Figure 7. CDFs of the localization error of different algorithms for SNR = 50 dB.

7. CONCLUSION

This paper has addressed the passive TOA-based localization of a target from range measurements collected at several receivers with known positions. The localization problem has been formulated as a nonlinear least squares optimization problem, and a hybrid metaheuristic method combining a Genetic Algorithm with the Nelder-Mead local search has been proposed to solve it. The GA performs the global exploration of the multimodal objective function, while the NM method efficiently refines the resulting solution, so that the hybrid GA-NM estimator combines the advantages of both techniques.

The CRLB has been derived for the considered TOA model and used, together with the RMSE and the CDF of the localization error, to evaluate the performance of the proposed method. The simulation results show that the hybrid GA-NM method attains the CRLB over a wide range of SNR values and consistently outperforms both the standalone GA, which suffers from a limited final accuracy, and the closed-form WLS estimator, whose linearization bias degrades the accuracy at low SNR. The proposed method therefore provides accurate and robust passive localization in noisy environments.

Future work will focus on extending the proposed approach to three-dimensional localization, to scenarios involving multiple targets and non-line-of-sight propagation, and on incorporating adaptive strategies for tuning the parameters of the metaheuristic algorithm.

Abstract: *This paper describes in detail a steganography method that embeds information into the difference between neighboring pixel values. The efficiency analysis of the method was performed through the aspects of imperceptibility, security, robustness, capacity, and complexity. Imperceptibility was analyzed using objective image quality assessment methods. For security analysis, statistical imperceptibility based on histogram were employed. Robustness was analyzed through the accuracy of extracting the embedded message at a given embedding capacity and under the influence of additive noise of different intensities. Capacity was measured depending on the characteristics of the cover image, while the complexity of the hiding algorithm was determined by measuring the information embedding execution time. The obtained results were compared with the characteristics of a steganography method based on least significant bit substitution. It was shown that neither of the two methods demonstrated superior efficiency across all considered criteria. Analysis of the obtained results for all cover images showed that imperceptibility and security favored the method based on pixel value differences, while robustness, capacity, and complexity favored the method based on least significant bit substitution. The method that should be used in practical applications depends on the requirements of the transmission system. It is necessary to find a compromise between the advantages and disadvantages of the considered methods, especially since the differences in performance for individual characteristics may not necessarily be significant. This requires an appropriate selection of the cover image, which is an important factor in steganography systems.*

Keywords: *pixel value differences, cover image, imperceptibility, capacity*

1. INTRODUCTION

In the modern digital environment, the rapid expansion of the Internet and the growing exchange of sensitive data have significantly increased the demand for secure communication. In this context, steganography and cryptography play a crucial role in information protection. Cryptography techniques rely on encrypting data and transmitting it in an unreadable form, which may draw the attention of unauthorized users [1]. In contrast, steganography aims to conceal the very existence of a secret message by embedding data into appropriate cover media, thereby reducing the likelihood of attracting attention and revealing the communication [2]. The combined application of cryptography and steganography can further enhance the level of data security.

The term steganography originates from the Greek words stegos, meaning to "to conceal" or "covered", and graphia, meaning "writing". Thus, the term literally translates as "concealed writing".

The origins of steganography date back to ancient times, when secret messages were concealed using various methods, such as tattooing or invisible ink. With the development of digital technologies, steganography has undergone a significant transformation and is now primarily based on embedding information within various types of digital cover media [3].

The cover media used to conceal secret messages or files may include various types of digital content, such as images, audio recordings, video sequences, and text documents. Among these, digital images are particularly well suited for steganography applications due to their widespread use and their ability to accommodate imperceptible modifications [4]. In this study, a digital image is selected as the cover medium for embedding hidden information.

The key performance aspects of steganography include imperceptibility, security, robustness, embedding capacity, and computational complexity. An important

DOI: 10.5937/OTEH26088K

question is which of these aspects is the most significant when evaluating the effectiveness of different steganography techniques [5]. Since it is not possible to simultaneously optimize all of these performance criteria, an appropriate trade-off must be established among them. Consequently, the suitability of a particular steganography method depends on the requirements and constraints of the intended application.

The objective of this study is to provide a comprehensive analysis of the Pixel Value Differencing (PVD) method and to compare its performance characteristics with those of the Two Least Significant Bits (2-LSB) method in order to identify their respective advantages and limitations.

The remainder of this paper is organized as follows. Section 2 describes the methods and techniques employed in the conducted study. Section 3 presents and discusses the obtained results, while Section 4 summarizes the main conclusions.

2. METHODOLOGY

2.1. Characteristics of the Cover Images and the Secret Message

For the purposes of this study, a dataset consisting of 50 images obtained from a publicly available image database was used [6]. All selected images have a resolution of 1920×1080 pixels and were employed as cover images for embedding the secret message. Prior to the embedding process, all images were converted to grayscale, in which each pixel is represented by a single 8-bit intensity value within the range [0-255].

The methods were compared from the standpoint of maximum embedding capacity. A fixed binary sequence of 4,147,200 bits was used as the secret message, corresponding to the maximum embedding capacity of the 2-LSB method for a 1920×1080 grayscale image. The same payload was applied to the PVD method, whose embedding capacity depends on the characteristics of each individual cover image.

2.2. Description of the PVD Method

In this study, the PVD method proposed in [7] was employed. In this method, data are embedded into the differences between the intensity values of neighboring pixels, enabling secret information to be concealed within the cover image. The magnitude of the pixel-value difference determines the amount of data that can be embedded. Small differences between adjacent pixel values correspond to smooth regions of the image and therefore allow only a limited amount of information to be embedded. In contrast, larger differences, typically found in high-contrast regions or along edges, provide a higher embedding capacity while maintaining the imperceptibility of the embedded information.

In this study, an approach based on forming pairs of adjacent pixels along the image rows is adopted. First, the image is partitioned into pairs of neighboring, non-overlapping pixels. For each pixel pair, denoted by p_i and p_{i+1}, the difference is calculated as:

$$d = p_{i+1} - p_i, \tag{1}$$

as well as its absolute value $|d|$, which can take values in the range 0 to 255. The absolute values of the differences are classified into predefined ranges R_k, where $k = 1, 2, ..., n$. The lower and upper bounds of the k-th range are denoted by l_k i u_k, respectively. The minimum value of the first range is $l_1 = 0$, while the maximum value of the last range is $u_n = 255$. The width of the k-th range, denoted by W_k is determined by the following expression:

$$W_k = u_k - l_k + 1. \tag{2}$$

Here, the width of each range is chosen as a power of two. Accordingly, the following ranges are defined: [0-7], [8-15], [16-31], [32-63], [64-127], and [128-255]. Consequently, ranges corresponding to small pixel-value differences have narrow widths and represent smooth image regions. In contrast, ranges associated with large differences are assigned wider intervals and correspond to edge regions. The purpose of this range selection is to achieve greater visual imperceptibility. The number of bits embedded into the difference of each pixel pair depends on the range to which the difference belongs. It is denoted by t and determined according to the following expression:

$$t = \log_2(W_k). \tag{3}$$

Then, a substring consisting of t bits is extracted from the secret message. This binary substring is converted to the corresponding decimal value, denoted by b. New difference d' is calculated as

$$d' = \begin{cases} l_k + b, & d \geq 0 \\ -(l_k + b), & d < 0 \end{cases} \tag{4}$$

The goal is to compute new pixel values so that their difference is exactly equal d'. After determining the new difference d', the value m is calculated, which represents the difference between the new and original pixel difference:

$$m = d' - d. \tag{5}$$

Based on the value of m, the modification of pixel values is performed and depends on the parity of the original difference d. If the value $m/2$ is not an integer, rounding is applied so that one part of the change is rounded down to a smaller integer and the other to a larger integer. This ensures that the new difference between the modified pixels is equal to the value d', while the total change is distributed almost evenly between the pixels. This reduces image distortion, achieving a higher level of imperceptibility. The new pixel values are obtained by applying the following relations:

$$\left(p_i', p_{i+1}'\right) = \begin{cases} p_i - \left\lceil \frac{m}{2} \right\rceil,\ p_{i+1} + \left\lfloor \frac{m}{2} \right\rfloor, & \text{if } d \text{ is odd} \\ p_i - \left\lfloor \frac{m}{2} \right\rfloor,\ p_{i+1} + \left\lceil \frac{m}{2} \right\rceil, & \text{if } d \text{ is even} \end{cases} \tag{6}$$

During the computation of the new pixel values, it is possible for one or both values to fall outside the valid

intensity range. In the original approach, problematic blocks are excluded from the embedding process [7]. In contrast, some modifications of the PVD method employ various correction procedures that involve adjusting pixel values to bring them back into the allowable range [1].

In this work, pixel-value shifting correction is applied, in which both pixels are shifted by the same amount to bring their values back into the permissible range. In this way, the difference between their values remains unchanged. If one of the values is less than 0, both pixel values are increased by the corresponding amount. If one of the values exceeds 255, both pixel values are decreased by the amount of the overflow. This procedure avoids discarding pixel pairs while preserving the difference that carries the embedded information. The correction can be formally expressed as:

$$\Delta = \begin{cases} -\min(p_i', p_{i+1}'), & \text{if } \min(p_i', p_{i+1}') < 0, \\ 255 - \max(p_i', p_{i+1}'), & \text{if } \max(p_i', p_{i+1}') > 0, \\ 0, & \text{otherwise.} \end{cases} \quad (7)$$

The corrected pixel values are then given by:

$$p_i'' = p_i' + \Delta, \quad (8)$$

$$p_{i+1}'' = p_{i+1}' + \Delta. \quad (9)$$

The extraction process follows the same image processing principle as the secret message embedding process, processing the image sequentially in pairs of pixels. The absolute value of the difference d'' between adjacent pixels of the stego image is calculated, determining the range to which it belongs and the number of bits embedded in the observed pair of pixels. The value b, that is, the part of the message that was inserted into the corresponding pair of pixels, is extracted based on the following expression:

$$b = d'' - l_k. \quad (10)$$

When extracting a secret message from a stego image, it is not necessary to use the original image for comparison.

The following example illustrates the secret message embedding process. Let $(p_i, p_{i+1}) = (100, 70)$ be a pair of cover image pixels. The difference between the pixels is

$$d = p_{i+1} - p_i = 70 - 100 = -30.$$

The absolute value of the difference $|d| = 30$ belongs to the interval [16-31]. The width of the interval is:

$$W_k = u_k - l_k + 1 = 31 - 16 + 1 = 16,$$

so the number of bits that can be embedded is equal to:

$$t = log_2 16 = 4.$$

Assume that 1100 are the next four bits of the message to be embedded. Their decimal value is $b = 12$. Since $d < 0$, then:

$$d' = -(l_k + b) = -(16 + 12) = -28.$$

Therefore, the new difference is:

$$m = d' - d = -28 - (-30) = 2.$$

Since |d|=30 is even, the resulting pair of stego pixels is obtained according to Equation (6): $(p_i', p_{i+1}') = (99, 71)$.

During the extraction process, the resulting pair of stego pixels is used $(p_i', p_{i+1}') = (99, 71)$. The absolute value of the difference between the stego pixels is $|d''| = 28 \in$ [16-31]. The number of extracted bits is determined according to the previously presented equations. Therefore:

$$W_k = u_k - l_k + 1 = 31 - 16 + 1 = 16,$$

$$t = \log_2 16 = 4.$$

The decimal value of the embedded bits is:

$$b = |d''| - l_k = 28 - 16 = 12,$$

which, converted into a binary record of 4 bits length, gives 1100.

2.3. 2-LSB Method

The LSB method is one of the fundamental and most commonly used techniques in spatial domain steganography. This method involves replacing the least significant bits of the cover image pixel with the corresponding bits of the secret message [8]. It is a basic method and most often is part of hybrid methods, as well as in implementations of message hiding in transform domains, such as the Discrete Cosine Transform (DCT) or the Discrete Wavelet Transform (DWT). In order to compare the characteristics with the PVD method, a 2-LSB steganography method was implemented. In this variant of the LSB method, 2 bits of the secret message are embedded in each pixel. In previous comparisons, the case where the LSB method changes exactly one bit (the least significant one) has been the primary focus [9].

2.4. Measurement Methods

In order to evaluate the effectiveness of information hiding from the aspects of imperceptibility, robustness, security, capacity, and complexity, appropriate objective metrics were used.

The imperceptibility of the embedded secret message was evaluated using the following objective image quality assessment metrics: Peak Signal-to-Noise Ratio (PSNR) [10], Structural Similarity Index Metric (SSIM) [11], and Additive Impairments and Detail Losses Metric (ADM) [12]. These metrics were used to determine the degree of similarity between the cover image and the stego image.

The robustness was analyzed against Additive White Gaussian Noise (AWGN) in the context of a potential jamming attack. Robustness assessment was performed using the Bit Error Rate (BER). The metric represents the ratio between the number of incorrectly extracted bits and the total number of embedded bits, thereby evaluating the success of the hidden message reconstruction.

The security of the analyzed methods is confirmed by statistical imperceptibility. For analysis purposes, the histograms of the cover and stego images were used. The degree of histogram similarity was determined using the histogram correlation metric and the Root Mean Square Error (RMSE). Based on the obtained values, the extent of changes in the pixel intensity distribution introduced during the embedding process was assessed. In addition to

histogram-based analysis, security should also be considered from the aspect of steganalysis. As the considered methods are fundamentally different, different steganalysis techniques will show greater efficiency on the method for which they were originally developed [13].

The computational complexity of the algorithm was estimated based on the time required to embed the secret message into the cover image. The execution time was measured using corresponding MATLAB functions on a computer equipped with an Intel Core i7-1255U processor, 16 GB of RAM, and the Microsoft Windows 10 Pro operating system.

The capacity of a method represents the maximum amount of data that can be embedded in a cover image. It is determined by calculating the number of bits that can be embedded in the pixels of the cover image.

3. RESULTS ANALYSIS

Figures 1, 2, and 3 present the results obtained using the PSNR, SSIM, and ADM metrics for a dataset of 50 cover images. The PSNR results shown in Figure 1 indicate that the 2-LSB method achieves nearly constant values of approximately 44 dB for all tested images, whereas the PVD method yields lower values. It can be observed that the PSNR values of the PVD method vary depending on the characteristics of the cover image, ranging from approximately 35 dB to 43 dB. Since higher PSNR values indicate a lower difference between the cover and the stego image, it can be concluded that the 2-LSB method provides better imperceptibility.

The SSIM results presented in Figure 2 show that both methods achieve values close to 1, indicating a high degree of similarity between the cover and the stego image. However, the PVD method yields slightly higher SSIM values, suggesting better preservation of the image's structural characteristics after the embedding process.

The results obtained using the ADM metric are presented in Figure 3. According to this metric, the PVD method achieves higher values for most of the observed images. These results indicate better image quality preservation and greater similarity between the cover and stego image when the PVD method is applied.

Analyzing the obtained results, we came to the conclusion that the choice of metric affects the imperceptibility of the method. This observation can be explained by the fact that different metrics evaluate different aspects of image quality.

Figure 4 shows the BER values obtained using the 2-LSB and PVD methods as a function of the variance of the AWGN (σ^2_{AWGN}). Lower BER values indicate greater robustness of the method, while a BER value of 0 indicates accurate and complete reconstruction of the embedded secret message. The values of σ^2_{AWGN} are calculated on the pixel range from 0 to 255.

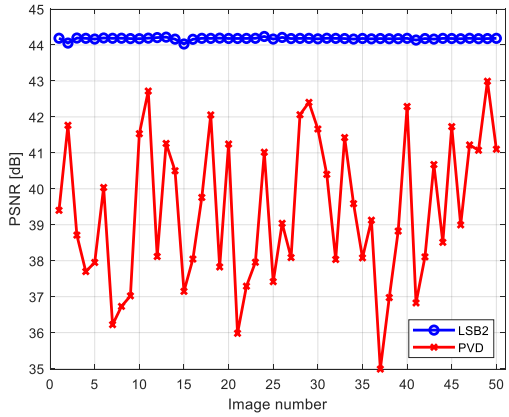

Figure 1. PSNR values for 2-LSB and PVD method

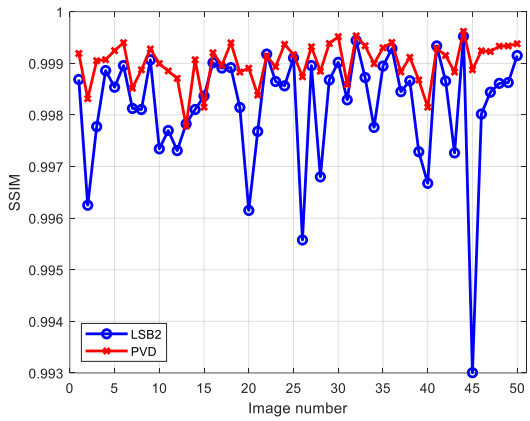

Figure 2. SSIM values for 2-LSB and PVD method

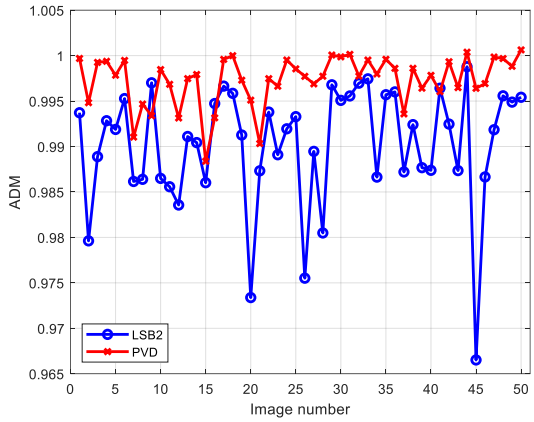

Figure 3. ADM values for 2-LSB and PVD method

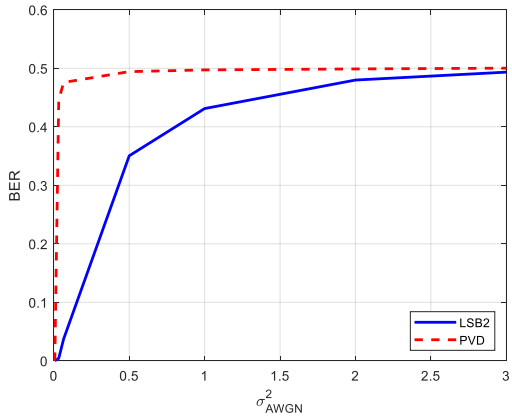

Figure 4. BER values for 2-LSB and PVD method

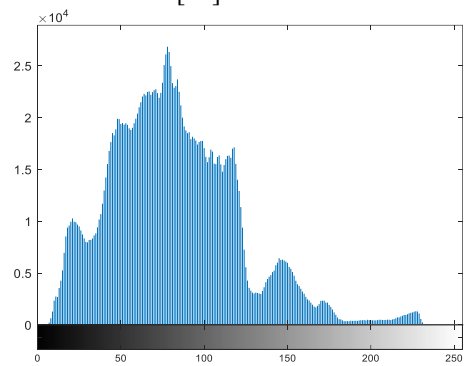
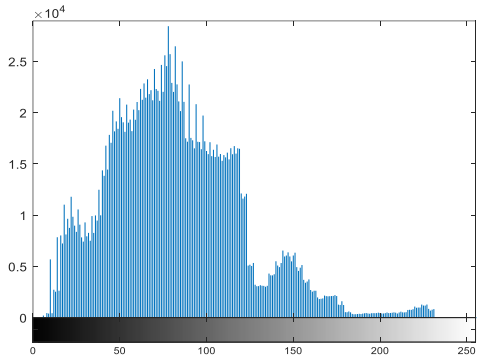
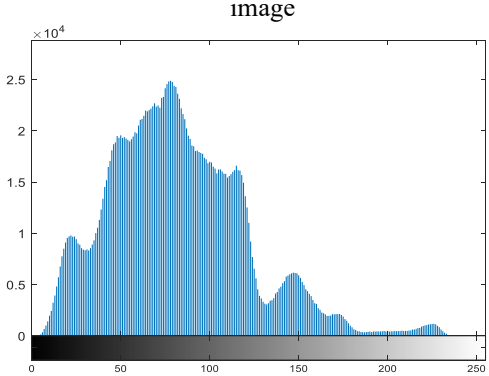
As shown in the graph, both methods achieve a BER of 0 in the absence of AWGN. It can be observed that the 2-LSB method exhibits a gradual increase in BER as the AWGN intensity increases, whereas the BER of the PVD method rises sharply even at low AWGN levels and approaches a value of 0.5. At higher AWGN levels, both methods produce BER values of approximately 0.5, making reliable reconstruction of the embedded secret message impossible. These results indicate that the 2-LSB method is more robust against AWGN than the PVD method, but both methods are highly error prone even at low noise levels. The obtained results are in accordance with previous research [14].



(a) Histogram of the cover image



(b) Histogram of a 2-LSB stego image



(c) Histogram of PVD stego image

Figure 5. Histograms of the cover and stego images

The histogram of the cover image is shown in Figure 5.a, while the histograms of the stego images obtained using the 2-LSB and PVD methods are presented in Figures 5.b and 5.c, respectively. The histograms shown correspond to one of the images from the dataset and illustrate the distribution of pixel intensity, where the horizontal axis represents the pixel intensity and the vertical axis represents the number of pixels. The histogram shown in Figure 5.b exhibits more pronounced deviations in the distribution of pixel intensity, manifested by the presence of noticeable peaks and valleys. In contrast, the histogram in Figure 5.c retains a shape that is more similar to the shape of the cover image. These observations are further confirmed by the histogram correlation and RMSE results shown in Table 1.

Correlation represents a measure of similarity between the histograms of the cover and stego images. Correlation values closer to unity indicate greater similarity of pixel intensity distributions. Based on the mean correlation values, 0.9539 for the 2-LSB method and 0.9796 for the PVD method, it can be concluded that PVD method achieves values closer to unity, and therefore the histograms are more similar to those of the cover images. RMSE is a measure of the deviation between histograms. The average RMSE values are 2613.7 for the 2-LSB method and 1753.3 for the PVD method. Smaller values indicate smaller deviations, so the obtained results confirm that the PVD method introduces smaller deviations in the histograms of the cover and stego images.

Table 2 shows the results of the assessment of the algoritham complexity of the analyzed methods. The results shown in the table indicate that embedding the secret message into the cover image using the 2-LSB method requires significantly less time than using the PVD method. The average execution time for the 2-LSB method is 0.3175 s, while for the the PVD method is 0.9491 s, meaning that the PVD method takes approximately three times longer. From the above results, it can be concluded that the 2-LSB method is more efficient in terms of the execution time, which is expected given that the PVD method involves additional calculations related to determining the range of differences and correcting pixel values.

Table 1. Results of correlation and RMSE using 2-LSB and PVD method

Methods		Metrics	
		Correlation	RMSE
2-LSB	Min	0.6859	816.68
	Mean	**0.9539**	**2613.7**
	Max	0.9931	3134.8
PVD	Min	0.8243	168.63
	Mean	**0.9796**	**1753.3**
	Max	0.9997	2769.5

Table 2. Algorithm complexity measurement results

Time [s]	Min	**Mean**	Max
2-LSB	0.2773	**0.3175**	0.3762
PVD	0.9081	**0.9491**	0.9870

Table 3. Results of measuring the capacity of the method

Capacity	Min	**Mean**	Max
2-LSB	4.147.200	**4.147.200**	4.147.200
PVD	3.114.494	**3.268.800**	3.489.559

Table 3 shows the results of measuring the capacity of the 2-LSB and the PVD method for all 50 observed images.

The capacity of the 2-LSB method is fixed and amounts to 4,147,200 bits. On the other hand, it can be observed that the capacity of the PVD method varies and depends on the characteristics of the cover image. The average capacity across all 50 images is 3,268,800 bits, which means that the PVD method allows embedding a smaller amount of data compared to the 2-LSB method. This difference in capacity can be explained by the fact that the number of bits that can be embedded in a given pixel pair using the PVD method depends on the range to which the pixel difference belongs, whereas in the 2-LSB method it is constant.

4. CONCLUSION

This paper analyzes the effectiveness of the steganography method based on pixel value differencing. The obtained results were compared with those obtained using the method based on the replacement of the two least significant bits. The analysis was conducted in the context of imperceptibility, robustness, security, algorithm complexity and capacity.

It can be concluded that neither of the evaluated methods provides the best performance across all considered criteria. Both methods exhibit specific advantages and limitations, depending on the aspect being analyzed. The obtained results show that the 2-LSB method outperforms the PVD method in terms of embedding capacity, robustness against AWGN, and computational complexity based on execution time measurements. In contrast, the imperceptibility analysis indicates that the PVD method achieves better performance according to the majority of the applied image quality metrics, relative to maximum embedding capacity. Furthermore, the PVD method demonstrates a higher level of statistical imperceptibility with respect to cover image, based on two histogram metrics. Overall, the results indicate that the choice of the embedding method depends on the specific application requirements and the desired trade-off among imperceptibility, robustness, security, embedding capacity, and computational complexity.

In future work, it is planned to analyze improved versions of the PVD method and develop own modifications of the algorithm in order to increase its efficiency. Additionally, the application of cryptography techniques prior to embedding the message in the cover image could further increase the level of security, so it would be useful to consider that possibility as well.

Abstract: *The effectiveness of text retrieval systems depends on the quality of underlying document representations. For morphologically rich languages such as Serbian, the choice of embedding model is particularly important due to complex inflectional patterns that affect lexical matching. This paper presents a systematic evaluation of five transformer-based embedding models for information retrieval in Serbian military technical texts. Three monolingual models pre-trained on Serbian corpora (BERTic, Jerteh-81, Jerteh-355) are compared against two multilingual sentence transformers (multilingual-e5-base, paraphrase-multilingual-MiniLM). The evaluation is conducted on a corpus of 566 articles from Vojnotehnicki glasnik (Military Technical Courier), the scientific journal of the Serbian Ministry of Defence, using 90 domain-specific queries with graded relevance judgments. Retrieval performance is measured using normalized discounted cumulative gain (nDCG), mean reciprocal rank (MRR), and precision at k. The results reveal that the BM25 lexical baseline and the best multilingual sentence transformer perform on par (nDCG@10 = 0.757 for both; MRR = 0.985 vs. 0.989), while monolingual Serbian models perform substantially worse (best: Jerteh-355, nDCG@10 = 0.235). This finding demonstrates that for domain-specific technical text with specialized vocabulary, lexical matching remains fully competitive with dense retrieval at a fraction of the computational cost, and that cross-lingual contrastive training, rather than monolingual pre-training, is what makes dense retrieval viable for Serbian. Monolingual models without contrastive training objectives are unsuitable for retrieval tasks. The benchmark provides practical guidance for the selection of retrieval components in search systems designed for defence organizations operating in the Serbian language.*

Keywords: *embedding models, information retrieval, Serbian language, transformer models, military technical documentation.*

1. INTRODUCTION

The rapid growth of digital documentation in military and defence organizations creates an increasing need for automated information retrieval (IR) systems capable of locating relevant documents in response to domain-specific queries. In the Serbian-speaking defence context, the primary publication venue for military technical research is Vojnotehnicki glasnik (Military Technical Courier), the scientific journal of the Serbian Ministry of Defence, which has published over 1,700 articles spanning topics from weapons systems and communications to logistics and military management.

Modern information retrieval increasingly relies on dense retrieval methods, where documents and queries are mapped to vector representations (embeddings) using neural language models, and relevance is computed as vector similarity [1]. The quality of these embeddings directly determines retrieval performance. For morphologically rich languages such as Serbian, which exhibits extensive inflectional paradigms (nouns decline for 7 cases in 2 numbers across 3 genders), the choice of embedding model is particularly consequential: a model that fails to capture morphological variants of the same lexeme will produce poor representations of both documents and queries.

Two families of transformer-based models are available for Serbian text: monolingual models pre-trained specifically on Serbian (or South Slavic) corpora, such as BERTic [2] and Jerteh [3], and multilingual models trained on diverse multilingual data, such as multilingual-e5 [4] and paraphrase-multilingual-MiniLM [5]. A priori, it is unclear which approach yields better embeddings for Serbian: monolingual models have deeper exposure to Serbian morphology and vocabulary, while multilingual models benefit from cross-lingual transfer learning and are explicitly trained for semantic similarity tasks.

To the best of our knowledge, no prior study has systematically evaluated embedding models for Serbian-language information retrieval in a technical domain. The present work addresses this gap by constructing a benchmark consisting of a corpus of 566 articles from Vojnotehnicki glasnik, a set of 90 domain-specific queries with graded relevance judgments, and a comparative evaluation of five transformer-based embedding models. The main contributions are:

DOI: 10.5937/OTEH26089S

1. A domain-specific benchmark for Serbian military technical text retrieval, including a corpus, query set, and relevance judgments.

2. A systematic comparison of monolingual versus multilingual embedding models on this benchmark.

3. Practical recommendations for embedding model selection in Serbian-language retrieval systems.

2. RELATED WORK

Dense retrieval using neural embeddings has been extensively studied for English [1, 6]. The BEIR benchmark [7] provides a standardized evaluation framework across multiple domains and retrieval tasks, but does not include Serbian or any South Slavic language.

For Serbian, BERTic [2] is a BERT-based model pre-trained on Bosnian, Croatian, Montenegrin, and Serbian web corpora, primarily designed for token-level tasks (POS tagging, NER) rather than sentence-level similarity. The Jerteh models [3] are encoder models pre-trained specifically on Serbian text, available in 81M and 355M parameter variants. Neither BERTic nor Jerteh was trained with a contrastive or sentence similarity objective, which is known to be important for producing effective retrieval embeddings [8].

Multilingual sentence transformers, such as multilingual-e5 [4] and paraphrase-multilingual-MiniLM [5], are trained on large-scale multilingual parallel data with explicit contrastive objectives. These models support 50-100+ languages and have demonstrated strong cross-lingual transfer performance on sentence similarity benchmarks [9].

Retrieval from technical documents has been studied for high-resource languages, including a dedicated technical-documents CLIR task at TREC [10], but comparable work for Serbian technical texts, military or civilian is absent from the literature. The companion paper [11] extends the present evaluation by integrating the best-performing retrieval model into a complete Retrieval-Augmented Generation system with a locally deployed LLM.

Serbian is a morphologically rich language with complex inflectional patterns (7 cases, 3 genders, 2 numbers) that affect lexical matching in retrieval systems [12]. Available NLP resources include the srLex morphological dictionary with 1.86 million word forms [13]. Lexical retrieval methods such as BM25 [14] may benefit from morphological normalization (lemmatization) as a preprocessing step, a direction we explore in future work.

3. METHODOLOGY

3.1. Corpus construction

The evaluation corpus was constructed from publicly available articles published in Vojnotehnicki glasnik between 2014 and 2025. Article metadata was retrieved via the Crossref API, yielding 1,752 records. Full-text PDFs were downloaded from the journal's website and the SCIndeks platform. After text extraction and cleaning (removal of headers, footers, references, and non-textual content), the final corpus contains 566 articles with a total of 16.6 MB of clean text.

Vojnotehnicki glasnik was selected as the evaluation source for two reasons: operational defence documentation (technical manuals, standards, and internal reports) is sensitive and cannot be used in a public evaluation, while the journal offers publicly available texts that share the terminology and style of military technical writing. This choice keeps the benchmark fully reproducible and shareable, while the findings are expected to transfer to the broader class of defence documents.

For retrieval, documents were segmented into chunks based on structural boundaries (title, abstract, body sections), producing 15,514 chunks with an average length of 1,247 characters. This chunking strategy preserves semantic coherence within each segment and reflects the granularity at which users typically seek information.

3.2 Query set and relevance judgments

A set of 90 queries was constructed to cover three categories of information needs:

- Title queries (30): queries derived from article titles, representing exact-match retrieval scenarios (e.g., "evaluation of ballistic protection materials").
- Abstract-derived queries (30): queries paraphrasing key findings from article abstracts, representing semantic similarity scenarios (e.g., "impact of temperature on composite armor performance").
- Domain-specific queries (30): general military-technical questions not tied to a specific article (e.g., "communication systems used in Serbian armed forces").

Relevance judgments were assigned on a 4-point scale: 0 (not relevant), 1 (marginally relevant), 2 (relevant), 3 (highly relevant), and constructed by pooling: for each query, the top-10 results of all six evaluated systems were merged, yielding 3,547 unique query-document pairs. Chunks of the source document for title and abstract-derived queries were assigned the highest grade by the known-item convention. Each pooled pair was independently graded by two locally deployed open-weight language models (Gemma 3 4B and Qwen 2.5 7B); a third model (Llama 3.1 8B) adjudicated disagreements by majority, which resolved 94% of pairs automatically, and the remaining 220 pairs (6%) were graded by a domain expert. Excerpts consisting mainly of reference lists were treated as at most marginally relevant. The judging protocol was calibrated on 35 expert-graded pairs, reaching within-one-grade agreement with the expert on 97% of automatically resolved pairs. An initial manual expert review of an earlier, programmatically generated label set had found systematic over-scoring of marginally related pairs (and a latent lexical bias that

could unfairly favor sparse retrieval), which motivated this protocol.

3.3 Embedding models

Five transformer-based models were evaluated (Table 1), representing the two families described above.

For base encoder models (BERTic, Jerteh), embeddings were obtained by mean-pooling the last hidden layer token representations. For sentence transformer models (e5, MiniLM), the native encoding interface was used, which applies an appropriate pooling strategy internally.

Table 1. Embedding models evaluated

Model	Type	Parameters	Languages	Embedding dim.	Size (MB)
BERTic [2]	Base encoder	111M	BCMS	768	420
Jerteh-81 [3]	Base encoder	81M	Serbian	768	310
Jerteh-355 [3]	Base encoder	355M	Serbian	1024	1,351
multilingual-e5-base [4]	Sentence transformer	278M	100+	768	1,061
paraphrase-multilingual-MiniLM [5]	Sentence transformer	118M	50+	384	449

3.4 Evaluation protocol

For each model, all 15,514 corpus chunks were encoded into dense vectors. For each of the 90 queries, the query was encoded using the same model, and the top-k most similar chunks were retrieved using cosine similarity. Retrieval performance was measured using:

- nDCG@k (normalized discounted cumulative gain): measures ranking quality accounting for graded relevance, at cutoffs k = 1, 5, 10, 20.
- MRR (mean reciprocal rank): average of the reciprocal rank of the first relevant result.
- P@k (precision at k): fraction of retrieved documents that are relevant.

All experiments were conducted on a single consumer machine (Apple M2, 16 GB RAM) without a discrete GPU; models ran on the integrated GPU via the Metal (MPS) backend.

4. RESULTS

4.1 Overall retrieval performance

Table 2 presents the main retrieval results across all 90 queries.

Table 2. Retrieval performance across all 90 queries.

Model	Type	nDCG@5	nDCG@10	MRR
BM25	Sparse	0.793	0.757	0.985
multilingual-e5-base	Dense	0.788	0.757	0.989
paraphrase-MiniLM	Dense	0.752	0.701	0.994
Jerteh-355	Dense	0.266	0.235	0.659
Jerteh-81	Dense	0.244	0.213	0.634
BERTic	Dense	0.067	0.064	0.278

The BM25 lexical baseline and multilingual-e5-base achieve statistically indistinguishable overall performance (nDCG@10 = 0.757 for both; paired permutation test, $p = 0.99$), demonstrating that keyword-based matching remains fully competitive for domain-specific technical text where queries and documents share specialized terminology. Both significantly outperform paraphrase-MiniLM (nDCG@10 = 0.701, $p < 0.01$). The monolingual Serbian models perform substantially worse, with Jerteh-355 achieving only nDCG@10 = 0.235 and BERTic scoring very low (nDCG@10 = 0.064).

Three key findings emerge. First, BM25 matches the best dense model on this benchmark while requiring no neural encoding, indicating that the high lexical overlap between technical queries and domain-specific documents makes exact term matching a strong baseline. Second, multilingual sentence transformers dramatically outperform monolingual models (3.2-fold improvement in nDCG@10 of e5-base over Jerteh-355). Third, BERTic, despite being the most widely used South Slavic language model, is unsuitable for retrieval, confirming that models not trained with a sentence-level similarity objective produce poor document representations.

4.2 Performance by query type

Table 3 presents nDCG@10 and MRR broken down by query type.

Table 3. Retrieval performance by query type (nDCG@10 / MRR).

Model	Title	Abstract-derived	Domain-specific
BM25	0.855 / 0.978	0.758 / 1.000	0.660 / 0.978
e5-base	0.825 / 0.983	0.765 / 0.983	0.681 / 1.000
MiniLM	0.751 / 0.983	0.714 / 1.000	0.636 / 1.000
Jerteh-355	0.198 / 0.574	0.303 / 0.793	0.203 / 0.611
Jerteh-81	0.163 / 0.568	0.251 / 0.680	0.226 / 0.654
BERTic	0.031 / 0.152	0.051 / 0.234	0.112 / 0.448

BM25 leads on title queries (nDCG@10: 0.855 vs. 0.825 for e5-base), where exact term overlap is strongest, while e5-base leads on abstract-derived (0.765 vs. 0.758) and domain-specific queries (0.681 vs. 0.660), where semantic matching beyond exact keywords pays off. MRR is close to its ceiling for all three strong systems across query types (0.978-1.000), so ranking quality differences are visible mainly in nDCG. All models perform worst on

domain-specific queries, which require broader topical matching beyond exact keyword overlap.

4.3 Computational efficiency

Table 4 presents the processing speed and resource requirements.

The paraphrase-multilingual-MiniLM model is by far the fastest, encoding the entire corpus in 3.2 minutes at 79.9 chunks per second - over 10 times faster than e5-base and 53 times faster than Jerteh-355. Given that MiniLM also achieves the second-best dense retrieval performance (nDCG@10 = 0.701, MRR = 0.994), it represents the best accuracy-efficiency trade-off for practical deployment.

Table 4. Computational efficiency (corpus: 15,514 chunks, Apple M2, no discrete GPU).

Model	Encoding speed (chunks/s)	Corpus encoding time	Model size (MB)
BERTic	6.7	38.9 min	420
Jerteh-81	14.0	18.5 min	310
Jerteh-355	1.5	2.8 hours	1,351
e5-base	7.4	34.7 min	1,061
MiniLM	79.9	3.2 min	449

5. DISCUSSION

The evaluation reveals two central findings: (1) BM25 lexical retrieval performs on par with the best dense model on this domain-specific benchmark at a fraction of the computational cost, and (2) among dense models, multilingual sentence transformers dramatically outperform monolingual Serbian models.

Why lexical retrieval remains competitive on technical text. The strong performance of BM25 (nDCG@10 = 0.757, on par with the best dense model) is explained by the nature of military technical documentation: articles use a highly specialized and consistent vocabulary where queries and relevant documents share many of the same technical terms. In such domains, exact keyword matching naturally achieves high precision. This finding aligns with observations in the BEIR benchmark [7], which showed that BM25 remains competitive with dense models on domain-specific corpora with specialized terminology.

Why monolingual dense models fail. The monolingual models (BERTic, Jerteh) were pre-trained with masked language modeling (MLM), which learns contextual word representations but does not optimize for sentence-level semantic similarity. The contrastive training objective used by multilingual sentence transformers directly optimizes the property needed for retrieval: semantically similar texts should have similar vector representations. This explains the 3.2-fold gap in nDCG@10 between e5-base (0.757) and Jerteh-355 (0.235). BERTic's very low retrieval scores (nDCG@10 = 0.064) confirm that widely used language models are not automatically suitable for all downstream tasks.

Cross-lingual transfer compensates for monolingual depth. The multilingual models benefit from training on parallel data across 50-100+ languages, enabling knowledge transfer from high-resource languages to Serbian. This cross-lingual alignment implicitly maps morphological variants to similar regions of the embedding space, providing robustness to Serbian's rich inflectional morphology.

Practical recommendations. For deployment in defence organizations, the choice between sparse and dense retrieval depends on the application scenario. BM25 is recommended when queries use domain-specific terminology: it requires no GPU, minimal memory, and matches the accuracy of the best dense model on this benchmark. For applications requiring semantic matching (e.g., cross-language queries, paraphrase detection), multilingual-e5-base provides the best dense alternative. Paraphrase-multilingual-MiniLM offers the best speed-accuracy trade-off for real-time applications (10x faster encoding than e5-base). A hybrid approach combining BM25 with dense retrieval [1] is likely to provide the best overall performance, as the two methods capture complementary relevance signals.

6. CONCLUSION

This paper presented the first systematic benchmark of retrieval models for Serbian military technical texts, comparing BM25 lexical retrieval against five transformer-based dense models on a corpus of 566 articles from *Vojnotehnicki glasnik* with 90 domain-specific queries. The results demonstrate that BM25 performs on par with the strongest dense model (nDCG@10 = 0.757 for both) while requiring no neural encoding, confirming the continued effectiveness of lexical matching for domain-specific technical text. Among dense models, multilingual sentence transformers (e5-base, MiniLM) achieve competitive performance and substantially outperform monolingual Serbian models (BERTic, Jerteh), with the training objective (contrastive vs. MLM) identified as the primary factor explaining this gap.

Future work will explore hybrid retrieval approaches combining BM25 with dense models to capture both lexical and semantic relevance signals, domain-adaptive fine-tuning of multilingual models on Serbian military text, and the integration of morphological normalization (lemmatization) as a preprocessing step to improve lexical matching for morphologically rich Serbian text.

Abstract: *The growing volume of military technical documentation in the Serbian language creates a need for efficient search and question-answering systems that can provide accurate answers to domain-specific queries. This paper presents a Retrieval-Augmented Generation (RAG) system designed for Serbian military technical texts, built entirely on locally deployed open-source components to ensure data sovereignty and eliminate dependence on external cloud services. The system combines BM25 lexical retrieval with a locally hosted large language model (Gemma 3 4B) for answer generation grounded in retrieved document segments. The system is evaluated on a corpus of 566 publicly available articles from Vojnotehnicki glasnik (Military Technical Courier), the scientific journal of the Serbian Ministry of Defence, using 90 domain-specific queries. Retrieval performance achieves an MRR of 0.985 and nDCG@10 of 0.757, while the generation component produces domain-relevant responses for 98% of queries with an average response time of 45 seconds per query on consumer hardware without a discrete GPU. A companion study demonstrates that BM25 matches the best dense neural retrieval model on this benchmark at a fraction of the computational cost, motivating the choice of lexical retrieval as the primary retrieval component. The results demonstrate that a fully local RAG system can serve as a practical tool for knowledge management within defence organizations operating in the Serbian language.*

Keywords: *retrieval-augmented generation, Serbian language, military technical documentation, information retrieval, large language models.*

1. INTRODUCTION

Defence organizations generate and maintain large volumes of technical documentation, including standards, regulations, research articles, technical manuals, and operational reports. Locating specific information within these collections is a time-consuming task that traditionally relies on manual search or basic keyword queries. The emergence of Retrieval-Augmented Generation (RAG) systems [2] offers a promising alternative: rather than returning a list of matching documents, a RAG system retrieves relevant passages and uses a large language model (LLM) to synthesize a direct answer grounded in the source material.

However, deploying RAG systems in defence contexts presents unique challenges. First, military documentation often contains sensitive information that cannot be transmitted to external cloud services, necessitating fully local deployment [3]. Second, Serbian is a morphologically rich language with complex inflectional patterns that affect both retrieval and generation quality [4]. Third, domain-specific military terminology requires specialized evaluation to ensure that retrieved passages are genuinely relevant to the query.

This paper presents a RAG system for Serbian military technical documentation that addresses these challenges through three design decisions: (1) all components run locally on consumer hardware without internet connectivity or a discrete GPU, ensuring data sovereignty; (2) BM25 lexical retrieval is used as the primary retrieval method, motivated by our companion study [1] which demonstrated that BM25 matches the best neural dense retrieval model on this domain-specific corpus at a fraction of the computational cost; and (3) a lightweight locally deployed LLM (Gemma 3 4B) generates answers in Serbian, grounded in retrieved passages.

The system is evaluated on a corpus of 566 articles from Vojnotehnicki glasnik (Military Technical Courier), the scientific journal of the Serbian Ministry of Defence, using 90 domain-specific queries covering three categories of information needs. The main contributions are:

1. A complete RAG architecture for Serbian military technical text that operates entirely on local infrastructure without cloud dependencies.

2. An empirical evaluation demonstrating that BM25-based retrieval combined with a 4B-parameter local LLM achieves practical performance (MRR = 0.985, 98% query coverage) on consumer hardware.

3. A reproducible benchmark consisting of a publicly

E-mail: nikola.vukotic@akademijanis.edu.rs
DOI: 10.5937/OTEH26090V

available corpus, query set, and evaluation framework for Serbian-language military technical retrieval.

2. RELATED WORK

RAG was introduced by Lewis et al. [2] as a method for combining retrieval and generation to produce factually grounded outputs. The approach has since been applied to domain-specific question answering, including passage-level retrieval with generative models [5] and retrieval from large-scale token databases [6]. Gao et al. [7] provide a comprehensive survey of RAG architectures, categorizing approaches by retrieval method (sparse vs. dense vs. hybrid) and generation strategy.

For morphologically rich languages, retrieval quality depends heavily on the ability to match inflected word forms. In our companion study [1], we demonstrated that BM25 lexical retrieval matches the best dense neural model (multilingual-e5-base) on technical text in Serbian language (nDCG@10 = 0.757 for both), while monolingual models such as BERTic are unsuitable for retrieval. Equal accuracy at a fraction of the computational cost motivates our choice of BM25 as the retrieval backbone.

The deployment of LLMs on local infrastructure has become increasingly viable with the release of efficient small models such as Llama 3 [8], Gemma [9], Mistral [10], and Phi-3 [11]. Frameworks such as Ollama [12] and llama.cpp [13] enable inference on consumer CPUs without GPU hardware. For defence applications, local deployment is essential to maintain data sovereignty and comply with information security requirements [3].

Serbian presents specific challenges for NLP due to its rich inflectional morphology (nouns decline for 7 cases, 2 numbers, 3 genders), two-script system (Latin and Cyrillic), and dialectal variation (ekavian vs. ijekavian) [14]. Available language resources include the srLex morphological dictionary [15], the SETimes.SR corpus [16], and transformer models such as BERTic [17] and Jerteh [18]. In prior work, we developed POS tagging systems for Serbian [19, 20] with detailed error analysis on the MULTEXT-East tagset [21]. The present work extends this line of research to information retrieval and question answering in a specialized domain.

3. SYSTEM ARCHITECTURE

The RAG system consists of three components operating in sequence: document preprocessing, retrieval, and answer generation. The complete pipeline runs locally on consumer hardware (Apple M2, 16 GB RAM) without internet connectivity, using only the integrated GPU.

3.1 Corpus and preprocessing

The evaluation corpus consists of 566 articles published in Vojnotehnicki glasnik between 2014 and 2025. Article metadata was collected via the Crossref API, and full-text PDFs were downloaded from the journal website and SCIndeks platform. Text was extracted from PDFs and cleaned to remove headers, footers, reference lists, and non-textual content, producing 16.6 MB of clean text.

For retrieval, documents were segmented into 15,514 chunks based on structural boundaries (title, abstract, body sections), with an average chunk length of 1,247 characters. This granularity balances retrieval precision (shorter chunks are more focused) with context sufficiency (longer chunks provide more information for answer generation).

3.2 BM25 retrieval

BM25 (Best Matching 25) [22] is a probabilistic lexical retrieval model that ranks documents by term frequency, inverse document frequency, and document length normalization. We use the Okapi BM25 implementation with default parameters ($k1 = 1.5$, $b = 0.75$).

For each query, BM25 scores are computed against all 15,514 corpus chunks, and the top-k chunks ($k = 5$) are selected as context for answer generation. The choice of BM25 over dense retrieval is empirically motivated: our companion study [1] showed that BM25 achieves an MRR of 0.985 and nDCG@10 of 0.757 on this corpus, statistically indistinguishable from the best dense model (multilingual-e5-base) while requiring no neural encoding. This competitiveness stems from the high lexical overlap between technical queries and domain-specific documents containing specialized vocabulary.

The BM25 index is built in 3.1 seconds and requires negligible memory beyond the corpus text, making it suitable for deployment on resource-constrained hardware.

3.3 Answer generation with local LLM

Retrieved chunks are assembled into a context window and passed to a locally deployed LLM along with the user query. We use Gemma 3 4B [9], a 4-billion parameter language model from Google, served locally via the Ollama framework [12]. The model runs locally on an Apple M2 (integrated GPU via the Metal backend), with no discrete GPU required.

The generation prompt, shown below, instructs the model to answer based only on the provided context, to respond in Serbian (ekavian dialect), and to indicate when the context does not contain sufficient information:

"You are a knowledgeable assistant for Serbian military technical documentation. Answer the following question based ONLY on the provided context. If the context does not contain enough information, say so. Always answer in Serbian language using ekavian dialect. CONTEXT: {retrieved chunks} QUESTION: {query} ANSWER:"

Generation parameters are set to temperature = 0.3 and top-p = 0.9 to favor focused, factual responses over creative output.

The choice of Gemma 3 4B is motivated by three factors: (1) it fits in 3.3 GB of memory, enabling deployment on consumer hardware; (2) it supports Serbian text through

multilingual pre-training; and (3) it generates coherent responses typically within about 40 seconds per query, which is acceptable for non-real-time information retrieval scenarios.

4. EVALUATION

4.1 Query set

A set of 90 queries was constructed across three categories:

- Title queries (30): queries derived from article titles, representing exact-match retrieval scenarios.
- Abstract-derived queries (30): queries paraphrasing key findings from abstracts, testing semantic understanding.
- Domain-specific queries (30): general military-technical questions not tied to specific articles.

Relevance judgments were assigned on a 4-point scale (0-3) by pooling the top-10 results of six retrieval systems and grading each pooled pair with an ensemble of three locally deployed open-weight language models, with disagreements adjudicated by a domain expert; the full protocol, its calibration against 35 expert-graded pairs, and the resulting judgments are described in the companion study [1].

4.2 Retrieval performance

Table 1 presents the retrieval performance of the BM25 backbone across query types.

Table 1. Retrieval performance (BM25) established in our companion study [1], serving as the retrieval backbone for the RAG system.

Metric	All queries	Title	Abstract	Domain
MRR	0.985	0.978	1.000	0.978
nDCG@5	0.793	0.905	0.853	0.621
nDCG@10	0.757	0.855	0.758	0.660
P@5	0.918	0.947	0.887	0.920

BM25 retrieval achieves strong performance across all query types, with MRR close to its ceiling everywhere (0.978-1.000). Ranking quality is highest for title queries (nDCG@10 = 0.855), which share exact terminology with target documents, and lowest for domain-specific queries (nDCG@10 = 0.660), which require broader topical matching.

4.3 Answer generation quality

Table 2 presents the answer generation statistics.

The system generates domain-relevant responses for 98% of queries. Two queries resulted in a refusal due to insufficient context. Answers average 621 characters in length, providing concise summaries of the relevant information.

Generation time averages 44.7 ± 31.8 seconds per query (median 38.2 seconds), with the large variance reflecting differences in answer length; this is acceptable for document analysis and research tasks but would need optimization for interactive applications. The entire system (BM25 index + LLM) fits within 4 GB of memory, well within the capacity of modern consumer hardware.

Table 2. Answer generation statistics (Gemma 3 4B, no discrete GPU).

Metric	Value
Queries answered	90/90 (100%)
Non-trivial answers	88/90 (98%)
Refusals (insufficient context)	2/90 (2%)
Average answer length	621 characters
Average generation time	44.7 ± 31.8 s (median 38.2 s)
Model size	3.3 GB
Hardware	Apple M2, 16 GB RAM, no discrete GPU

4.4 Answer quality examples

Table 3 presents representative examples of system outputs across query types.

Table 3. Representative query-answer pairs.

Query type	Query (abbreviated)	Answer (abbreviated)
Title	Bidirectional stack decoding of polar codes	The algorithm uses sequential decoding from both left and right sides to reduce latency...
Abstract	Role of Serbian Army in chemical hazard management	The text describes procedures for CBRN accident response, including decontamination and evacuation...
Domain	Thermal barrier coatings for military equipment	Thermal barrier plasma spray coatings protect turbo jet engine parts from high temperatures, oxidation and corrosion...

The examples illustrate that the system generates responses that reference specific information from the retrieved context and provide domain-specific technical details. However, a systematic evaluation of answer faithfulness (e.g., through human annotation or automated metrics such as RAGAS) remains necessary to quantify the rate of hallucinated content and is left for future work.

5. DISCUSSION

The results demonstrate that a fully local RAG system, combining BM25 retrieval with a small (4B parameter) LLM, achieves practical performance for Serbian military

technical documentation. Several aspects merit discussion.

Our companion study [1] showed that BM25 matches the best dense neural model on this corpus; equal accuracy with a negligible resource footprint makes it the natural choice for the retrieval component. This finding is consistent with observations in the broader IR literature [23], where BM25 remains competitive on domain-specific corpora with specialized vocabulary. For defence applications, BM25 offers additional advantages: it requires no neural model loading, builds indexes in seconds, and operates with minimal memory.

The complete system runs on consumer hardware (Apple M2, 16 GB RAM) without a discrete GPU or internet connectivity. The total resource footprint is approximately 4 GB (3.3 GB for the LLM, 0.7 GB for the corpus and index). This demonstrates that RAG systems for specialized domains no longer require cloud infrastructure, enabling deployment in air-gapped environments where data sovereignty is paramount.

The current system has several limitations. First, the 45-second average response time, while acceptable for research tasks, is too slow for interactive applications; a discrete GPU or model quantization would address this. Second, the LLM occasionally generates responses mixing Serbian and Croatian forms, reflecting the multilingual training data; fine-tuning on Serbian-specific data would improve language consistency. Third, answer quality evaluation in this study relies on automated metrics and qualitative inspection; a systematic human evaluation with multiple annotators would provide stronger evidence of answer quality. Fourth, the system does not currently support hybrid retrieval (combining BM25 with dense models), which our companion study suggests could further improve performance.

In prior work [19, 20, 21], we developed POS tagging tools for Serbian that improve downstream NLP accuracy. Integrating lemmatization as a preprocessing step for BM25 retrieval could improve recall by matching morphological variants of query terms, representing a promising direction for future work.

6. CONCLUSION

This paper presented a Retrieval-Augmented Generation system for Serbian military technical documentation, built entirely on locally deployed open-source components. The system combines BM25 lexical retrieval (MRR = 0.985) with a locally hosted Gemma 3 4B language model for answer generation, processing queries in 45 seconds on average on consumer hardware without a discrete GPU. The complete system fits within 4 GB of memory and requires no internet connectivity, making it suitable for deployment in air-gapped defence environments. Evaluation on 90 queries against 566 articles from Vojnotehnicki glasnik demonstrates that the system produces domain-relevant responses for 98% of queries.

Future work will explore hybrid retrieval combining BM25 with dense models for improved semantic matching, GPU-accelerated inference for interactive response times, fine-tuning the LLM on Serbian military technical data, and systematic human evaluation of answer quality.

Abstract: *The increasing sophistication of deepfake generation methods poses a direct threat to the integrity of video and audio communication channels used in defense organizations. Manipulated content can be employed for identity spoofing during video conferences, fabrication of false orders, or targeted disinformation campaigns against military personnel. This paper examines three deepfake detection architectures, two convolutional neural networks (XceptionNet and EfficientNet-B4) and a Vision Transformer (ViT-B/16), with respect to the two constraints that characterize defense communication channels: video compression and limited processing time. Detection accuracy under compression is analyzed on the basis of published results on the FaceForensics++ benchmark at its three compression levels, while the per-frame inference latency of all three architectures is measured on GPU and CPU hardware, in single and half precision, to assess their suitability for real-time deployment. The analysis shows that the reported accuracy of the selected architectures degrades significantly under heavy compression, used here as a proxy for bandwidth-limited military channels, highlighting the gap between benchmark performance and operational readiness. We discuss practical implications for integrating deepfake detection into existing defense communication infrastructure and propose a tiered detection strategy that balances computational cost with detection reliability in resource-constrained environments.*

Keywords: *deepfake detection, defense communications, real-time detection, convolutional neural networks, vision transformers, cybersecurity.*

1. INTRODUCTION

Modern defense organizations increasingly rely on digital video and audio channels for command and control, coordination between units, and communication with allied structures. The same technological progress that enables this connectivity has also produced generative models capable of synthesizing convincing fake video and audio content, commonly referred to as deepfakes [1], [2]. In a military context, the consequences of successful manipulation extend far beyond reputational damage: a fabricated video order, a spoofed participant in a command video conference, or a synthetic voice message attributed to a superior officer can directly influence operational decisions. The war in Ukraine provided an early demonstration of this threat when a manipulated video of President Zelensky calling on soldiers to lay down their arms was distributed through compromised media channels in March 2022 [3].

Research on deepfake detection has produced a range of deep learning models that achieve excellent results on academic benchmarks [1], [4]. However, published evaluations are typically conducted on high-quality video material and without constraints on processing time. Defense communication systems operate under fundamentally different conditions: tactical channels are bandwidth-limited, which forces aggressive video compression, and detection must often be performed in real time, on hardware that ranges from data-center servers to embedded devices at the tactical edge. A model that performs well on uncompressed benchmark videos but fails on heavily compressed streams, or one that is accurate but too slow for streaming analysis, is of limited operational value.

This paper examines the gap between benchmark performance and operational readiness for three representative detection architectures: XceptionNet [5], EfficientNet-B4 [6], and the Vision Transformer ViT-B/16 [7]. The contribution is threefold. First, we analyze published detection results on the FaceForensics++ benchmark [4] across its three compression levels, using compression as a proxy for the degradation present in bandwidth-limited military channels. Second, we measure the per-frame inference latency of all three architectures on GPU and CPU hardware, in single and half precision, to establish which deployment scenarios permit real-time operation. Third, on the basis of both analyses we propose a tiered detection strategy that distributes detection workload across endpoint, accelerated, and procedural layers in accordance with available computational resources.

The remainder of the paper is organized as follows. Section 2 reviews deepfake threats specific to defense communication systems. Section 3 describes the three

Corresponding author: M. Ristić;
E-mail: milan.ristic@akademijanis.edu.rs
DOI: 10.5937/OTEH26091R

evaluated architectures. Section 4 defines the evaluation methodology. Section 5 presents and discusses the results, Section 6 introduces the tiered detection strategy, and Section 7 concludes the paper.

2. DEEPFAKE THREATS TO DEFENSE COMMUNICATION SYSTEMS

Deepfake content is generated by deep generative models, most notably generative adversarial networks [8], autoencoders, and, more recently, diffusion and transformer-based architectures [2]. The wide availability of these tools has lowered the technical barrier to producing convincing synthetic media, and studies have shown that AI-generated faces are frequently perceived as more trustworthy than real ones [9], which makes human observers an unreliable last line of defense.

In defense communication systems, four threat categories are of particular concern. The first is identity spoofing in video teleconferencing. Real-time face reenactment and face-swapping techniques allow an adversary who has compromised a communication channel to impersonate a legitimate participant, gaining access to sensitive discussions or injecting false information directly into the decision-making process. The second is the fabrication of orders. A synthetic video or audio message attributed to a commanding officer exploits the inherent authority of the chain of command; under time pressure, subordinate units may act on such an order before its authenticity can be verified through independent channels. The documented use of a cloned executive voice to authorize a fraudulent transfer of 243,000 USD in 2019 [10] demonstrates that voice-based authority spoofing is already operationally viable, and the military command context differs from the corporate one only in the severity of consequences.

The third category is targeted disinformation against personnel and the public. Deepfake material tailored to local language and context can be used to demoralize troops, discredit commanders, or manufacture apparent evidence of events that never occurred, with the Zelensky video [3] as the canonical example. Once such content enters social media distribution, cascading amplification makes subsequent correction slow and only partially effective. The fourth category is the manipulation of biometric authentication. Face and voice verification systems used for access control are vulnerable to presentation and injection attacks based on synthetic samples [2], which undermines single-factor biometric authentication in security-critical facilities and systems.

A common property of all four categories is that the attack surface is the communication channel itself, and the content traversing it is compressed, resized, and re-encoded by the transport infrastructure. Any detection mechanism intended for this environment must therefore be evaluated under compression and latency constraints, not only on pristine benchmark data.

3. DETECTION ARCHITECTURES

Learning-based deepfake detection is dominated by two architectural families: convolutional neural networks and vision transformers. From each family we select representative models that are widely used in the detection literature and for which published benchmark results are available.

XceptionNet [5] is a 71-layer convolutional network built entirely from depthwise separable convolutions, which factorize spatial filtering and channel mixing into separate operations. It was adopted as the reference detector in the FaceForensics++ study [4] and has since served as the de facto baseline of the field, owing to its strong ability to capture the local, pixel-level artifacts introduced by face manipulation pipelines. With the two-class (real/fake) output layer used here in place of the ImageNet head, the model has 20.8 million parameters (22.9 million with the ImageNet head) and processes input at 299×299 pixels.

EfficientNet-B4 [6] belongs to a family of networks obtained by compound scaling of depth, width, and input resolution under a fixed computational budget. It processes input at 380×380 pixels and has 17.6 million parameters (19.3 million with the ImageNet head). EfficientNet backbones dominated the top solutions of the DeepFake Detection Challenge [11], the winner being based on EfficientNet-B7 [12]; EfficientNet-B4 and its attention-augmented variant form the backbone of the ensemble of Bonettini et al. [13], which matches or exceeds XceptionNet on FaceForensics++.

The Vision Transformer [7] departs from convolutional processing entirely: the input image is divided into fixed-size patches that are linearly embedded and processed by a stack of self-attention layers. The ViT-B/16 variant used here operates on 224×224 inputs divided into 16×16 patches and, with a two-class output layer, has 85.8 million parameters (86.6 million with the ImageNet head). Self-attention provides a global receptive field from the first layer, which allows the model to relate distant image regions, a property hypothesized to help detect the global inconsistencies of manipulated faces, complementing the local artifact sensitivity of CNNs. Transformer-based detectors have reported competitive results on FaceForensics++ across compression levels [14].

These three architectures span the relevant design space along two axes: local versus global feature extraction, and parameter count versus computational structure. As Section 5 shows, the relationship between model size, theoretical computational cost, and actual inference latency is not straightforward, which has direct consequences for deployment planning.

4. EVALUATION METHODOLOGY

4.1. Detection accuracy analysis

Detection accuracy is analyzed on the basis of published results on FaceForensics++ [4]; no detector was trained or tested by the authors. The dataset contains 1,000 original videos and their counterparts manipulated by four methods (DeepFakes, Face2Face, FaceSwap, NeuralTextures), more than 1.8 million frames in total, distributed at three compression levels: raw, c23 (H.264,

constant rate factor 23, visually near-lossless), and c40 (constant rate factor 40, strong compression with visible artifacts). The c40 level serves as a proxy for the video quality of bandwidth-limited tactical channels, not as a measurement of such links, whose encoders typically operate under rate control and are additionally affected by packet loss. Since published per-compression comparisons predominantly report accuracy, Section 5 uses accuracy as the common basis and reports AUC separately where only AUC is available.

4.2. Latency measurement

Inference latency was measured with PyTorch 2.11.0 [15] and timm 1.0.27 [16] (CUDA 12.8) on Google Colaboratory, with an NVIDIA Tesla T4 GPU (16 GB) and an Intel Xeon CPU (2 vCPUs). cuDNN autotuning (cudnn.benchmark) was enabled and the default channels-first (NCHW) memory format was used, i.e. channels_last was not enabled. Each model, instantiated with a two-class output layer, was run in inference mode with batch size 1 at its native resolution (299×299, 380×380, and 224×224 pixels), corresponding to frame-by-frame streaming processing. On the GPU, 300 forward passes were timed with CUDA events and explicit synchronization after 50 warm-up iterations; on the CPU, 30 passes were timed with a high-resolution wall-clock timer after 5 warm-up iterations, using both threads. Besides FP32 inference on both devices, FP16 GPU inference (weights and inputs converted to half precision) was evaluated, as reduced precision is the typical mode of edge accelerators; these results come from a single GPU type and are not claimed to transfer to other accelerators. We report the mean, standard deviation, and 95th percentile of latency, the maximum frame rate, and peak GPU memory in FP32. Since latency depends on architecture, input resolution, and hardware rather than on learned weights or pixel content, ImageNet-pretrained weights and random input tensors were used. Only the classifier forward pass is timed; video decoding, face detection, alignment, and preprocessing, which are common to all detectors, are excluded. The results therefore compare architectures but are not complete-pipeline latencies, in which face detection is often the most expensive stage. The real-time threshold is 33.3 ms per frame (30 FPS).

5. RESULTS AND DISCUSSION

5.1. Detection accuracy under compression

Table 1 summarizes the accuracy reported for the evaluated architectures at the three compression levels. As the sources use different protocols, the protocol is given for each entry: frame-level over all four manipulations [4], video-level over all four manipulations (Table 7, Appendix A.1 of [17]), and the Face2Face subset [14]. The values are therefore not directly comparable in absolute terms, although the compression-induced degradation is consistent across protocols; they describe the three selected architectures, not the state of the art of the field. No per-compression accuracy breakdown exists for EfficientNet-B4 (see below). Figure 1 visualizes the trend.

Table 1. Reported detection accuracy (%) on FaceForensics++ (binary real/fake classification, trained and tested at the same compression level; [17]: Table 7, Appendix A.1). EfficientNet-B4: see text after Figure 1.

Model	Protocol	raw	c23	c40	Source
XceptionNet	frame-level, all manipulations	99.26	95.73	81.00	[4]
XceptionNet	video-level, all manipulations	99.0	97.0	89.0	[17], Table 7
ViT-B/16	Face2Face subset	99.07	97.38	86.06	[14]

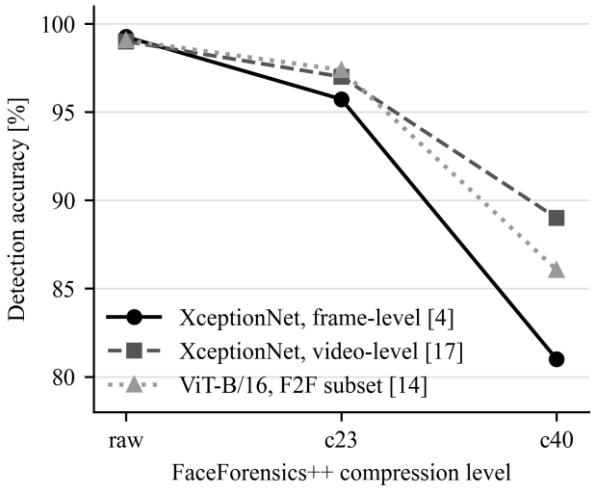

Figure 1. Reported detection accuracy as a function of FaceForensics++ compression level [4], [14], [17]

For EfficientNet-B4, Bonettini et al. [13] report at c23 an AUC of approximately 0.98 for both EfficientNet-B4 and XceptionNet in the same framework, with ensemble and attention variants giving further gains. These AUC values are not comparable with the accuracies in Table 1, and no per-compression accuracy breakdown has been published; DFDC results [11], [13], obtained on heterogeneously degraded material, suggest robustness of the same order as the CNN baseline.

Three observations follow from Table 1. First, on uncompressed material all listed models exceed 99%, which explains the optimistic perception created by headline benchmark results. Second, mild compression (c23), typical of commercial video services, costs two to four percentage points. Third, strong compression (c40) produces a qualitative change: frame-level XceptionNet accuracy drops to 81% [4], and approaches that aggregate evidence over time [17] or capture global structure [14] reach 86–89%. This range characterizes the selected architectures, not the best current detectors: compression-robust methods reach 94.2% (LipForensics) and 96.1% (RealForensics) at c40 under the same video-level protocol ([17], Table 7). The mechanism is well understood: manipulation pipelines leave high-frequency traces, and lossy compression removes precisely this content.

Operationally, the classification performance of the selected architectures is substantially reduced in the c40

regime. Overall accuracy does not show how errors divide between missed manipulations and false alarms, so the miss rate cannot be derived from Table 1; an overall error rate of 11–19%, however split, is acceptable for screening but insufficient as the sole authority for authenticating an order or a conference participant.

5.2. Inference latency

Table 2 presents our latency measurements. Figure 2 visualizes the mean per-frame latency against the 30 FPS real-time threshold.

Table 2. Measured per-frame latency of the classifier forward pass (batch size 1, native resolution): mean ± standard deviation, 95th percentile, maximum frame rate, and peak GPU memory in FP32

Model	Latency [ms]	p95 [ms]	FPS	Mem. [MB]
GPU, FP32				
XceptionNet	6.91±0.29	7.09	144.7	128
EfficientNet-B4	17.12±6.06	29.45	58.4	130
ViT-B/16	12.94±0.17	13.17	77.3	345
GPU, FP16				
XceptionNet	6.48±0.88	7.99	154.4	–
EfficientNet-B4	18.35±3.39	25.83	54.5	–
ViT-B/16	5.40±1.52	8.50	185.0	–
CPU, FP32				
XceptionNet	365.6±202.0	628.5	2.7	–
EfficientNet-B4	338.8±234.3	715.5	3.0	–
ViT-B/16	504.7±302.6	927.2	2.0	–

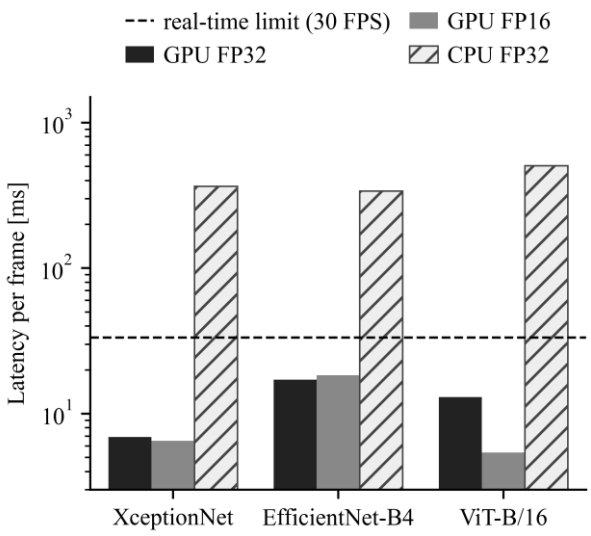

Figure 2. Per-frame inference latency on GPU (FP32/FP16) and CPU; the dashed line marks the 30 FPS real-time threshold (logarithmic scale)

On the GPU, all three architectures meet the real-time criterion in FP32, with mean latencies of 6.9–17.1 ms. EfficientNet-B4, despite the lowest theoretical cost (4.5 GMACs per frame, i.e. billions of multiply–accumulate operations as counted with fvcore, against 8.4 for XceptionNet and 16.9 for ViT-B/16), shows the highest GPU latency and by far the largest variance, with a 95th percentile of 29.45 ms, close to the 33.3 ms budget. The low arithmetic intensity of depthwise convolutions at 380×380 may contribute but cannot be the full explanation, since XceptionNet uses the same type of convolution and runs at a stable 6.9 ± 0.3 ms. Plausible further causes are the many small memory-bound kernels of the squeeze-and-excitation blocks and activations, and load from other tenants on the shared Colab GPU, which would also explain the variance; these hypotheses were not verified with a profiler. The measurement does establish that operation counts are a misleading proxy for latency. Conversely, ViT-B/16, with four times more parameters than either CNN, sustains 77 FPS in FP32, and FP16 reduces its latency by a factor of 2.4, to 5.4 ms (185 FPS), consistent with its dense matrix multiplications mapping onto tensor cores; the CNNs show marginal or no FP16 gains. On the T4 the transformer is thus the fastest model in half precision; whether this holds on other edge accelerators must be verified on the target hardware.

On the CPU, mean latencies of 340–505 ms (2–3 FPS) fall an order of magnitude short of real time, with high variance plausibly due to shared virtualized cores. Obtained with eager-mode FP32 PyTorch on two shared cores, these values are a pessimistic lower bound; even so, they support sampled screening at one frame per second, the strategy of commercial scanning services, with capacity to spare.

5.3. The operational gap

Combining both analyses quantifies the gap referenced in the title. Accuracy above 99% exists only for uncompressed material that tactical channels cannot deliver; at strong compression the selected architectures fall to 81–89%, and even compression-robust methods stay below their uncompressed level [17]. In our measurements, real-time classifier throughput required GPU acceleration, while unoptimized CPU inference is limited to sampled screening. None of the evaluated models, deployed at a single point, can therefore provide full-rate, high-confidence detection under operational conditions, which motivates the following strategy.

6. TIERED DETECTION STRATEGY

We propose organizing deepfake detection in defense communication infrastructure into three tiers that explicitly match detection workload to available resources and decision stakes. Figure 3 summarizes the proposed architecture.

Tier 1 provides continuous endpoint screening. Every endpoint, including CPU-only terminals, runs a lightweight detector on sampled frames (about 1 FPS), which is feasible without acceleration (Section 5.2). XceptionNet-class CNNs suit this tier owing to their low latency and small memory footprint (Table 2). The measured 2–3 FPS is a lower bound: optimized runtimes such as ONNX Runtime or OpenVINO with INT8 quantization can be expected to reach tens of frames per second on a workstation CPU, leaving headroom for higher sampling rates and face detection. Frame scores must be aggregated over a temporal window (e.g. averaging or majority voting over several seconds) before

an alert is raised. The purpose of this tier is triage, not authoritative classification: flagging suspicious segments for deeper analysis.

Tier 2 provides accelerated full-rate analysis. Streams flagged by Tier 1 and all high-value channels (command video conferences, order transmission) are analyzed at full frame rate on GPU-equipped nodes (data-center servers or tactical edge accelerators in FP16). The 185 FPS of ViT-B/16 on the T4 suggests that one device may serve more than one stream, but it excludes decoding, face detection, and alignment, so the number of streams per device must be determined for the complete pipeline. Combining a local-artifact CNN and a global-context transformer at this tier is intended to mitigate the single-model accuracy ceiling at strong compression, on the hypothesis, not tested here, that the two families have complementary failure modes.

The evaluated detectors are visual, whereas order fabrication and biometric spoofing (Section 2) are often audio-driven; dedicated audio detectors must therefore operate alongside them at Tiers 1 and 2, while Tier 3 covers both modalities.

Tier 3 is procedural and organizational. Because the residual error rate at operational compression levels remains too high to delegate authentication decisions to any detector, technical detection must be embedded in a zero-trust communication doctrine [18]: orders received through video or audio channels require out-of-band confirmation, participants in sensitive conferences authenticate through multiple independent factors rather than biometrics alone, and personnel are trained to treat urgency combined with channel-exclusive communication as an attack indicator. In this framework, Tiers 1 and 2 reduce the volume of manipulated content that reaches human decision points, while Tier 3 ensures that no single successful evasion translates directly into an executed false order.

The strategy is deliberately incremental: Tier 1 deploys on existing hardware immediately, Tier 2 requires targeted acceleration investment at identified choke points, and Tier 3 is a doctrinal measure whose cost is primarily organizational.

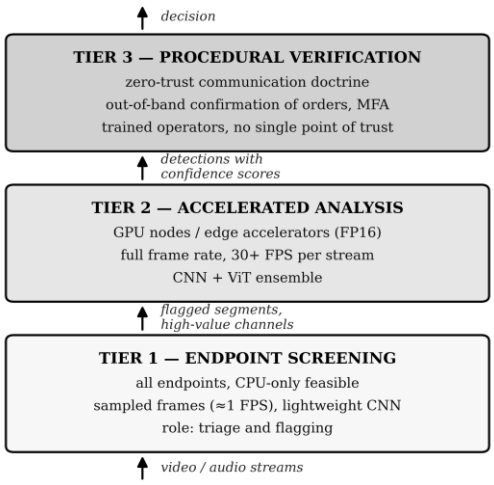

Figure 3. Tiered deepfake detection architecture for defense communication infrastructure

7. CONCLUSION

This paper examined two convolutional networks and a Vision Transformer for deepfake detection against the two constraints of defense communication: compression imposed by limited bandwidth and processing time imposed by real-time operation. Published FaceForensics++ results show the accuracy of these architectures falling from above 99% on uncompressed material to 81–89% under strong compression, while compression-robust methods reach 94–96% [17]. Our measurements of the classifier forward pass show that real-time operation is achievable on a GPU (NVIDIA T4) for all three architectures, with the Vision Transformer, contrary to expectations based on parameter count, the fastest in half precision, whereas unoptimized FP32 inference on a shared virtual CPU is limited to sampled screening. Theoretical computational cost proved an unreliable predictor of latency, underscoring the need for benchmarking on target hardware. The proposed tiered strategy assigns screening, in-depth analysis, and procedural verification to the resources capable of sustaining them. Future work will cover the complete detection pipeline, optimized CPU and embedded hardware, audio deepfake detection, and compression-robust training.

Abstract: *Brute-force attacks targeting Server Message Block (SMB) and Remote Desktop Protocol (RDP) services remain among the most common techniques used to gain unauthorized access to Windows systems. Traditional detection approaches are typically based on manually defined rules and event correlation mechanisms, which may be difficult to maintain and adapt to evolving attack patterns. Recent advances in Large Language Models (LLMs) have demonstrated promising capabilities in log analysis and anomaly detection; however, their applicability to authentication-based attack detection in Windows environments remains insufficiently explored. This paper evaluates the effectiveness of a locally deployed GPT-OSS model in detecting SMB and RDP brute-force attacks from Windows Security logs. A controlled experimental environment was established consisting of a Windows host with SMB and RDP services enabled, a Kali Linux attack host executing brute-force attacks using Hydra, and an NXLog-based log collection pipeline. Authentication-related security events were preprocessed and analyzed using a context-aware approach in which the model received a sliding window of recent log entries and classified the latest event as benign or malicious. The experimental results demonstrate that the proposed approach achieves high detection performance, obtaining F1 scores of 0.999 for SMB and RDP brute-force attacks in contextual judgement. The findings indicate that combining targeted preprocessing of authentication logs with context-aware reasoning performed by a Mixture-of-Experts (MoE) LLM enables accurate identification of attack patterns without relying on handcrafted detection rules. The main contributions of this work include the development of a reproducible framework for LLM-based analysis of Windows Security logs, the creation of a labeled dataset of SMB and RDP brute-force events, and the experimental validation of GPT-OSS as an effective locally deployable solution for real-time security monitoring.*

Keywords: *RDP, SMB, brute-force attacks, GPT-OSS, LLM log analysis.*

1. INTRODUCTION

Remote administration services such as Server Message Block and Remote Desktop Protocol are widely used in enterprise and personal computing environments. The massive use of these services has opened up many opportunities for launching attacks, among which brute force attacks are very common way for gaining unauthorized access to Windows systems [1]. By repeatedly attempting different username and password combinations, attackers seek to compromise valid accounts and establish an initial foothold within a target network.

Traditional detecting approaches are primarily based on predefined rules, signatures, or threshold-based correlation mechanisms implemented within Security Information and Event Management platforms, but modern use of technology demands novel approach and automatization of detection process. In addition, the increasing volume and complexity of security logs generated by modern information systems create important challenges for security analysts responsible for monitoring and incident response. Recent advances in Large Language Models (LLMs) have demonstrated promising capabilities in understanding, analyzing, and reasoning over semi-structured and unstructured textual data [2]. Unlike conventional machine learning approaches that typically require extensive feature engineering and model training, LLMs can leverage

DOI: 10.5937/OTEH26092P

contextual information contained within log sequences and provide interpretable explanations for their decisions. Despite these developments, the effectiveness locally deployable LLMs for detecting authentication-based attacks from Windows Security logs remains insufficiently explored, especially when it comes to mixture of experts models that more rationally use the hardware resources of the servers on which they are run.

This paper presents a proof-of-concept framework for detecting SMB and RDP brute-force attacks using a locally deployed GPT-OSS model. The experimental environment consists of a Windows host with SMB and RDP services enabled, a Kali Linux attack machine executing brute-force attacks using Hydra, and an NXLog-based log collection pipeline. Windows Security events are preprocessed and provided to the GPT-OSS model in the form of a sliding context window containing the most recent log entries. The model is then tasked with determining whether the latest event corresponds to benign activity or to an ongoing brute-force attack.

The main contributions of this work are:

(1) the development of a practical framework for LLM-based real-time analysis of Windows Security logs,

(2) the experimental evaluation of a locally deployed GPT-OSS model in detecting SMB and RDP brute-force attacks,

(3) novel dataset of attack-driven and processed log messages, generated through controlled execution of brute-force attack scenarios. and

(4) an assessment of the feasibility of employing LLMs as components of future security monitoring and threat detection systems.

2. RELATED WORKS

Brute-force attacks targeting Windows authentication services remain one of the most prevalent techniques used to gain unauthorized access to enterprise systems. In particular, SMB and RDP services are frequently exposed within organizational networks and are therefore common targets for password-guessing attacks. RDP has become one of the primary attack vectors used by adversaries to obtain initial access [4], while repeated authentication attempts against SMB services continue to represent a significant security concern in Windows environments. The large volume of authentication-related events generated during such attacks makes timely detection difficult and motivates the development of more intelligent log analysis approaches.

Recent advances in Large Language Models (LLMs) have opened new possibilities for automated security log analysis. LogPrécis demonstrated the applicability of LLMs in cybersecurity by analyzing Unix shell attacks captured in honeypot environments and generating concise yet informative interpretations of security events [5]. Similarly, Bokkena investigated the use of LLMs for predictive threat detection in IT security and reported experimental results exceeding 95% accuracy, outperforming several conventional machine learning approaches while simultaneously reducing false positive detections [6]. The growing success of LLMs in complex reasoning tasks has also encouraged their adoption for higher-level behavioral analysis, where contextual understanding is essential for identifying malicious activities [3].

The potential of LLMs for anomaly detection and semantic interpretation of system behavior has been further demonstrated by different frameworks [7,8]. Furthermore, the survey presented in [9] highlights the increasing importance of LLM-based anomaly detection and Retrieval-Augmented Generation techniques for cybersecurity applications, while also identifying a lack of research focused on real-time log analysis scenarios.

For locally deployed LLM solutions, Mixture-of-Experts (MoE) architectures have shown particular promise due to their ability to utilize hardware resources more efficiently while maintaining strong inference performance. Among these models, the locally deployed GPT-OSS model has demonstrated favorable results on systems equipped with 32 GB of VRAM, making it a suitable candidate for real-time cybersecurity applications [2]. For this reason, GPT-OSS was selected as the foundation of the detection framework evaluated in this work.

3. EXPERIMENTAL SETUP

The experimental environment was designed to evaluate the capability of a locally deployed GPT-OSS model to detect SMB and RDP brute-force attacks from Windows Security logs. The overall architecture enabled the generation of authentication-related security events, collection and preprocessing of Windows logs, and automated classification of security events using the GPT-OSS model.

3.1. Test Environment

Figure 1 illustrates the architecture of the proposed experimental framework.

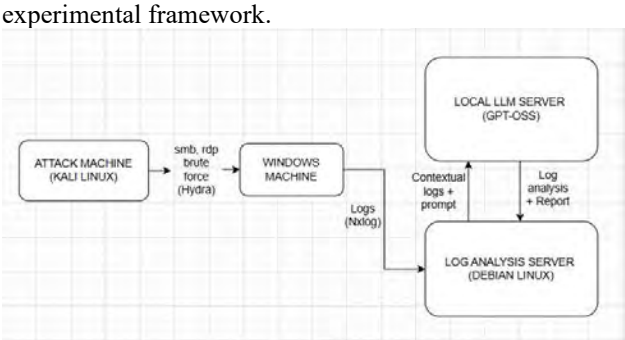

Figure 1. Experimental architecture

Figure 1 shows the architecture of the implemented framework. In order to achieve objectivity in evaluating the performance of the locally deployed GPT-OSS model, an experimental data set was created through SMB and RDP brute force attacks directed at a Windows machine. Log messages were collected and processed using the NXLOG event collection system on Windows operating

systems. The collected log messages are taken over by a specially designed application for real-time log analysis installed on a Debian Linux server and forwarded to GPT-OSS, which assigns a "malicious" or "benign" rating to the latest log message in correlation with a set of 50 previous log messages. Table 1 summarizes the main components of the experimental environment.

Table 1. Experimental environment components

Component	Description
Attacker Host	Kali Linux
Attack Tool	Hydra
Target Host	Windows system with SMB and RDP enabled
Log Collection	NXLog
AI Analysis Host	Local GPT-OSS deployment
Monitored Services	SMB and RDP

3.2. Attack Scenarios

In order to confirm the effectiveness of the locally deployed LLM GPT-OSS in assessing the maliciousness of log messages received from a Windows machine, it is necessary to establish a system in which it would be precisely known whether a log message is malicious or not. For this reason, 2 brute force attack scenarios were created that are directed at services opened on a Windows machine (SMB and RDP) with pre-prepared wordlists containing the real credentials of the machine. By launching the attack, every log message related to activity directed at the SMB and RDP services would be malicious in nature, which allows an objective assessment of the effectiveness of the observed framework. The attacks were implemented using the Hydra tool on a Kali Linux attack machine, and the attack flow is demonstrated in Figure 2.

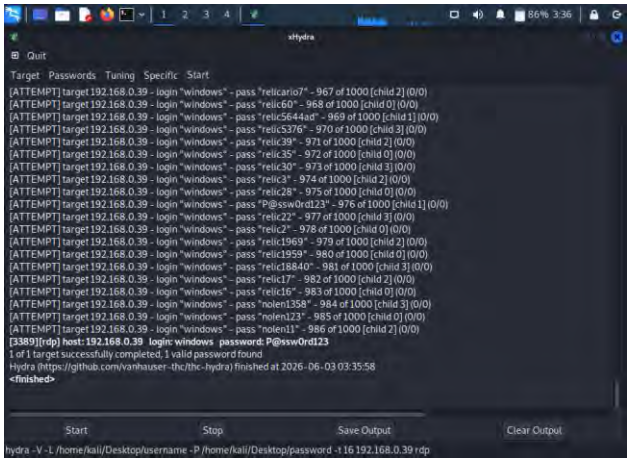

Figure 2. Generating log dataset by RDP brute-force attack using Hydra tool

3.3. Log Collection and Context Generation

Windows Security logs generated during the experiment were collected using NXLog and transformed into a structured representation containing the most relevant authentication-related attributes. Examples of extracted fields included Event ID, timestamp, username, source IP address, logon type, and authentication status.

Due to the simplicity of processing, the NXlog configuration allows for the collection of only log messages related to the SMB and RDP services, which are processed in such a way that each event is recorded as a single line in the log message, as presented:

2026-06-01 23:46:55 DESKTOP-8KVG4F0 An account failed to log on. Subject: Security ID: S-1-0-0 Account Name: - Account Domain: - Logon ID: 0x0 Logon Type: 3 Account For Which Logon Failed: Security ID: S-1-0-0 Account Name: admin Account Domain: Failure Information: Failure Reason: Unknown user name or bad password. Status: 0xC000006D Sub Status: 0xC0000064 Process Information: Caller Process ID: 0x0 Caller Process Name: - Network Information: Workstation Name: \\192.168.0.46 Source Network Address: 192.168.0.46 Source Port: 63342 Detailed Authentication Information: Logon Process: NtLmSsp Authentication Package: NTLM Transited Services: - Package Name (NTLM only): - Key Length: 0

Instead of analyzing individual events in isolation, the proposed framework used a sliding context window approach, which has proven effective in previous research using the same locally deployed model [2]. For each classification request, the GPT-OSS model received the most recent 50 log entries, including the event under investigation. This design was intended to provide temporal and contextual information that could help the model recognize repetitive authentication failures characteristic of brute-force attacks. The GPT-OSS model was instructed to analyze the supplied log sequence and determine whether the latest event represented normal activity, an SMB brute-force attack, or an RDP brute-force attack. The generated classification was subsequently compared with the ground-truth label associated with the experimental scenario.

4. GPT-OSS-BASED DETECTION APPROACH

The proposed detection framework performs real-time analysis of Windows Security logs using a locally deployed GPT-OSS model. After collection and preprocessing by NXLog, each log event is forwarded to an analysis pipeline that evaluates both the individual event and its surrounding context. To provide temporal awareness, a sliding window containing the most recent security events is maintained in memory and continuously updated as new logs arrive. For every newly received log entry, system evaluates the same log together with a context window consisting of previously observed events. This approach enables the model to identify behavioral patterns that are characteristic of brute-force attacks, such

as repeated authentication failures originating from the same source host or targeting the same user account.

The GPT-OSS model receives the log data through a structured prompt that instructs it to classify the observed activity as either benign or malicious. When malicious behavior is detected, the model is additionally required to identify the attack category and provide a short explanation supporting its decision. The generated output is subsequently stored together with the original log entry and metadata for further evaluation.

To support future analysis and reproducibility, all processed events and corresponding model decisions are archived in a vector database and exported to a structured dataset. This design enables direct comparison between classifications obtained from single-event analysis and those produced using contextual information, allowing the effectiveness of context-aware LLM-based detection to be systematically evaluated.

5. RESULTS AND DISCUSSION

As the technical feasibility of the system was presented in the previous chapter, it was necessary to confirm the efficiency of GPT-OSS in log analysis. The metric used to evaluate model performance, as well as statistical analysis, is the F1 score. The results important for calculating the F1 score (for RDP and SMB brute-force attacks) are given in Table 2.

Table 2. Confusion matrix results for single-log and contextual log analysis of logs

Attack type	GPT-OSS 20B single log judgement				GPT-OSS 20B contextual log judgement			
	TP	FP	TN	FN	TP	FP	TN	FN
RDP brute-force	975	0	0	17	991	0	0	1
SMB brute-force	761	0	0	217	976	0	0	2

The presented results represent the evaluation of the GPT-OSS 20B model listed in the table in classifying log messages as malicious or benign for two specific attack scenarios - RDP and SMB brute force attacks on Windows 10 machine. All log messages generated as a system response to attacks were considered malicious. By using parameters given in Table 2, Precision, Recall and F1 score are calculated and presented in Table 3.

Table 3. Confusion matrix results for single-log and contextual log analysis of logs

Attack type	GPT-OSS 20B single log judgement			GPT-OSS 20B contextual log judgement		
	Precision	Recall	F1	Precision	Recall	F1
RDP brute-force	1	0.983	0.991	1	0.999	0.999
SMB brute-force	1	0.778	0.875	1	0.998	0.999

Given results show that GPT-OSS 20B achieves very high accuracy in detecting both RDP and SMB brute-force attacks, with very high F1 score in all experiments, indicating a complete absence of false positive detections. However, analysis of individual logs shows a significantly lower recall, especially for SMB brute-force attacks (0.778), suggesting that the model misses a large number of malicious events when it lacks additional context. By introducing context from 50 previous logs, the performance improves drastically, with Recall reaching 0.999 for RDP and 0.998 for SMB brute-force attacks. Consequently, the F1 measure increases from 0.991 to 0.999 for RDP and from 0.875 to 0.999 for SMB, confirming that contextual information plays a key role in correctly recognizing attack patterns. The results indicate that such a system has significant potential for application as an additional layer of protection within security operations centers and incident detection and response systems. It is particularly suitable for continuous analysis of large volumes of logs and early detection of attack patterns through event correlation, which can improve the overall effectiveness of cyber protection and reduce the likelihood of missing malicious activities.

5. CONCLUSION

This paper presented an approach for applying a locally deployed GPT-OSS large language model to the detection of SMB and RDP brute-force attacks using Windows Security logs. The motivation for this research originates from the continued prevalence of authentication-based attacks against critical Windows services and the limitations of traditional rule-based detection mechanisms when dealing with large volumes of security events. To address these challenges, a proof-of-concept framework was developed that combines Windows log collection, NXLog-based preprocessing, context-aware event correlation, and LLM-driven classification.

The experimental evaluation was conducted in a controlled environment consisting of a Windows target host with SMB and RDP services enabled and a Kali Linux attack host executing brute-force attacks using Hydra. A dedicated dataset of Windows Security events was generated and labeled based on the performed attack scenarios. To improve the relevance of the information provided to the model, the preprocessing stage focused on authentication-related events and attributes associated with the monitored services, reducing noise while preserving security-critical context.

The obtained results demonstrate that the GPT-OSS model is highly effective in identifying brute-force activity from Windows Security logs. The model achieved an F1 score of 0.999 for RDP brute-force detection and SMB brute-force detection, indicating excellent classification performance across both attack scenarios in contextual judgement. These results confirm that a context-aware analysis approach enables the model to recognize repetitive authentication patterns and distinguish malicious activity from legitimate user behavior with a high degree of accuracy.

An additional contribution of this work is the demonstration that Mixture-of-Experts (MoE) architectures can be effectively deployed on commodity server hardware equipped with 32 GB of VRAM while

still delivering high detection performance. The GPT-OSS model was selected based on its previously demonstrated efficiency under these hardware constraints, and the results obtained in this study further validate its suitability for real-time cybersecurity applications. The proposed framework demonstrates that locally deployed open-weight language models can serve as practical components of modern security monitoring systems without requiring extensive feature engineering or manually crafted detection rules.

Abstract: *Despite rapid progress in evaluating large language models, the Lost in the Middle phenomenon — a persistent weakness of Transformer-based models whereby information near the middle of the context window exerts less influence on generation — remains unresolved. This paper examines the phenomenon in Serbian, among the first such studies outside English, evaluating three recent open-weight small language models on a filtered multi-document QA dataset. Each query contains a question and ten documents, only one of which holds the answer; its position is shifted from first to tenth place to measure the resulting change in accuracy. A dedicated evaluation procedure was developed to account for the morphological complexity of Serbian, combining string-based matching with a final LLM-based judgment stage (Claude Haiku) for cases obscured by grammatical case variation. Within this dataset and context length, a Cochran's Q test revealed no statistically significant accuracy degradation for any of the three models as the gold document approached the middle of the context. Larger differences were instead observed between the models: Gemma-4-26B-A4B (92.9%) and Qwen3.6-35B-A3B (91.9%) could not be distinguished statistically ($p = 0.151$), while GPT-OSS-20B (87.3%) was reliably weaker than both ($p < 0.0001$), suggesting that model choice may play a more important role than gold-document position.*

Keywords: *position bias, lost in the middle, information retrieval, language-specific bias, open-weight LLMs*

1. INTRODUCTION

Large language models largely represent the most advanced technology in the world of natural language processing. Although very widespread in everyday use, the Transformer architecture, as the basis of most contemporary language models, faces many problems that have not been completely overcome to date. Most of these shortcomings are related to the context window, a component that in many ways negatively affects the accuracy of the model. One of the most well-known disadvantages of language models is referred to as the Lost in the Middle phenomenon. It assumes that the performance of the model is higher when important information is located at the beginning or at the end of the input context, while on the other hand, the ability of the model to find relevant information drops significantly when position of relevant information tends to the middle of the context window [1].

The research on this phenomenon is of great importance primarily due to a significant number of systems based on language models and designed for tasks such as Retrieval-Augmented Generation, information retrieval and multi-document QA. These systems have in common that finding an answer is directly related to the described phenomenon, which significantly affects their adoption in production environments. So far, most of the research dealing with this problem is focused on the English language, while only a few experiments considered other languages. Accordingly, this research considers the Lost in the Middle phenomenon in the context of the Serbian language.

Since there is no narrowly specialized language model for the Serbian, in this research we consider three open-weight general-purpose multilingual language models: Qwen3.6-35B-A3B, Gemma-4-26B-A4B and GPT-OSS-20B. For none of these models has already been examined whether the Lost in the Middle phenomenon has the same correlation with all the languages or whether the position bias reflects differently for different languages. Since a multilingual model shares all of its parameters across languages, language-specific behavior arises from the composition of the training data and from the tokenizer, and can therefore induce specific phenomena that manifest differently for different models and languages. The Lost in the Middle phenomenon is not exclusively related to open-weight models, but is also present in large language models such as GPT-4 and Claude 3 Opus [2,3].

DOI: 10.5937/OTEH26093J

However, this research is aimed at examining the Lost in the Middle phenomenon in language models applied to Serbian, which is a highly inflective and morphologically rich language.

The main contributions of this work are:

(1) This research is one of the first studies on the Lost in the Middle phenomenon in language models applied on Serbian.

(2) An evaluation procedure was developed that accounts for the morphological complexity of the Serbian language.

(3) A comparative evaluation of three current small open-weight models was conducted, showing that Gemma-4-26B-A4B and Qwen3.6-35B-A3B perform comparably in extractive question answering in Serbian, while GPT-OSS-20B is reliably weaker.

2. RELATED WORKS

The Lost in the Middle phenomenon was first described in [1], where the performance of language models, plotted against the position of the relevant information, forms a characteristic "U-curve". Later work proposed ways to mitigate it without fine-tuning, such as Multi-scale Positional Encoding [4] and rescaling a single dimension of the hidden states at inference time, which improves results by up to 15% [5]. Other work examined its causes, showing that residual connections significantly affect cumulative attention and thereby contribute to the U-curve [6]. Menschikov et al. showed that position effects differ across languages and pointed out the lack of evaluation for languages with fewer speakers [3]. Among broader long-context benchmarks, RULER showed that models which solve vanilla "Needle In A Haystack" tests still lose accuracy as the context grows [7], and the bilingual LongBench showed that Chinese is similarly affected when the answer must be found among many documents [8].

The single-gold-document design used in this work goes back to [1], where each question is accompanied by several documents, only one of which contains the answer. Later benchmarks extended multi-document question answering in other directions: the "Leave No Document Behind" benchmark, for example, is built so that every document is relevant to the final answer, and only one of its four task types (spotlight locating) places the evidence in a single document [9]. In this work, the distractors are taken from the same topic as the gold document, which is expected to make the task more demanding than when the documents come from different topics.

3. DATASET

At the moment of writing this paper, there was no publicly available dataset aimed at the research and evaluation of the Lost in the Middle phenomenon for Serbian language. Generally speaking, the Serbian language lacks a sufficient number of data corpora that will contribute to the development of language models for this language. Therefore a significantly modified version of the SQuAD-sr-md part of the dataset [10] was used. Originally, it was defined as a QA dataset in the Serbian language, suitable for training or fine-tuning models for extracting data from text. The dataset was created by translating texts from foreign languages using the adapted Translate-Align-Retrieve method, while also manual revision of the entire translation process was performed.
The dataset originally consists of 7484 questions and 1739 contexts (documents) in which the answer to them is found. The documents vary in length, but for each question it has been determined which document contains the necessary information for the answer.

Table 1. Dataset preview for first topic

Doc.	Question	Answer
1	Koliko akcija postoji u imovini Arsenala?	62.217
2	Koliki procenat akcija u Arsenalu je Kroenke posedovao do 2011. godine?	62.89
3	U kom filmu je prikazan FK Arsenal?	misterija Arsenalovog stadiona
4	Ko je pobedio Arsenal 2011. godine u Liga kupu?	Birmingem Sitija
5	U kom takmičenju je Arsenal prvi ušao u finale?	UEFA Lige šampiona
6	Koja je razlika u plavoj boji gostujuće sportske opreme Arsenala posle 1983.godine?	tamnijom nijansom
7	Koji brend je bio dobavljač sportske opreme pre 1994. godine?	Adidasa
8	Iz kojih zajednica dolaze pristalice Arsenala?	različitih društvenih klasa
9	Koji trener je krajem devedesetih godina prošlog veka doneo uspeh Arsenalu?	Arsena Vengera
10	Koji bivši igrač Arsenala je postao trener 1986. godine?	Džordža Grejema

To adopt this dataset for the purpose of this work, the filtering procedure was designed to ensure that the answer to each question appears in exactly one document. It was applied in four steps. First, questions were removed if their answer appeared in any other document belonging to the same topic (case sensitivity was not used), which reduced the number of questions from 7484 to 5960. Second, to account for the rich morphology of Serbian, questions were additionally removed if the stem of any word from the answer occurred in another document of the same topic; this step can only make the filtering stricter. Third, duplicate questions were eliminated, i.e., a small number of repeated questions whose answers differed only in minor variations; after the second and third steps, 5381 questions in 1650 documents remained. Finally, the documents were balanced in length:

documents whose word counts fell outside predefined lower (121) and upper (188) bounds were discarded, so that all documents in a query are of comparable length. Of the 48 topics, only the fifteen that retained at least ten documents within these bounds were kept; from each of them, ten documents were selected at random, and for each document one question was selected at random among the questions that survived filtering. This yields the final set of 150 questions and documents (fifteen topics with ten documents each).

This design ensures a consistent context length across queries: within a topic, all queries contain the same ten documents and differ only in their order, so their length is identical, while differences between topics are negligible. Furthermore, the topics span a wide range of domains (including sports, notable individuals, emotional wellbeing, music, the internet, history, and politics) so the evaluation does not depend on any narrowly specialized subject matter.

Table 1 shows the first topic of the dataset: each of its ten documents is accompanied by one question and the reference answer, which is a verbatim span of that document.

4. EXPERIMENTAL SETUP

The main concepts of the experiment are based on testing the Lost in the Middle phenomenon for open weight models that are deployed in a local infrastructure physically separated from the Internet. The goal is to investigate and evaluate the model's ability to find the answer to a given question and investigate whether the location of the document containing the answer directly affects the model's performance, while using modest models in the controlled environment.

4.1. Language Models

For the purposes of this work, we used one of the most current open-weight models of large companies whose architecture is based on Mixture-of-Experts technology and which can be deployed on consumer hardware that has 32 GB of VRAM. Three models were selected:

(1) Qwen3.6-35B-A3B, developed by Alibaba Cloud, released on April 15, 2026.

(2) Gemma-4-26B-A4B, developed by Google, released on April 2, 2026.

(3) GPT-OSS-20B, developed by OpenAI, released on August 5, 2025.

All three models were run using the llama.cpp inference framework, version 9859 (commit 4fc4ec554). Gemma-4-26B-A4B and Qwen3.6-35B-A3B were used with Q8_0 quantization; since the Q8_0 weights do not fit entirely within 32 GB of VRAM, the portion of the weights that exceeded the available VRAM was offloaded to system memory, which affects inference speed but not the model's output. GPT-OSS-20B was used as the full model in the MXFP4 format in which its weights were released, without additional quantization. The context window allocated on the server was 100,000 tokens. For Qwen3.6-35B-A3B, the temperature was set to 1.0, top-p to 0.95, and top-k to 20, while thinking mode was enabled. For Gemma-4-26B-A4B, the temperature was set to 1.0, top-p to 0.95, and top-k to 64, while thinking mode was enabled. For GPT-OSS-20B, the temperature was set to 1.0, top-p to 1.0, and top-k was disabled, while the reasoning effort was set to medium. These decoding parameters were selected according to the recommendations of the respective model developers for general-purpose tasks. The maximum output length was not limited, so generation ended at the model's end-of-sequence token. A fixed seed (42) was sent with every request. If a response did not contain the “<odgovor>” tag, or the request failed at the network level, the same request was repeated, up to three attempts in total, and the response of the last attempt was kept. All system and user prompts were written in Serbian using the Latin script.

These three models represent the latest generation models of the world's largest companies that contribute to the development of multilingual open-weight models, in the absence of language models specialized for the Serbian language.

4.2. Methodology

Each query contains all ten documents of one topic followed by the question, and exactly one of the documents, the gold document, contains the answer. Every document of a topic takes the role of the gold document in turn, and in ten consecutive queries it is placed at each position from the first to the tenth, while the nine distractors keep the same relative order. With fifteen topics of ten documents each, this gives 15 × 10 × 10 = 1500 queries per model, 150 for each gold position.

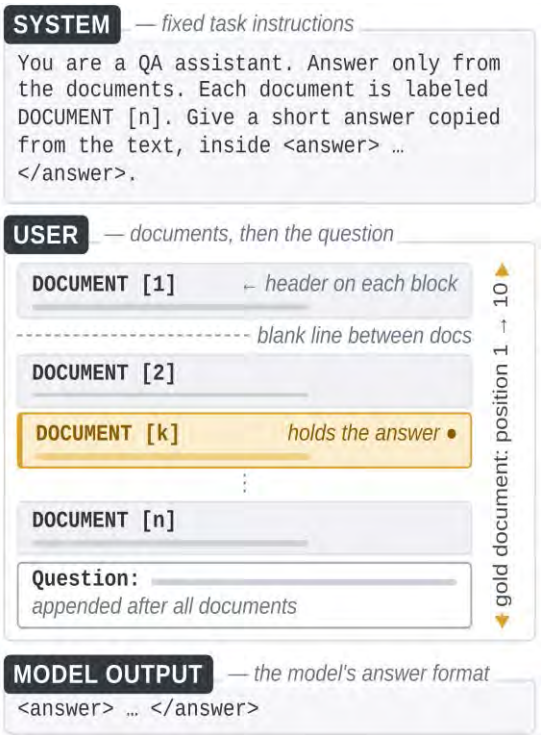

Figure 1. Structure of the prompt, with the gold document changing position across queries.

Unlike [1], which used contexts of ten, twenty, and thirty

documents and three gold positions (the first, fifth, and tenth) in its ten-document setting, only ten documents are used here, but the gold document is placed at all ten positions. In [1], accuracy was highest when the relevant document was at the beginning or the end of the context and lowest in the middle, giving the characteristic "U-curve"; comparing the edge positions with the middle ones is therefore the main aim of the design. Figure 1 shows the structure of a query. The system part instructs the model not to answer in its own words, but to return the part of the document that contains the answer inside the <odgovor> tag. This reflects the extractive nature of the dataset, in which every reference answer is a verbatim span of its document, and also makes it possible to check whether the model follows the instruction. For readability, the markers in Figure 1 are shown in English; the actual prompts use the Serbian equivalents (DOKUMENT [n], Pitanje:, <odgovor>).

5. RESULTS AND DISCUSSION

As already mentioned, the original dataset gives an answer to each question that represents a text sequence extracted from the document to which it belongs and without any change of word form. If we take into account the nature of the Serbian language, it is clear that it is not possible to use only the "exact match" method to evaluate the results of the model because the language models gave answers of different lengths, even though they all had the same instructions.

Because Serbian is a morphologically different language from English, a model can give a completely correct answer that still differs from the ground truth answer only in grammatical form — for example, a name may appear in a different case ending depending on its role in the sentence. Judging answers with a plain, character-by-character comparison would therefore unfairly mark many correct answers as wrong. To address this, each model's answers were evaluated using three checks, applied in sequence, where each approach's resulting curve is plotted and shown on figures 2, 3 and 4. First, we checked for an exact match between the model's answer and the reference answer. Second, for answers that did not match exactly, we normalized both texts (lowercasing them, removing quotation marks and trailing punctuation, and collapsing extra spaces) and compared them again, which accounts for purely cosmetic differences. Third, for answers still unmatched after the first two checks, we evaluated the remaining pairs using an LLM-as-a-judge approach: the judge model (Claude Haiku 4.5) was given the question, the reference answer, and the model's answer, together with a fixed, explicit set of criteria - grammatical and case-ending differences, synonyms, and minor differences in phrasing were to be treated as correct, while a different, incorrect, or unrelated answer was to be treated as incorrect - and asked to judge whether the two carry the same information. This step was introduced because even a permissive character-level comparison cannot recognize an answer that is phrased in an entirely different way while still conveying the correct information, which becomes increasingly relevant for longer or more paraphrased model answers. The same explicit criteria were applied uniformly to every answer, regardless of which model produced it or where the gold document had been placed in the context, and the judge was given no information about the experimental setup itself; this step was also only applied to the subset of answers left unresolved by the first two checks, rather than being used to re-evaluate every answer. Taken together, this keeps the evaluation consistent across all models and positions and confines the more permissive judgment to genuinely ambiguous cases. The judge was used on 26 September 2026 with its default decoding settings. In total, 779 answers of Gemma-4-26B-A4B, 819 of Qwen3.6-35B-A3B, and 983 of GPT-OSS-20B (2,581 overall) reached this stage, of which 673, 698, and 792 were accepted. To validate this stage, a native speaker of Serbian independently judged a random sample of the judge's decisions, stratified by model (50 per model, 150 in total), including both accepted and rejected answers. The human judgments agreed with the judge in all 150 cases (100%; 95% Wilson confidence interval 97.5–100%), and in all 50 cases for each model (95% Wilson interval 92.9–100% per model).

Because the judge never learns where the gold document was placed, the position analysis was also repeated on the outcomes of the first two stages alone, which the judge does not affect. The position effect was again not significant for any model (Cochran's Q: Gemma-4-26B-A4B $Q = 2.88$, $p = 0.969$; Qwen3.6-35B-A3B $Q = 4.44$, $p = 0.880$; GPT-OSS-20B $Q = 10.86$, $p = 0.286$), so the conclusion about position does not depend on the judge.

In the next three subsections the results per used LLM are provided. To evaluate results, three matching criteria explained earlier in this section, are shown for each evaluated LLM.

5.1. Gemma-4-26B-A4B results

Gemma-4-26B-A4B reaches the highest final accuracy of the three models (92.9% after all three evaluation stages) and shows a largely flat curve across all ten gold-document positions, ranging only from about 91% to 95% (though not significantly higher than Qwen3.6-35B-A3B, see Section 6). There is no visible dip when the gold document sits in the middle of the context, which is the pattern the original Lost in the Middle study reported for many models. As shown in Figure 2, Gemma-4-26B-A4B maintains a consistently high and stable accuracy across all gold document positions, with the 95% Wilson confidence intervals overlapping substantially at every position and no pronounced drop near the middle of the context window. A Cochran's Q test across the ten positions finds no statistically significant position effect ($Q = 5.18$, $p = 0.818$), and McNemar tests contrasting the first and the tenth position against the fifth position (the design used by Liu et al. [1]) likewise find no significant differences (92.7% and 93.3% vs. 91.3%; Holm-corrected $p = 0.750$ in both cases). The differences between the edge positions and the fifth position are +1.3 percentage points (95% CI −2.3 to +5.3) and +2.0 points (95% CI −1.3 to +5.8), so a drop toward the middle larger than about 6 points is unlikely, whereas a smaller one cannot be excluded; the position-to-position fluctuations visible in the curve therefore cannot be distinguished from sampling noise at this sample size (n=150 per position).

In 1499 of 1500 queries (99.9%), the model returned a correctly formatted <odgovor> tag on the first attempt, and only a single query remained without it. In 84.5% of cases, the extracted answer appeared verbatim in the gold document. The answers were generally short (median of three words, comparable to the reference answers), with only 7.3% exceeding ten words despite the instruction to return only a few words.

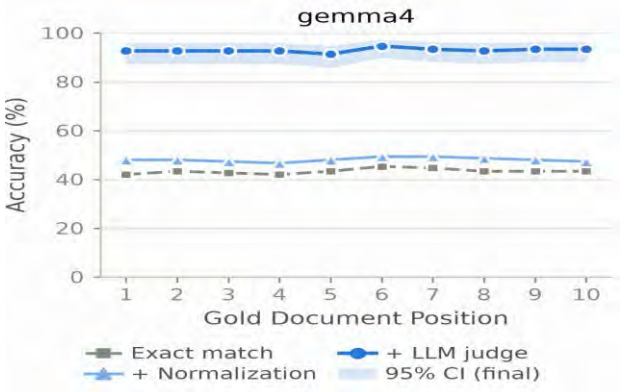

Figure 2. Gemma-4-26B-A4B accuracy by gold document position after exact matching, normalization, and LLM judge (final); shaded: 95% Wilson CI of final accuracy (n=150 per position).

5.2. Qwen3.6-35B-A3B results

Qwen3.6-35B-A3B performs close to Gemma-4-26B-A4B in absolute terms (91.9% at the final stage) and, like Gemma-4-26B-A4B, shows a largely flat curve across positions, staying within a narrow 89%–94% band with no clear dip in the middle. Its raw exact-match accuracy (42.6%) is noticeably lower than its final accuracy, and the largest jump in the cascade comes from the LLM-as-a-judge stage rather than from normalization alone, indicating that most of its apparent errors are surface-level or paraphrastic mismatches rather than genuine failures to locate the correct information. As shown in Figure 3, Qwen3.6-35B-A3B exhibits accuracy comparable to Gemma-4-26B-A4B, remaining largely stable across gold document positions and likewise showing no strong Lost in the Middle effect. A Cochran's Q test across the ten positions comes closer to conventional significance than for the other two models but still does not reach it ($Q = 15.48$, $p = 0.079$), and McNemar tests contrasting the first and the tenth position against the fifth position likewise find no significant differences (93.3% and 91.3% vs. 91.3%; Holm-corrected $p = 0.906$ and $p = 1.000$; differences +2.0 points, 95% CI −1.8 to +6.2, and 0.0 points, 95% CI −3.3 to +3.3), so the dips visible in the curve cannot be distinguished from sampling noise at this sample size. The model returned a well-formed tag on the first attempt in all 1500 queries (100%). In 79.5% of cases, the extracted answer appeared verbatim in the gold document. It also produced the shortest answers of the three models with only 5.6% exceeding ten words.

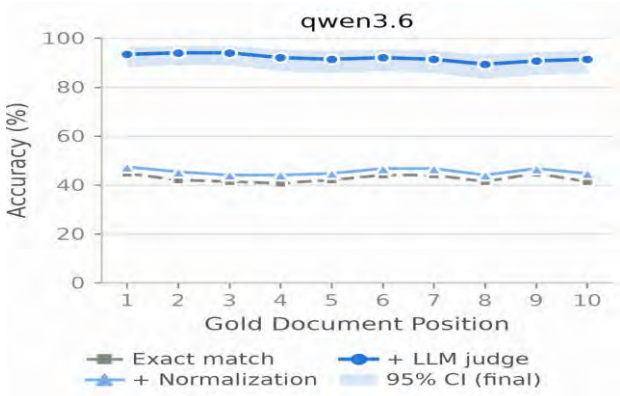

Figure 3. Qwen3.6-35B-A3B accuracy by gold document position after exact matching, normalization, and LLM judge (final); shaded: 95% Wilson CI of final accuracy (n=150 per position).

5.3. GPT-OSS-20B results

GPT-OSS-20B produces the lowest overall accuracy of the three models (87.3% at the final stage), swinging between roughly 85% and 89% across positions. The lowest point falls at position 5 and the highest at position 1, but this difference is within the range of sampling noise.

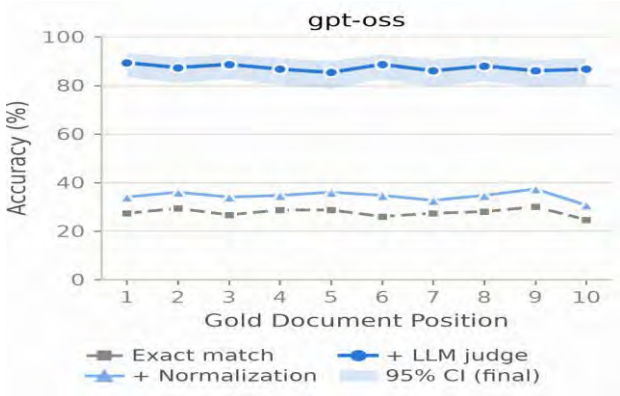

Figure 4. GPT-OSS-20B accuracy by gold document position after exact matching, normalization, and LLM judge (final); shaded: 95% Wilson CI of final accuracy (n=150 per position).

As shown in Figure 4, GPT-OSS-20B achieves the lowest overall accuracy among the tested models; however, its position-to-position swing (about 4 percentage points) is no larger than Qwen3.6-35B-A3B's (about 5 percentage points), and a Cochran's Q test across the ten positions finds no statistically significant position effect ($Q = 6.45$, $p = 0.694$) — if anything, a weaker signal than for Qwen3.6-35B-A3B. McNemar tests contrasting the first and the tenth position against the fifth position likewise show no significant differences (89.3% and 86.7% vs. 85.3%; Holm-corrected $p = 0.420$ and $p = 0.727$; differences +4.0 points, 95% CI −1.3 to +9.6, and +1.3 points, 95% CI −2.7 to +5.5). Taken together, these results suggest that GPT-OSS-20B's lower overall accuracy reflects a general weakness at extracting the correct answer rather than a heightened sensitivity to where that answer appears in the context.

A correctly formatted tag was obtained on the first attempt in 1498 of 1500 queries (99.9%), while the remaining two required a second attempt. The extracted answer appeared verbatim in the gold document in 64.8% of cases, noticeably less often than for the other two models. It also produced the longest answers (12.0% exceeded ten words), suggesting a weaker adherence to the instruction to return a short excerpt taken directly from the text.

6. CONCLUSION

This paper examined the Lost in the Middle phenomenon in the context of the Serbian language, using a filtered Multi-document QA dataset in which the position of the gold document was varied across ten positions. With awareness of the rich morphology of the Serbian language, a dedicated three-stage evaluation procedure was introduced, in which a large language model (Claude Haiku) acted as an automatic judge in the final stage. The obtained results, based on three current open-weight small language models, did not reveal a statistically significant accuracy degradation when the gold document was positioned near the middle of the context (Cochran's Q, all $p > 0.05$). The 95% confidence intervals of the edge-to-fifth-position differences reach at most about 6 percentage points for Gemma-4-26B-A4B and Qwen3.6-35B-A3B and 10 for GPT-OSS-20B, so a drop of the size Liu et al. [1] reported for GPT-3.5-Turbo in a comparable ten-document setting (about 16 points) is well outside what the data allow, whereas a drop of a few points could have gone unnoticed. This finding is specific to this dataset and these three models and suggests that the Lost in the Middle effect may not be equally manifested across all models and languages; whether this reflects the models, the length and composition of the context, or the Serbian language remains an open question for future work. By contrast, larger differences were observed between the models: GPT-OSS-20B performed reliably worse than both Gemma-4-26B-A4B (Holm-corrected $p = 1.3 \times 10^{-11}$) and Qwen3.6-35B-A3B ($p = 6.8 \times 10^{-9}$), whereas the difference between the latter two did not reach significance ($p = 0.151$), suggesting that model choice may have had a greater impact on retrieval accuracy than the position of the relevant information. The proposed evaluation methodology proved effective in correctly identifying answers despite grammatical case variation confirming that language-specific characteristics must be taken into account when evaluating large language models. For extractive question answering over ten documents in Serbian, in the configurations tested here, Gemma-4-26B-A4B and Qwen3.6-35B-A3B are equally suitable choices, whereas GPT-OSS-20B is less suitable.

Abstract: *This paper will considered that the strongest instructional model is not "AI replaces analysis", but evidence-first reverse engineering, AI-assisted interpretation, human verification, secure remediation, and reflective ethical review. In the study below, a 12-week AI+RE intervention outperformed a conventional control on knowledge post-test, practical labs, retention, problem-solving quality, and ethical reasoning. The effects are intentionally plausible rather than dramatic: large enough to matter instructionally, but not so large as to imply that tools eliminate the need for human expertise.*

Keywords:*artificial intelligence (AI), reverse engineering (RE), constructive learning, cybersecurity education, software-intensive operations*

1. INTRODUCTION

Industry 4.0 combines connected production systems, software-intensive operations, and cyber-physical integration, which raises the educational value of secure software analysis, systems thinking, and workforce-aligned cybersecurity practice. In that setting, reverse engineering is not a niche specialty: it is a core method for understanding opaque software, diagnosing abnormal behavior, supporting vulnerability discovery, and building security judgment. Constructive alignment is therefore a strong pedagogical fit, because it explicitly links higher-order learning outcomes, authentic hands-on activities, and assessment. [1]

The research base also suggests a dual conclusion about large language models. LLMs can improve code explanation, tutoring, and feedback in computing education, especially when embedded in structured workflows; however, unguided access can reduce engagement for some learners, and code-focused models still generate insecure or misleading output often enough that secure-development controls and responsible-use policies are mandatory. [2]

Based on that evidence, the strongest instructional model is not "AI replaces analysis", but evidence-first reverse engineering, AI-assisted interpretation, human verification, secure remediation, and reflective ethical review. In the study below, a 12-week AI+RE intervention outperformed a conventional control on knowledge post-test, practical labs, retention, problem-solving quality, and ethical reasoning. The effects are intentionally plausible rather than dramatic: large enough to matter instructionally, but not so large as to imply that tools eliminate the need for human expertise.

The conceptual foundation of this research is a three-way synthesis. First, Industry 4.0 emphasizes digitally integrated, software-dependent production and service environments. Second, reverse-engineering research frames RE as a disciplined path from opaque artifact to actionable understanding. Third, constructive alignment and guided hands-on cybersecurity exercises show that students learn best when authentic analytical tasks are scaffolded rather than either fully scripted or completely open-ended. [3]

The semester shape assumed here is a 12-week applied course, with a one-semester intervention and a 4-week delayed retention check. That duration is adapted from the uploaded course outline, which describes a 12-week, six-credit applied computing course with prerequisite software/programming background; this report reorients that template from CMS development to cybersecurity education.

The assumed tool stack is intentionally conservative and classroom-safe: decompilation/disassembly with Ghidra; debugging and trace-based analysis with standard debuggers and syscall tracing; vulnerability vocabulary via CWE and ATT&CK; secure-development framing via SSDF; AI-risk framing via AI RMF; and training targets such as Juice Shop or DVWA that are explicitly intended for education in controlled environments [4].

Table 1. Assumed tool stack

Assumption	Value used in this report
Cohort size	72 students, randomized 1:1
Delivery model	Blended lecture + supervised lab
Duration	12 teaching weeks + 4-week retention test
Student profile	Upper-division computing/cybersecurity students with prior programming

Corresponding author: E. Mekić;
E-mail: ediemceach3@gmail.com
DOI: 10.5937/OTEH26094M

Assumption	Value used in this report
Intervention	Reverse engineering + LLM-assisted code analysis + secure coding
Comparison arm	Conventional security labs without integrated LLM workflow
LLM access	Institutionally approved interface with logging and policy controls
Lab infrastructure	Isolated VMs/containers, no public targets, sanitized artifacts only

These starting points are analytically useful because they are large enough for plausible section-level randomization, but small enough to resemble a real applied university course rather than a MOOC-scale experiment. They also align with current guidance to map educational outcomes to workforce-relevant cybersecurity knowledge and skills [5].

2. STUDY DESIGN

The study design is a mixed-method, parallel-group, randomized classroom experiment. Students are assigned to either a control condition or an AI+RE intervention. Both groups receive the same learning objectives, contact hours, instructor team, and grading weight. The difference is instructional workflow: the control arm uses conventional readings, demos, and lab writeups, while the intervention arm adds structured reverse-engineering notebooks, prompt-governed LLM support, AI critique tasks, and mandatory verification of AI-suggested explanations and remediations [6].

Table 2. Study design

Component	
Participants	72 students; Control n = 36, AI+RE n = 36
Learning activities	Reverse-engineering labs, LLM-assisted code analysis, secure coding remediation tasks
Primary knowledge measure	Pre/post cybersecurity analysis test, 0–100
Performance measures	Reverse-engineering lab score, code-analysis task score, secure-coding remediation score, practical composite
Higher-order measures	Problem-solving rubric (1–5), ethical reasoning rubric (1–5)
Retention measure	Delayed test at 4 weeks, 0–100
Qualitative data	Reflection memos, lab annotations, two focus groups, instructor observations
Statistical methods	Baseline equivalence tests; group difference in gain scores; endline group comparisons; Cohen's d for effect size; thematic coding for qualitative data
Fidelity controls	Same instructor, same capstone brief, common rubric, supervised labs, restricted tool policy

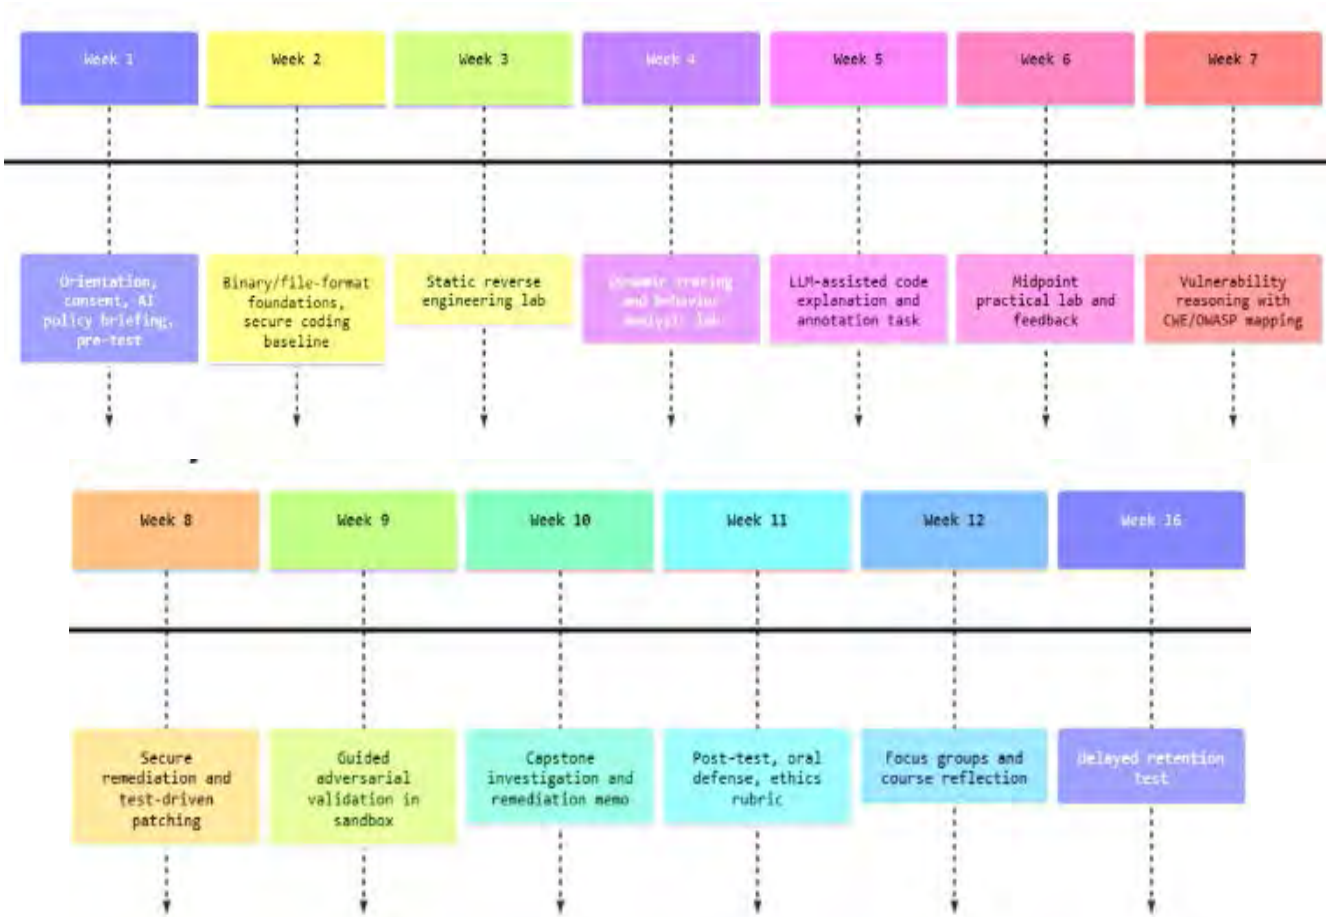

Figure 1. Design choices

A plausible weekly sequencing is to start with static structure, move to dynamic traces, then add LLM support only after students can independently produce baseline evidence. That ordering reduces the chance that students treat the model as an oracle and is consistent with findings that LLM benefits are strongest when they augment, rather than replace, student reasoning.

3. RESEARCH RESULTS

Here are empirical results from implemented study

Quantitative results

Table 3. Quantitative results

Metric	Control M(SD)	AI+RE M(SD)	p-value	Effect size d
Knowledge pre-test (0– 100)	47.8 (10.4)	48.6 (10.7)	.749	0.08
Knowledge post-test (0–100)	58.6 (11.2)	67.6 (10.9)	.001	0.81
Knowledge gain (post – pre)	10.8 (7.6)	18.6 (8.2)	< .001	0.99
Retention test at 4 weeks (0–100)	55.4 (10.3)	63.0 (10.0)	.003	0.75
Ethical reasoning rubric (1–5)	3.40 (0.50)	3.75 (0.50)	.004	0.70

Practical performance metric	Control M (SD)	AI+RE M (SD)	p-value	Effect size d
Reverse-engineering lab average (0–100)	69.0 (10.7)	76.0 (9.8)	.005	0.68
Code-analysis task (0–100)	66.5 (11.0)	78.1 (10.2)	< .001	1.09
Secure-coding remediation task (0–100)	68.2 (10.4)	77.4 (9.6)	< .001	0.92
Practical composite (0–100)	67.9 (9.8)	76.2 (9.1)	< .001	0.88
Problem-solving rubric (1–5)	2.90 (0.60)	3.35 (0.60)	.002	0.75

The largest lift appears on code explanation and remediation, not on baseline factual recall. That mirrors the current literature: LLM-assisted support tends to be most useful on feedback, explanation, and stuck-point recovery, while raw code generation still requires verification because security and engagement risks remain material.

The results also imply that AI+RE does not simply boost output speed; it improves delayed retention and ethical reasoning when the model is embedded in a supervised verification loop. That is consistent with constructive alignment and with hands-on cybersecurity work showing that analysis skills improve when exercises are designed around meaningful evidence, guided inquiry, and explicit reflection on how and why tools are used.

Qualitative findings

Table 4. Quantitative results

Theme	Simulated interpretation
Faster recovery from confusion	Students reported that LLMs helped them get unstuck on unfamiliar APIs, assembly fragments, or trace output faster than forum-style searching.
Better articulation of reasoning	Lab reports in the intervention arm contained clearer causal explanations of “what the program is doing” and “why this behavior is suspicious.”
Improved remediation quality	Students more often connected observed weaknesses to concrete mitigations and validation steps.
Trust calibration problems	A recurring complaint was that the model could sound certain while being partially wrong, especially on low-level behavior.
Ethical boundary awareness	Students said the explicit “authorized target + evidence + justification” workflow made legal and ethical boundaries feel more concrete.
Uneven dependence risk	A minority of students over-relied on the assistant early and needed instructor intervention to return to evidence-first practice.

These qualitative themes fit the current evidence base. LLMs can improve tutoring and performance for some learners, but they can also reduce engagement or encourage shallow dependence if policies, prompts, and assessment do not force verification and explanation.

Proposed Curriculum and Assessment

The most defensible instructional model is a constructive loop in which students first gather evidence from software artifacts, then use AI to accelerate interpretation, but must validate every claim through tooling, tests, or replicated observations.

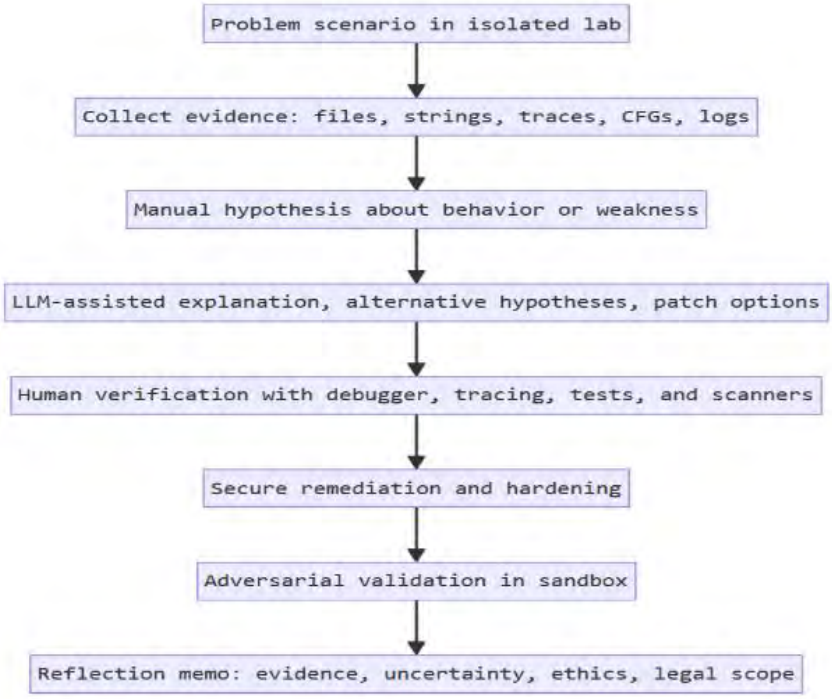

Figure 2. Instructional model (constructive loop)

That model is aligned with constructive alignment, workforce-oriented cybersecurity framing, and secure-development practice. It also matches classroom evidence that students need a middle ground between rote procedural labs and entirely unguided challenge solving.

Table 5. Constructive alignment

Curriculum block	Learning outcomes	Sample lab exercise	Assessment evidence
Foundations of secure systems and AI use	Distinguish static vs. dynamic evidence; explain where AI can and cannot be trusted	Compare a source-level flaw explanation written manually vs. with LLM assistance	Short concept quiz; AI-use policy check
Static reverse engineering	Recover program structure, identify suspicious imports/calls, annotate control flow	Analyze a toy binary or obfuscated utility in Ghidra and explain likely purpose	RE notebook; annotation quality
Dynamic behavior analysis	Validate or falsify static hypotheses with runtime evidence	Trace a trojanized utility and isolate anomalous file/network behavior	Trace lab score; oral defense
LLM-assisted code analysis	Use the model to summarize, critique, and refine code understanding while citing evidence	Map observed weakness to CWE and propose a secure patch plan	Code-analysis task; prompt log
Secure remediation and validation	Patch vulnerabilities, write tests, and confirm the fix	Repair injection/access-control flaws in a sandboxed training app	Secure-coding task; test suite
Capstone investigation	Produce an end-to-end analytical memo with ethical/legal justification	Investigate a benign simulated artifact, explain risk, and recommend mitigation	Capstone report; ethics rubric

Training targets should be deliberately educational rather than operational. Practice environments such as Juice Shop and DVWA exist specifically to support classroom-safe learning, while CWE and ATT&CK provide standardized ways to describe weaknesses and adversarial behavior.

Proposed assessment rubric

Table 6. Proposed assessment rubric

Criterion	What strong performance looks like	Weight
Evidence collection	Uses the right artifacts and tools; separates observed facts from guesses	20%
Technical explanation	Explains program behavior or weakness coherently and at the right abstraction level	20%
Vulnerability reasoning	Correctly maps issues to weakness/security concepts and prioritizes risk	20%
Secure remediation	Produces a sound patch and explains why it reduces risk without breaking functionality	20%
Validation and reflection	Verifies outcomes empirically and discusses uncertainty, ethics, and scope limits	20%

This rubric intentionally rewards reasoning quality and validation, not just "getting the right answer." That is important because LLM-era assessments must distinguish genuine understanding from polished but unverified output.

4. CONCLUSION

Recommended baseline governance is to align secure development with NIST's SSDF and AI use with its AI RMF; to use training targets and priority weakness categories from OWASP; and to structure threat and weakness language around taxonomies such as ATT&CK and CWE. In practice, that means every lab should specify the authorized target, expected evidence sources, allowed AI uses, and required validation steps before students begin [8-10].

For tooling, a defensible classroom baseline is National Security Agency's Ghidra for binary analysis; debuggers and syscall tracing for dynamic evidence; static analyzers and unit tests for secure remediation; and an institutionally governed LLM interface. If a copilot-style assistant is used, it should come with explicit responsible-use guidance, privacy controls, and a requirement that students submit prompt logs or AI-use disclosures [10-12].

For academic integrity, the key move is to assess process artifacts rather than only finished answers. Require individualized or randomized targets, evidence notebooks, short oral defenses, and a brief "what the model got right/wrong" reflection. That recommendation is supported by work showing both the educational upside of guided LLM use and the risk that generic chat access can lower engagement or encourage shallow task completion. Randomized reverse-engineering challenges are especially useful because they reduce answer sharing while preserving common learning objectives [13].

For safety and ethics, labs should run only in isolated VMs or containers with snapshot rollback, no live malware, no public targets, no institutional secrets in prompts, and no offensive deployment outside the classroom sandbox. In the United States, good-faith security-research exemptions are limited to lawful contexts and are not safe harbors against other laws. In the EU, observation, study, testing, and some decompilation are permitted only within specific legal conditions, especially interoperability and lawful use [14-19]. The course therefore needs an explicit rule: students may analyze only software and systems they own or are authorized to use for the lab's stated educational purpose.

The practical implication is straightforward: the most credible AI+RE curriculum is not the one with the most automation, but the one with the strongest verification culture [20-22]. Students should leave the course able to explain what they observed, what the model suggested, what they independently verified, what remained uncertain, and why their actions stayed within ethical and legal scope.

MRC COMBINER WITH THREE INPUTS IN THE PRESENCE OF FAST RICE FADING

ANA MATOVIĆ
Military Quality Control, Belgrade, ana.matovic4@gmail.com

MARIJA MATOVIĆ

ELMEDIN BIBEROVIĆ
Telecom Serbia , N.Pazar, elmedin@telekom.rs

Abstract: *This paper analyzes a three-branch maximal-ratio-combining (MRC) receiver operating over independent and identically distributed fast, flat Rician fading channels. The model is stated directly in terms of the instantaneous branch signal-to-noise ratios (SNRs), which removes the ambiguity between Rician and Rayleigh fading in the original formulation. For ideal coherent MRC with perfect channel-state information and equal noise power in all branches, the output SNR is the sum of three independent Rician branch SNRs. This sum is a scaled noncentral chi-square random variable with six degrees of freedom and noncentrality parameter. Closed-form expressions are given for the output-SNR probability density function, cumulative distribution function, moment-generating and characteristic functions, and arbitrary raw moments. These results are then used to evaluate threshold-outage probability, ergodic spectral efficiency, coherent BPSK bit-error probability, noncoherent orthogonal BFSK error probability, and (M)-PSK symbol-error probability. Numerical results, supported by Monte Carlo validation, show the third-order diversity behavior of the three-branch receiver and quantify the reduction in deep-fade probability as the Rician (K)-factor increases at fixed average branch SNR.*

Keywords: *maximal-ratio combining; Rician fading; diversity; noncentral chi-square distribution; outage probability; bit-error probability; ergodic capacity.*

1. INTRODUCTION

Using the statistical characteristics of first-order systems—specifically, the system error probability, signal failure probability, average signal value, and channel capacity—we analyze the performance of a wireless telecommunication system. The failure probability is defined as the probability that the signal falls below a predefined failure threshold. This failure threshold is determined based on the required quality of service [12]. We also determine the channel capacity, i.e., the amount of information that can be transmitted from the transmitter to the receiver in a given time interval. In this study, we calculate the error probability for coherent systems, non-coherent systems, and systems using quadrature modulation [13].

Diversity techniques are commonly used to improve the performance of wireless signal transmission systems in the presence of various types of interference. In mobile telephony, spatial diversity is most often employed, using multiple antennas and combining received signals at the output of a combiner. In this study, we consider a wireless digital telecommunication system that employs maximal ratio combining (MRC) as a diversity technique to reduce the impact of fast Rician fading on system performance [4][5]. In an MRC receiver, the squared magnitude of the combined output signal equals the sum of the squared magnitudes of the signals at each input branch.

Specifically, we analyze an MRC combiner with three input branches under fast Rician fading. The Rician distribution models rapid fluctuations of the signal envelope in a line-of-sight environment [7-12]. A Rician random variable's square is the sum of the squares of two independent Gaussian random variables with equal variance, at least one having a non-zero mean.

In this case, the output of the three-branch MRC combiner is the sum of three squared Rayleigh-distributed random variables (equivalently, the sum of six squared Gaussian variables). As a result, the combined output signal is a random variable. We derive the probability density function (PDF) of the MRC output in equation (11). This PDF is used to compute the system's error probability (equation 24). Using the cumulative distribution function (equation 17) of the MRC output, we determine the probability of system failure (equation 23).

For completeness, we derive the moments of the MRC output signal: the first moment (mean), the second moment (average power, see equation 20), the third moment, and the general n-th moment. Finally, the channel capacity is computed as the expected value of Shannon's capacity expression (equation 22), representing

the average information transmitted per unit time.

2. MRC COMBINER WITH THREE INPUTS IN THE PRESENCE OF FAST RICE FADING

2.1 Probability density of MRC combiner with three inputs in the presence of fast Rice fading

The probability densities of x_1, x_2 and x_3 are:

$$p_{x_1}(x_1) = \frac{2x_1}{\Omega} e^{-\frac{x_1^2+A^2}{\Omega}} I_0\left(\frac{2Ax_1}{\Omega}\right), \ x_1 \geq 0 \tag{1}$$

$$p_{x_2}(x_2) = \frac{2x_2}{\Omega} e^{-\frac{x_2^2+A^2}{\Omega}} I_0\left(\frac{2Ax_2}{\Omega}\right), \ x_2 \geq 0 \tag{2}$$

$$p_{x_3}(x_3) = \frac{2x_3}{\Omega} e^{-\frac{x_3^2+A^2}{\Omega}} I_0\left(\frac{2Ax_3}{\Omega}\right), \ x_3 \geq 0 \tag{3}$$

The signal x is equal to:

$$x = x_1^2 + x_2^2 + x_3^2 \tag{4}$$

The signal of the variable z is:

$$z = \frac{x}{\sigma^2}, \ x = z \cdot \sigma^2 \tag{5}$$

The probability density of z is:

$$p_z(z) = \frac{1}{2}\left(\frac{x}{\lambda}\right)^{\frac{1}{4}} e^{-\frac{\lambda+z}{2}} I_{1/2}\left((z\lambda)^{1/2}\right) \tag{6}$$

where is: $\lambda = \frac{3A^2}{\sigma^2}, \ \sigma^2 = \frac{\Omega}{3}, \ \lambda = \frac{A^2}{\Omega}$ (7)

The probability density of x is:

$$p_x(x) = \left|\frac{dz}{dy}\right| p_z\left(\frac{x}{\sigma^2}\right) \tag{8}$$

where is:

$$\frac{dz}{dy} = \frac{1}{\sigma^2} \tag{9}$$

By substituting (6) into (9) in (8) we get:

$$p_x(x) = \frac{1}{2\sigma^2\sqrt[4]{3A^2}}(x)^{\frac{1}{4}} e^{-\frac{3A^2+x}{3\sigma^2}} I_{1/2}\left(\frac{A\sqrt{3x}}{\sigma^2}\right) \tag{10}$$

The probability density of x can be written in the form:

$$p_x(x) = \frac{1}{2\sigma^2\sqrt[4]{3A^2}} x^{\frac{1}{4}} e^{-\frac{3A^2+x}{3\sigma}} I_{1/2}\left(\frac{A\sqrt{3}\,x^{1/2}}{\sigma^2}\right) =$$
$$\frac{1}{2\sigma^2\sqrt[4]{3A^2}} x^{\frac{1}{4}} e^{-\frac{3A^2+x}{2\sigma^2}} \sum_{i=0}^{\infty}\left(\frac{A\sqrt{3}}{2\sigma^2}\right)^{2i+1/2} \frac{1}{i!\Gamma(i+3/2)} x^{\frac{1}{4}} =$$
$$a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\ x^{i+\frac{1}{4}} \tag{11}$$

where is:

$$a = \frac{1}{2\sigma^2\sqrt[4]{3A^2}} x^{\frac{1}{4}} e^{-\frac{3A^2}{2\sigma^2}}$$

$$\alpha = \frac{1}{2\sigma^2}$$

$$f_3(A,\sigma,i) = \left(\frac{A\sqrt{3}}{2\sigma^2}\right)^{2i+1/2} \frac{1}{i!\Gamma(i+3/2)} \tag{12}$$

The probability density of x can be written in the form:

$$p(a) = \frac{1}{2\sigma^2\sqrt[4]{3A^2}} x^{\frac{1}{4}} e^{-\frac{3A^2+x}{3\sigma}} I_{1/2}\left(\frac{A\sqrt{3}\,x^{1/2}}{\sigma^2}\right) =$$
$$\frac{1}{2\sigma^2\sqrt[4]{3A^2}} x^{\frac{1}{4}} e^{-\frac{3A^2+x}{2\sigma^2}} \sum_{i=0}^{\infty}\left(\frac{A\sqrt{3}}{2\sigma^2}\right)^{2i+1/2} \frac{1}{i!\Gamma(i+3/2)} x^{\frac{1}{4}} =$$
$$a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\ x^{i+\frac{1}{4}} \tag{13}$$

where is:

$$a = \frac{1}{2\sigma^2\sqrt[4]{3A^2}} x^{\frac{1}{4}} e^{-\frac{3A^2}{2\sigma^2}}, \alpha = \frac{1}{2\sigma^2} \tag{14}$$

$$f_3(A,\sigma,i) = \left(\frac{A\sqrt{3}}{2\sigma^2}\right)^{2i+1/2} \frac{1}{i!\Gamma(i+3/2)} \tag{15}$$

The characteristic function of x is:

$$\mu_x(s) = \overline{e^{xs}} = \int_0^{\infty} e^{xs} f_x(x)\,dx =$$
$$\int_0^{\infty} e^{xs}\, a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\ x^{i+\frac{1}{4}} dx =$$
$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \int_0^{\infty} \sum_{r=0}^{\infty} \frac{s^k x^k}{k!}\, x^{\frac{1}{4}} e^{-\alpha x}\, x^{i+\frac{1}{4}} dx =$$
$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \sum_{r=0}^{\infty} \frac{s^k}{k!} \int_0^{\infty} x^{k+i+\frac{1}{2}} e^{-\alpha x} dx =$$
$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \sum_{r=0}^{\infty} \frac{s^k}{k!} \left(\frac{1}{\alpha}\right)^{k+i+\frac{1}{2}} \Gamma(k+i+3/2) \tag{16}$$

2.2 Cumulative probability of MRC combiner with three inputs in the presence of fast Rice fading

The cumulative probability of a random variable x is:

$$F_x(x) = \int_0^x dt\, f_x(t) =$$
$$\frac{1}{2\sigma^2\sqrt[4]{3A^2}} e^{-\frac{3A^2}{2\sigma^2}} \sum_{i=0}^{\infty}\left(\frac{A\sqrt{3x}}{\sigma^2}\right)^{2i+1/2} \cdot$$
$$\frac{1}{i!\Gamma(i+3/2)} (2\sigma^2)^{i+3/2} \Gamma\left(i+3/2, \frac{x}{\sigma^2}\right) \tag{17}$$

2.3 Moments of MRC combiner with three inputs in the presence of fast Rice fading

The n-ti order moment of x is:

$$m_n = \overline{x^n} = \int_0^{\infty} x^n p_x(x)\,dx =$$
$$\int_0^{\infty} x^n\, a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\ x^{i+\frac{1}{4}} dx =$$
$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \int_0^{\infty} x^{n+i+\frac{1}{2}} e^{-\alpha x} dx =$$
$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \left(\frac{1}{\alpha}\right)^{n+i+\frac{1}{2}} \Gamma(n+i+3/2) \tag{18}$$

For n=1, we get the first moment, that is, the mean value of *x*:

$$m_1 = \bar{x} = \int_0^{\infty} x\, p_x(x)\, dx =$$

$$a \sum_{i=0}^{\infty} f_0(A,\sigma,i) \left(\frac{1}{\alpha}\right)^{i+\frac{5}{2}} \Gamma\left(i + 5/2\right) \tag{19}$$

For n=2, we get the second moment, or the mean square value of *x*:

$$m_2 = \overline{x^2} = \int_0^{\infty} x^2 p_x(x)\, dx =$$

$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \left(\frac{1}{\alpha}\right)^{i+\frac{7}{2}} \Gamma\left(i + 7/2\right) \tag{20}$$

For n=3, we get the third moment, or the average cubic value of *x*:

$$m_3 = \overline{x^3} = \int_0^{\infty} x^3 p_x(x)\, dx =$$

$$a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \left(\frac{1}{\alpha}\right)^{i+\frac{7}{2}} \Gamma\left(i + 7/2\right) -$$

$$\left(a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \left(\frac{1}{\alpha}\right)^{i+\frac{5}{2}} \Gamma\left(i + 5/2\right) \right)^2 \tag{21}$$

2.4 Capacity of the channel MRC combiner with three inputs in the presence of fast Rice fading

Channel capacity:

$$c = \int_0^{\infty} \left(ln(1+x^2)\right) p_x(x)\, dx = \int_0^{\infty} \left(ln(1+x^2)\right) a\, x^{\frac{1}{4}} e^{-\alpha x}$$

$$\sum_{i=0}^{\infty} f_3(A,\sigma,i)\, x^{i+\frac{1}{2}} dx =$$

$$\sum_{i=0}^{\infty} f_3(A,\sigma,i) \int_0^{\infty} x^{i+\frac{1}{2}} e^{-\alpha x} \left(ln(1+x^2)\right) dx \tag{22}$$

2.5 Probability of signal failure of MRC combiner with three inputs in the presence of fast Rice fading

The probability of signal failure is:

$$p_0 = \int_0^{x_0} p_x(x)\, dx = F_x(x_0) \tag{23}$$

2.6 Error probability of systems of MRC combiner with three inputs in the presence of fast Rice fading

Error probability for coherent systems:

$$p_{e_1} = \int_0^{\infty} a_1 \left(erfc(bx^2)\right) p_x(x)\, dx = \int_0^{\infty} a_1 \left(erfc(bx^2)\right)$$

$$a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\, x^{i+\frac{1}{2}} dx =$$

$$a_1 a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \int_0^{\infty} \left(erfc(bx^2)\right) x^{i+\frac{i}{2}} e^{-\alpha x} dx \tag{24}$$

Error probability for incoherent systems:

$$p_{e_2} = \int_0^{\infty} a_1 e^{bx^2} p_x(x)\, dx = \int_0^{\infty} a_1 e^{bx^2}$$

$$a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\, x^{i+\frac{1}{4}} dx =$$

$$a_1 a \sum_{i=0}^{\infty} f_3(A,\sigma,i) \int_0^{\infty} x^{i+\frac{i}{2}} e^{-\alpha x} e^{bx^2} dx \tag{25}$$

Error probability for quadrature modulated signals is:

$$p_{e_2} = \int_0^{\infty} dx \left(a_1 erfc(b_1 x^2) + a_2 \left(erfc(b_2 x^2)\right) p_x(x) =\right.$$

$$\int_0^{\infty} dx \left(a_1 erfc(b_1 x^2) + a_2 \left(erfc(b_2 x^2)\right)\right)$$

$$a\, x^{\frac{1}{4}} e^{-\alpha x} \sum_{i=0}^{\infty} f_3(A,\sigma,i)\, x^{i+\frac{1}{4}} \tag{26}$$

3. NUMERICAL RESULTS

Figure 1 shows the dependence of the probability density at the output of an MRC combiner with three inputs *p(x)* on the signal envelope *x*. For smaller values of the signal envelope *x*, the probability density *p(x)* increases, while for larger values of the signal envelope *x*, the probability density *p(x)* decreases. For a signal envelope *x* value from 1 to 7, the probability density *p(x)* increases from 0.001 to 0.09, while for a signal envelope *x* value from 7 to 20, the probability density *p(x)* decreases from 0.09 to 0.01.

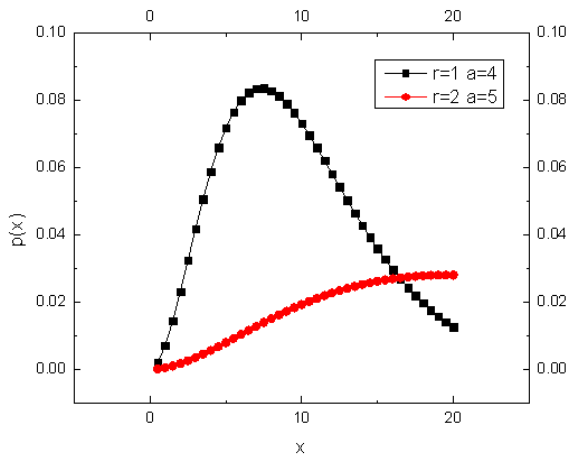

Figure 1. Dependence of the probability density at the output of the MRC combiner with three inputs on the parameter *x*

Figure 2 shows the dependence of the probability density at the output of an MRC combiner with three inputs on the parameter. For smaller values of the parameter, the probability density increases, while for larger values of the parameter, the probability density decreases. For parameter values from 0 to 5, the probability density rises from 0.048 to 0.078, while for parameter values from 5 to 10, the probability density decreases from 0.078 to 0.052.

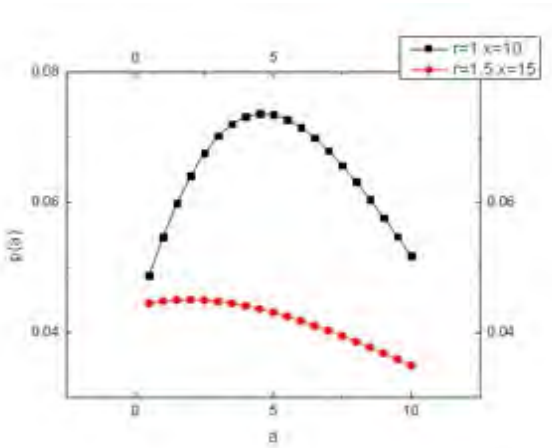

Figure 2. Dependence of the probability density at the output of an MRC combiner with three inputs on the parameter

Figure 3 shows the dependence of the mean square value of the signal at the output of the MRC combiner with three inputs, m_2, on the parameter a. For higher values of the parameter a, the mean square value of the signal m_2 increases. For a parameter a ranging from 0 to 10, the mean square value of the signal m_2 rises from 50 to 250.

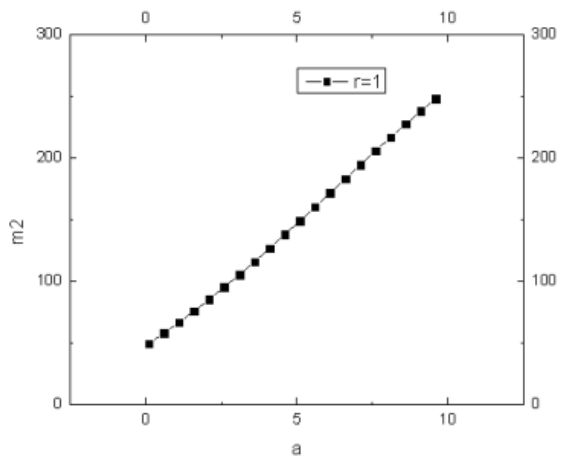

Figure 3. Dependence of the mean square value of the signal at the output of the MRC combiner with three inputs m_2 on the parameter a

4. CONCLUSION

This paper investigates an MRC combiner with three inputs in the presence of fast Rician fading. The probability density function and cumulative distribution function of the signal at the output of the three-input MRC combiner, as well as its first, second, and third moments, were derived under fast Rician fading conditions. Based on these results, the first-order statistical performance characteristics of the system were determined, including the system error probability, signal failure probability, average signal value, and channel capacity. Using the derived analytical expressions, the performance of the wireless communication system was analyzed, demonstrating the applicability of the MRC diversity technique for reducing the adverse effects of fast fading on system performance.

Abstract: *In government and military networks, a successful intrusion does not necessarily depend on breaking through the network perimeter. APT actors may obtain valid credentials and use them to gain additional privileges and move between systems. We compared two security configurations in a small testbed containing 28 hosts. We used the same six MITRE ATT&CK techniques in both environments. For each run, we measured detection and response time, attacker dwell time, lateral movement, compromised hosts, and data exfiltration. We derived Attack Containment Efficiency (ACE) from the number of compromised hosts and used it as an additional containment measure. Detection in the traditional environment averaged 38.4 min, whereas in the Zero Trust environment it averaged 6.9 min. Response time fell from 71.8 to 14.2 min. Following the initial compromise, we observed an average of 12.4 successful lateral transitions per run in the traditional environment and 1.7 in the Zero Trust environment. The mean number of compromised hosts was 23 and 3, respectively, while successful data exfiltration decreased from 78% to 11%. Paired analysis showed significant differences between the configurations for all evaluated variables ($p < 0.001$). These results reflect the combined effect of the controls implemented in the Zero Trust-oriented configuration and should not be interpreted as the effect of any single security control.*

Keywords: *Zero Trust, MITRE ATT&CK, Military Systems, Attack Containment, Lateral Movement*

1. INTRODUCTION

Malware is not the only way into a military network. An attacker who obtains valid user credentials may already have the access needed to establish a foothold. From there, the account can be used to seek additional privileges, retain access, or reach other systems [1]. Identity-based attacks have also been observed in public-sector networks [2]. In a military setting, this kind of access can have wider consequences when operational or administrative systems supporting mission activities are affected [3].

Traditional network security largely focuses on protecting the boundary between trusted and untrusted networks [4]. This approach becomes less useful once an attacker has crossed that boundary. An attacker with internal access may attempt to reach other hosts and services from inside the network. NIST SP 800-207 therefore treats network location as insufficient grounds for trust and considers threats that may be present both inside and outside the traditional perimeter [5].

Zero Trust does not assume that a user or device can be trusted simply because it is already inside the network. Access decisions are instead based on identity and other available security information [4], [6]. An access request must therefore be evaluated without relying on network location as proof of trust. This approach is also reflected in NSA guidance, which presents Zero Trust as a means of maintaining authorized users' access to mission data while limiting an adversary's access when part of the network has been compromised [4].

This study was motivated by the lack of quantitative evidence on Zero Trust effectiveness in military networks. We built two matched test environments with the same host and application inventory but different security configurations, ran the same attacks against both, and compared the results.

1.1 Related Work

Kindervag [6] proposed Zero Trust as a different way of thinking about network security. Instead of assuming that systems behind the perimeter are trustworthy, access must be considered separately for each resource. NIST SP 800-207 [5] later described this idea in greater technical detail,

DOI: 10.5937/OTEH26096S

specifying the components responsible for making and enforcing access decisions. Experimental studies have since examined micro-segmentation, including work based on network emulation and attack graphs.

Controlled attack simulations provide one way to examine how security controls behave during an intrusion. MITRE ATT&CK [7] provides the terminology for describing the adversary techniques used in such tests. Caldera can execute the same ATT&CK techniques in an emulated environment, allowing detection and response to be observed under controlled conditions [7]. Hutchins et al. [8] earlier structured an intrusion using the intrusion kill chain model, dividing an adversary campaign into stages.

Attack graphs have been used to examine how far an attacker can move through a segmented network [9]. Other researchers have tested micro-segmentation by reproducing attacks in controlled environments [10]. Most of this work, however, deals with enterprise networks. Military-oriented test environments are less frequently examined, and containment is rarely expressed through a metric such as ACE.

This study addresses that gap by evaluating Zero Trust Architecture against six MITRE ATT&CK techniques in a small-scale emulated military environment, using paired runs and a controlled experimental design. The selected post-compromise behaviors are also consistent with APT techniques summarized in the literature [11].

2. RESEARCH METHODOLOGY

2.1 Experimental Design

The experimental setup consisted of two matched environments running on a VMware vSphere cluster. The hardware and software inventory was kept the same in both cases: 25 Windows 10 endpoints, three Windows Server 2022 systems providing file, application, and database services, an Active Directory domain, and Splunk for centralized logging. This gave 28 hosts in each environment. The environments differed in the security configuration applied to them.

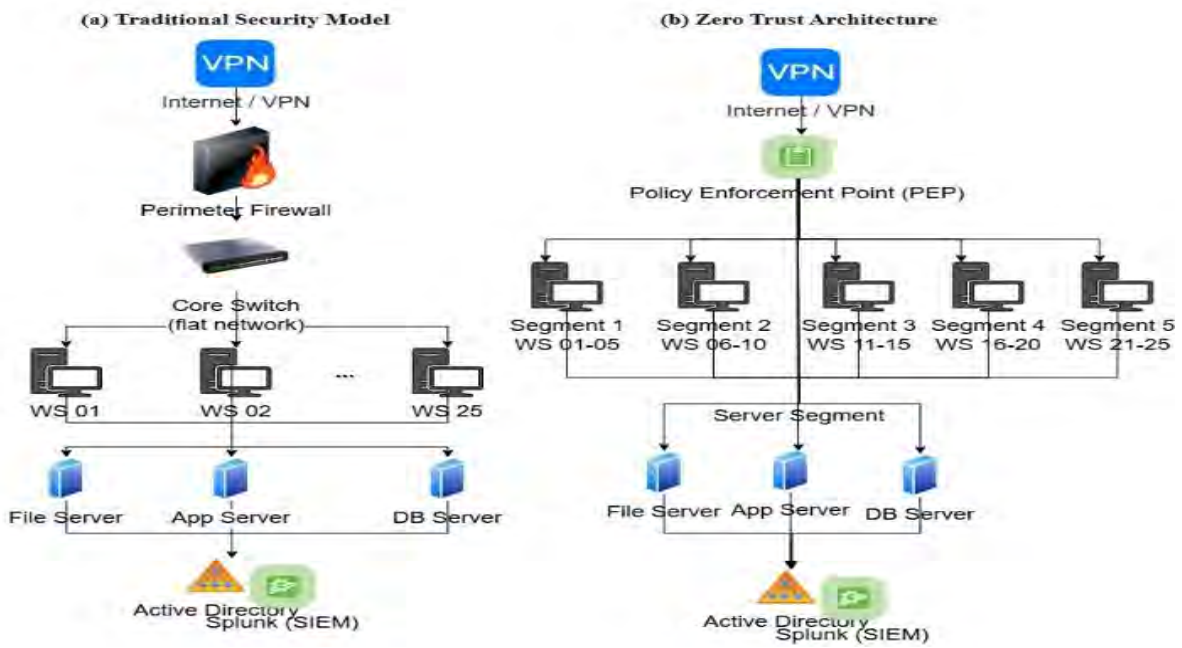

Figure 1. Topology of the two emulated environments: (a) Traditional Security Model with perimeter-only protection and implicit trust between hosts; (b) Zero Trust Architecture with five micro-segments, policy enforcement points (PEP), identity-aware access control, and least-privilege enforcement.

Environment A – Traditional Security Model: Flat internal network topology; perimeter firewall protection; VPN-based remote access; static authentication (password + MFA for external access); domain-based trust model.

Environment B – Zero Trust Architecture: We split the network into five segments and applied ABAC to control access between them. We included device posture in the access decision. We required re-authentication every 60 minutes and monitored user activity and active sessions between checks. Policy and user privileges limited access to resources [12].

2.2 Attack Simulation Scenarios

Six attack cases were executed in accordance with the MITRE ATT&CK Enterprise Framework [7]:

Table 1. MITRE ATT&CK Attack Cases

Attack Phase	Technique	Zero Trust Mitigation
Initial Access	T1078 - Valid Accounts	Periodic re-authentication + behavioral monitoring
Privilege Escalation	T1003 - Credential Dumping	Least-privilege access
Lateral Movement	T1550.002 - Pass-the-Hash	Network segmentation
Execution	T1059.001 - PowerShell	Application control
Lateral Movement	T1210 - Remote Service Exploit	Micro-segmentation
Propagation	T1570 - Lateral Tool Transfer	Traffic monitoring

An automated adversary emulation platform (MITRE Caldera) executed the attacks using predefined ability scripts mapped to the six ATT&CK techniques in Table 1. Each run executed a single technique against a freshly reverted snapshot. We reverted the environment to the baseline snapshot before each run and verified that Active Directory, the Splunk index, and the endpoint state were clean.

Both environments used the same Splunk-based SOC pipeline, with no changes to the correlation rules or alert thresholds. In Environment A, the analyst followed the standard response playbook and carried out the required actions manually. The same analyst handled the alerts in Environment B, but session termination and segment isolation could also be enforced automatically. Since the analyst knew which environment was being tested, the experiment was not blinded.

The first correlated alert recorded in Splunk marked the detection point for a run. We recorded containment after either isolating the compromised host or deactivating the account used in the attack. For LMS, we recorded each successful lateral transition during a run. DESR represented the share of the predefined canary files that successfully reached the external exfiltration listener.

We repeated each technique 20 times, for 120 runs per environment. We matched runs from the two environments by technique and initial access vector. Thus, both members of a pair started from the same access vector. This pairing allowed the two security configurations to be compared under equivalent starting conditions [10].

The security setup was not changed one control at a time. In Environment B, several controls were active simultaneously: network segmentation, ABAC, device-posture checks, application control, behavioral monitoring, periodic re-authentication, and policy enforcement. Environment A did not include these changes and retained the flat-network configuration. Consequently, the experiment compares the two implemented setups. It does not show which individual control drove a particular improvement. Answering that question would require additional tests in which the controls were introduced or removed separately.

2.3 Assessment Criteria

The following metrics were measured:

- **MTTD** – time from the initial compromise event to the first SOC alert.
- **MTTR** – time from the first SOC alert to the containment action.
- **ADT** – time from the initial compromise event to the eradication of the attacker's presence. ADT includes both the undetected and response periods.
- **LMS** – number of successful lateral transitions per run.
- **CH** – total number of systems compromised per run.
- **DESR** – percentage of the predefined canary file set successfully exfiltrated per run.

Note on MTTD and ADT. MTTD and ADT are not the same interval. MTTD ends at the first alert; ADT ends at eradication. In the traditional environment, the attacker remained active for 252 min because detection was late (38.4 min) and containment was slow (71.8 min); in the Zero Trust environment, ADT was 29 min because detection was fast (6.9 min) and containment was fast (14.2 min). The relationship ADT ≈ MTTD + MTTR + residual attacker activity is consistent with the recorded event sequence.

2.4 Attack Containment Efficiency (ACE)

ACE is a normalization of the compromised-host count to the interval [0, 1]:

$$ACE = 1 - \frac{CH}{TH} \tag{1}$$

where CH = number of compromised hosts and TH = total number of hosts (28). ACE values approaching 1 indicate stronger containment. ACE is a transformation of CH and TH already reported in Table 2.

2.5 Statistical Design

For every run in one environment, we selected the corresponding run in the other environment with the same ATT&CK technique and initial access vector. This produced 120 pairs for the analysis. We compared the values within these pairs using a paired t-test. We also checked the differences between paired observations with the Shapiro-Wilk test, and $p > 0.05$ for every variable. We obtained effect sizes directly from the paired-test statistic using Cohen's

$$d_z = t/\sqrt{n} \tag{2}$$

where $n = 120$ is the number of pairs. We interpreted the resulting $d_z$values using the benchmarks proposed by Sawilowsky [13].

3. EXPERIMENTAL RESULTS

Table 2. Security Performance Comparison (mean over 120 paired runs per environment)

Metric	Traditional	Zero Trust	Improvement
MTTD (min)	38.4	6.9	82.0% reduction
MTTR (min)	71.8	14.2	80.2% reduction
ADT (min)	252	29	88.5% reduction
Lateral Movements (count)	12.4	1.7	86.3% reduction
Compromised Hosts (count)	23	3	87.0% reduction
Data Exfiltration (%)	78	11	85.9% reduction

Changes were evident across all six measures. Attacker dwell time showed the largest reduction. The number of hosts reached during an attack also dropped sharply, and only a small number of lateral transitions were completed in the Zero Trust environment. The same pattern appeared in the exfiltration tests, where considerably less of the predefined test data left the environment. Some variation occurred between individual runs, as expected, but it did not alter the general pattern.

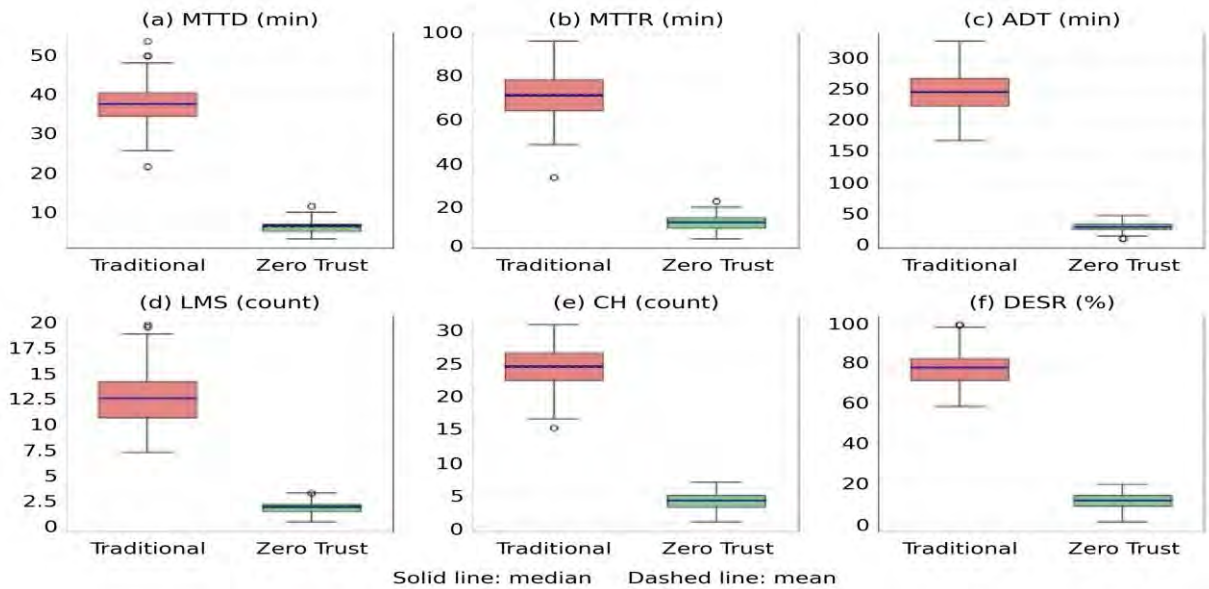

Figure 2. Comparison of the two environments over 120 paired runs. The plots present (a) MTTD, (b) MTTR, (c) ADT, (d) lateral movements, (e) compromised hosts, and (f) data exfiltration rate. The line inside each box marks the median, the box covers the middle 50% of observations, and the whiskers extend to 1.5 × IQR.

Attack detection took an average of 38.4 minutes in the traditional environment. With the controls used in Environment B, the corresponding time was 6.9 minutes. Response time followed the same pattern, decreasing from 71.8 to 14.2 minutes. This represents reductions of 82.0% and 80.2%, respectively. During the log review, we also found that containment generally started earlier in Environment B. Policy-violation alerts were one of the sources available to the analyst when deciding whether to initiate containment.

Dwell time showed the largest change. In the traditional setup, an attacker remained active for 252 min on average; in the Zero Trust setup, this value was 29 min (88.5% lower). A run in Environment A also produced 12.4 successful lateral transitions on average, compared with 1.7 in Environment B (86.3% lower). The mean number of affected hosts was 23 in the first environment and 3 in the second, corresponding to an 87.0% reduction. We observed the same direction of change for exfiltration: 78% of the predefined data set reached the external listener in Environment A, compared with 11% in Environment B. This is a 67-percentage-point difference, or an 85.9% relative reduction. Each comparison compared runs that shared the same ATT&CK technique and initial access vector.

4. STATISTICAL ANALYSIS

4.1 Paired-Samples t-Test

Table 3. Statistical significance results (paired runs, n = 120 per environment)

Variable	Traditional (mean ± SD)	Zero Trust (mean ± SD)	Mean diff.	SD(d)	t (df = 119)	p	Cohen's d_z
MTTD (min)	38.4 ± 6.2	6.9 ± 1.4	31.5	6.4	53.9	< 0.001	4.92
MTTR (min)	71.8 ± 11.5	14.2 ± 3.1	57.6	11.9	53.0	< 0.001	4.84
ADT (min)	252 ± 34	29 ± 7	223	34.7	70.4	< 0.001	6.43
LMS (count)	12.4 ± 2.8	1.7 ± 0.6	10.7	2.9	40.4	< 0.001	3.69
CH (count)	23 ± 3.1	3 ± 1.2	20.0	3.3	66.4	< 0.001	6.06
DESR (%)	78 ± 9	11 ± 4	67.0	9.9	74.1	< 0.001	6.77

The paired tests showed statistically significant differences between the two configurations ($p < 0.001$ for all evaluated variables). Under the null hypothesis of no paired mean difference, the reported p-values quantify how incompatible the observed test statistics are with that hypothesis. Cohen's d_z values derived from the paired t-statistics range from approximately 3.7 to 6.8, indicating large paired effects in the experimental dataset.

4.2 Pearson Correlation Analysis

We examined the relationship between detection time (MTTD) and attacker dwell time (ADT) across all runs. When we pooled all 240 runs, the correlation was $r = 0.87$ ($p < 0.001$). This pooled value partly reflects the large difference between the two environments rather than a within-environment relationship. When we analyzed each environment separately, the correlations were lower: $r = 0.42$ for the traditional setup and $r = 0.38$ for the Zero Trust setup. We therefore use the correlation results only to describe the observed data, not to infer causality.

5. CONTAINMENT ANALYSIS

5.1 Attack Containment Efficiency Calculation

Using the experimental data with TH = 28 (25 endpoints + 3 servers):

Traditional architecture:

$$ACE_{TRAD} = 1 - \frac{23}{28} = 0.179 \quad (3)$$

Zero Trust architecture:

$$ACE_{ZT} = 1 - \frac{3}{28} = 0.893 \quad (4)$$

ACE increased from 0.179 in Environment A to 0.893 in Environment B, giving a difference of 71.4 percentage points. This value comes directly from the compromised-host results in Table 2. We therefore use ACE only to express those results on a normalized scale, rather than treating it as a separate measurement.

6. DISCUSSION

The experimental results show that the Zero Trust-oriented configuration provided faster detection and containment and more effectively restricted post-compromise propagation than the traditional configuration under the evaluated ATT&CK scenarios.

Several security controls were active simultaneously in the Zero Trust environment, including micro-segmentation, ABAC, device-posture checks, application control, behavioral monitoring, periodic re-authentication, and policy enforcement. The measured improvement therefore cannot be assigned to any one of these controls. Our results describe the difference between the two configurations as they were tested.

We had to revise several rules while setting up the testbed. Some early rules restricted administrative tasks still necessary to operate the environment. After testing, we adjusted those rules so that the required tasks remained possible. This experience also showed a practical limitation of strict access control: security restrictions must be introduced without disrupting the administration of systems that need to remain available.

The 60-minute re-authentication requirement was likewise only one part of the setup: because a valid credential could still be abused between checks, behavioral monitoring, least-privilege restrictions, and session-termination mechanisms were used alongside it to identify suspicious activity and end a session when necessary.

Concrete Benefits for Military Systems:

- **Reduced Blast Radius:** Limiting the spread of a compromise can reduce the number of mission-supporting systems exposed after an attacker gains access.
- **Faster Incident Response:** Environment B combined the analyst's response workflow with automated session termination and segment isolation. The response-time comparison therefore reflects both the security controls and the response processes used in the testbed.
- **Operational Resilience:** In this setup, trust did not depend only on where a user or device was located in the network. Segmentation limited access between network areas, while identity policies and least-privilege rules restricted access to individual resources. Monitoring provided an additional check during active sessions. Together, these measures also allowed us to isolate an affected segment without necessarily disrupting services in other segments. This follows the basic idea of defense in depth [14].

7. LIMITATIONS OF THE STUDY

Our experiment compares the two environments as they were configured, not the effect of one security control in isolation. Several mechanisms used in Environment B were not present in Environment A, so we cannot assign the measured differences to any one of them. The experiment was also limited to 28 hosts and six ATT&CK techniques. We did not examine larger distributed networks, insider attacks, supply-chain compromise, DDIL operating conditions, or the performance cost of the implemented controls.

8. CONCLUSION

The two environments produced different results. In the 28-host testbed, Environment B detected attacks sooner and required less time to contain them. Attackers also completed fewer lateral transitions, reached fewer hosts, and exfiltrated less of the predefined test data. These results apply to Environment B as it was tested, with its security controls operating together. They do not show how much any one control contributed to the observed differences.

ACE expresses the compromised-host result on a normalized scale. Its value was 0.179 for Environment A and 0.893 for Environment B, a difference of 71.4 percentage points. The paired tests found significant differences for all variables included in the comparison. ATT&CK kept adversary actions organized consistently across runs and linked those actions to the observed defensive results.

These results come from testing all controls together. This experiment cannot determine which control produced which part of the difference. That would require another set of tests, changing one control at a time while leaving the rest of the setup unchanged.

A larger test environment would be a useful next step, particularly one that includes systems at more than one location. The attack set could also be expanded beyond the six ATT&CK techniques used here to cover insider activity, supply-chain compromise, and DDIL conditions. This experiment did not measure resource and performance costs, which should be included in further testing. Finally, testing the Zero Trust controls one at a time would help determine how much each control contributes to the observed results.

Abstract: *Conducted electromagnetic interference (EMI) is an important aspect of electromagnetic compatibility (EMC), especially in electronics system where noise can propagate through power and signal lines, and affect of operation of other circuits. Proper identification of the dominant type of noise is therefore essential for the of effective EMI suppression. This paper presents measurement based methodology for the analysis and characterization of conducted EMI, with particular emphasis on the separation of differential mode (DM) and common mode (CM)components. The proposed approach includes the configuration of measurement equipment, acquisition and analysis of measured data, and identification of dominant frequency dependent noise component. Based on measurement results, total conducted interference is decomposed into its DM and CM component. The obtained results are used to select appropriate suppression for each noise mode. The presented methodology provides a systematic approach for distinguishing EMI mode for identification of suppression, thereby improving the effectiveness of EMC filtering.*

Keywords: *Electromagnetic compatibility, Conducted EMI, common-mode noise, differential-mode noise, characterization, EMI suppression.*

1. INTRODUCTION

The rapid development of modern electronics has led to a significant increase in the use of power electronic convertors, switching power supply, high speed digital circuits, and digitally controlled subsystem. DC/DC convertors, AC/DC power supply, motor drives, etc., have become integral parts of a wide range of electronic and electrical equipment. Although these technologies provide high efficiency, compact dimension, and improved functionality and working stability, their switching operation represents a significant source of EMI.

The EMC performance of a modern electronic devices is determined not only by its intended electrical functionality, but also by its ability to limit the generation and propagation of unwanted electromagnetic energy. EMC requirements have become an essential part of the design, and verification process of electronic equipment. A device intended for commercial, industrial, automotive, aerospace, military, or other specialized applications must satisfy the applicable EMC requirements before it can be placed on the market or introduced into service.

Practically all country, around the world, require that electrical and electronic devices must meet strict requirements regarding EMC. [1]

Various international and industry specific standard define limits and measurement procedures for electromagnetic emissions and immunity. Examples include the CISPR series of standards, IEC 61000-4series, and military standard MIL-STD-461. The specific requirements depend on intended application and environment of the equipment. In particular, conducted emission measurements are used to determine the level of unwanted RF energy present on the power inputs and output interfaces of equipment under test (EUT). In the presented paper, conducted emission measurements are performed in accordance with the requirements of the MIL-STD-461 CE102 test method, which specifies limits and measurements procedures for conducted emissions on power input leads of equipment and subsystems. [2]

A limitation of conventional conducted emission measurement is that the measured spectrum represents the combined effect of different noise type. The measured interface may contain both DM and CM components. Although these two modes may appear as a single conducted emission spectrum at the measurement port, they are completely different in term of appearance and propagation (it will be clarified in next chapter) and

Corresponding author: P. Crnomarković;

DOI: 10.5937/OTEH26097C

require different suppression technique.

In this paper will be presented expansion of the MIL-STD-461 CE102 method in order to obtain more precise data on the type and level of interference in order to more precisely determine the parameter of filter for suppression, and way haw to choose right filter.

2. TEORETICAL BACKGROUND

Conventional conducted measurement represents both DM and CM noise Figure 1. The yellow line represents path of the sum of the CM and DM components, while the green line represents path of difference of CM and DM component, depending which port is used for measuring from line impedance network stabilizer (LISN), URF1 or URF2.

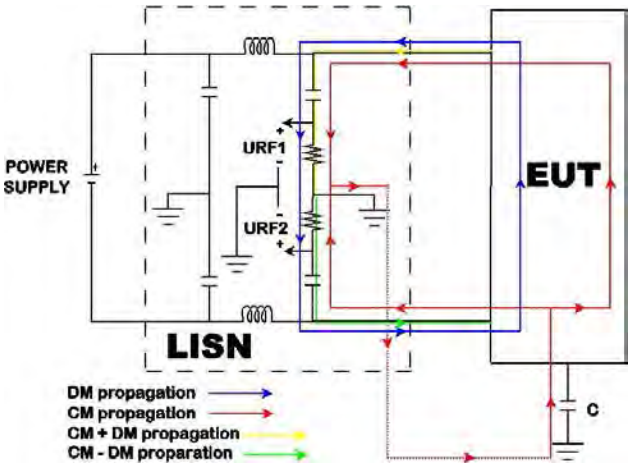

Figure 1. Conventional measurement

Identification and separation of DM and CM component represent an important step in the conducted EMI troubleshooting and process of choosing adequate filter. DM noise are associated with current flowing between power lines in opposite direction Figure 2, whereas CM noise are generally associated with currents flowing in same direction on power lines with respect to a chassis Figure 3.

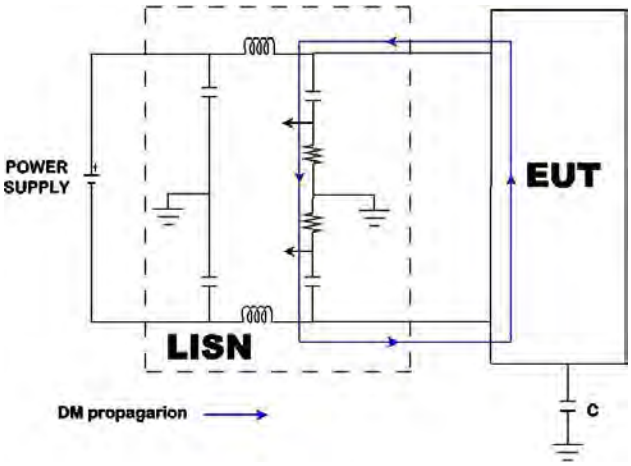

Figure 2. DM noise propagation

Mathematically speaking it is possible to distinguish U_{CM} and U_{DM} from URF1 and URF2 in following way:

$$U_{CM} = \frac{UREF1 + UREF2}{2} \quad (1)$$

$$U_{DM} = \frac{UREF1 - UREF2}{2} \quad (2)$$

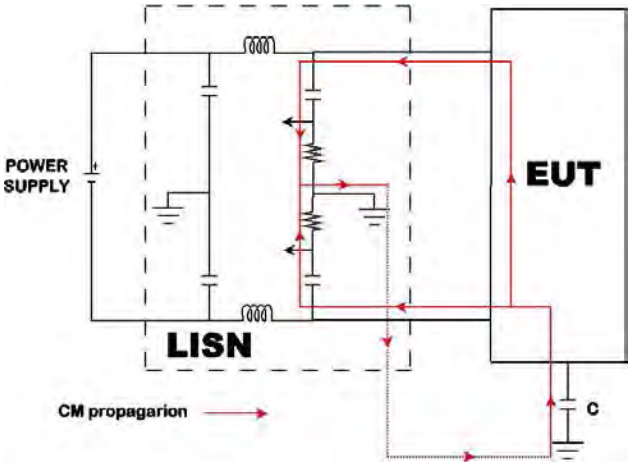

Figure 3. CM noise propagation

3. MEASUREMENT MODEL

The measurements were performed in EMC test chamber. General test setup was as proposed by MIL-STD-461 standard [2]. General test setup is shown on Figure 4. Same figure represents position of equipment distances of cable, size of ground plane, dimension of non-conductive standoff, separation of element relatively to the ground plane on the table and also to the ground of the EMC test chamber etc.

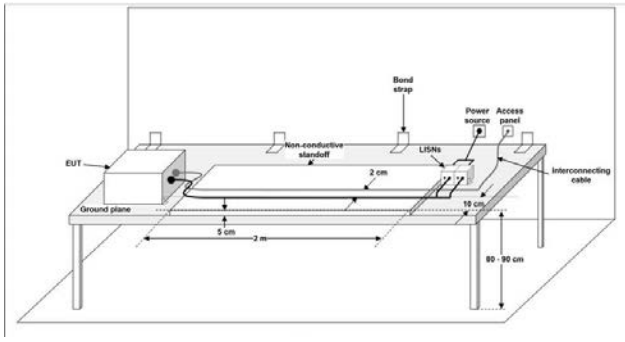

Figure 4. General test setup [2]

For MIL-STD-461, CE102 conducted emission measurement is used equipment setup as shown on Figure 5. The equipment are consists of 2 LISN unit, termination of 50ohm, which is used to terminate unused RF port from LISN unit, attenuation from 20dB, which is used to protect measuring equipment in case of appearance of very high level of conductive interference, EUT, measurement devices and data recording device. Lately last two devices are integrated in same unit. Also power supply should be galvanically isolated.

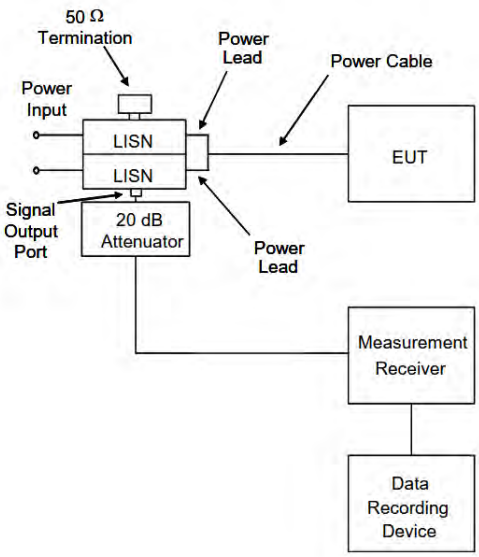

Figure 5. Measurement equipment setup [2]

Modification of measurement setup as proposed MIL-STD-461, CE102, consists of using MISN-MATE unit. This unit is feed from booth RF outputs, from each LISN unit, RF signal from LISN on positive power line is connected to the RF1 port of the LISN-MATE, and RF signal from LISN on negative power line is connected to the RF2 port of LISN-MATE unit.

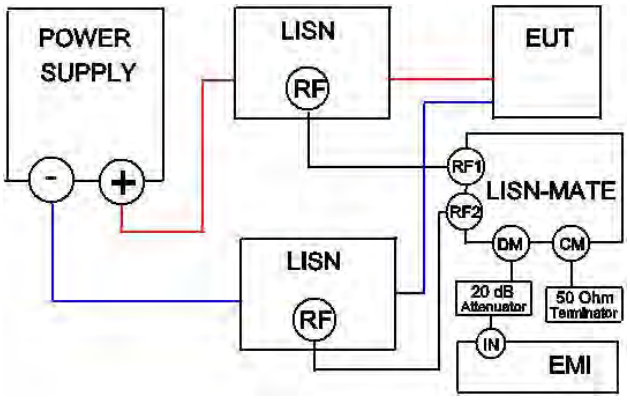

Figure 6. Expanded measurement equipment setup for DM component

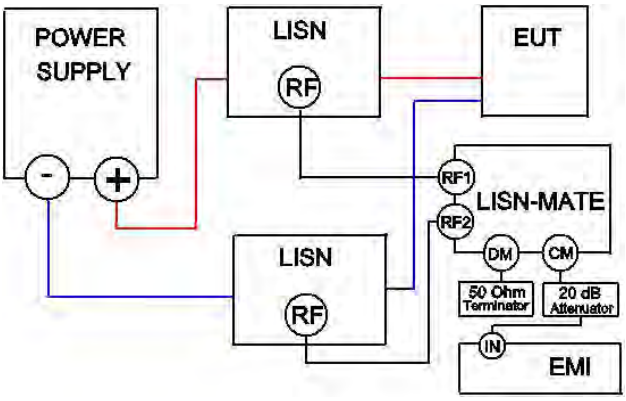

Figure 7. Expanded measurement equipment setup for CM component

LISN-MATE at its output provides DM signal output, which is calculated according to quotation (3), and CM signal output which is calculated according to quotation (4).

$$U_{CM} = URF1 + URF2 \tag{3}$$

$$U_{CM} = URF1 - URF2 \tag{4}$$

Comparing quotation (3) and (4) to quotation (1) and (2) respectively, is obvious that LISN-MATE provide twice the level on both outputs, so it is necessity to set attenuation of 3dB in measuring equipment, for compensation.

Proposed expanded measurement equipment setup is shown on Figure 6. and Figure 7., respectively.

Data presentation shall be as follows:

a. Continuously and automatically plot amplitude versus frequency profiles on X-Y axis outputs. Manually gathered data is not acceptable except for plot verification.
b. Display the applicable limit on each plot.
c. Provide a minimum frequency resolution of 1% or twice the measurement receiver bandwidth, whichever is less stringent, and a minimum amplitude resolution of 1 dB for each plot.
d. Provide plots for both the measurement system check and measurement portions of the procedure. [2]

The measurement system check is performed using the measurement system check chart for CE102, shown on Figure 8.

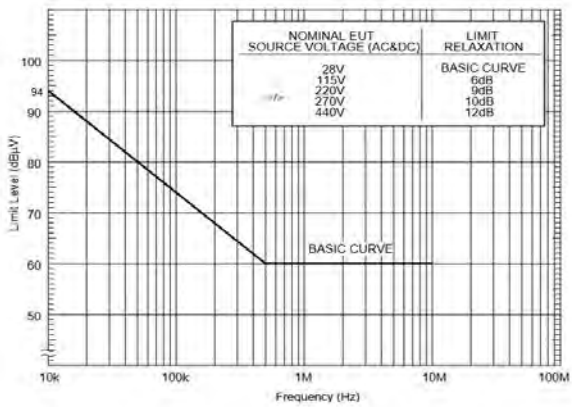

Figure 8. CE102 limit (EUT power leads, AC&DC) [2]

4. RESULTS

In this chapter, concrete measuring equipment, measurement results, a proposal for selecting a filter, and a verification measurement for confirmation will be presented.

4.1 Equipment

In conducted tests are used next equipment.

LISN is LI-3100 from COM-POWER, very powerful, up to 100Amps, can be used and for DC and for AC, and also very good quality, more detail is given at the reference [3]

LISN-MATE is TBLM2 from TEKBOX, with adequate parameters, and also very good quality, more details at the reference [4]

EMI from Agilent Technologies N9038A, nowadays is Keysight Technologies N9038A, it's a standards compliant EMI receiver and diagnostic signal analyzer built on an upgradeable platform. In the lab and on the bench, it provides the accuracy, repeatability, and reliability you need to test with confidence. [5]

Terminator 50 Ohm from HP, nowadays Keysight 909A coaxial terminator. Terminate a 50 Ω coaxial system in its characteristic impedance with this precision, low-reflection load. [6]

Attenuator 20dB from HP 8491B, nowadays Keysight Technologies, provides precision attenuation, flat frequency response, and low SWR over a broad frequency range. [7]

RF cables from HP very good quality, is good to mention, that cable for connection between LISNs and LISM-MATE unit should be from same manufacturer and same length, because difference in attenuation in this cable can affect this measurement and provides inaccurate data in difference in levels between CM and DM interference.

Power cables should be calculated according to maximum load of the EUT, and also cables length, between LISN and EUT must be 2 m long, as shown on Figure 4.

Power supply in our case was DC, and galvanically isolated.

EUT is multi rail switching power supply.

4.2 Equipment setup

For measurement is used setup as shown on Figure 6, for measurement of DM interference, and as shown on Figure 7, for CM interference.

EUT is set to 100% of load. Reason is that the switching power supply, what is EUT in this case, would generate the most interference at maximum load.

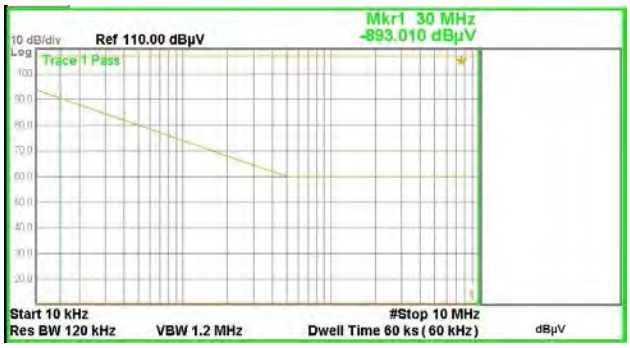

Figure 9. EMI state for CE102

Since we use EMI to collect and record data, the possibilities it offers are used, a state is created, (called state CE102) according to the requirements of data presentation and configuration of the equipment (Figure 6 and Figure 7). For the threshold curve according to the CE102 standard, Figure 8, basic curve is used, because power supply voltage was 24Vdc. Also, the attenuation of the attenuator from 20dB was entered, and an attenuation of 3dB was added due to LISN-MATE unit multiplication of output signal. This state is shown on Figure 9, before measurement.

4.3 Measurement

After calibration of equipment, all equipment were connected, as shown on figure 6, power supply is off, state CE102 is called and ambient noise is measured Figure 10.

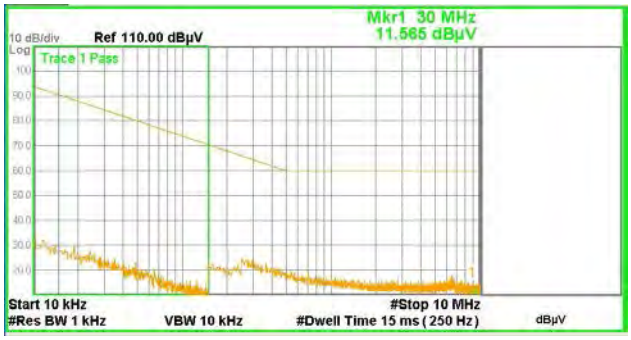

Figure 10. Ambient interference

4.3.1 DM component measurement

Difference to previous setup is that power supply was turn on, load is set to maximum load, everything else was the same, state CE102 was recalled and DM interference level was measured Figure 11.

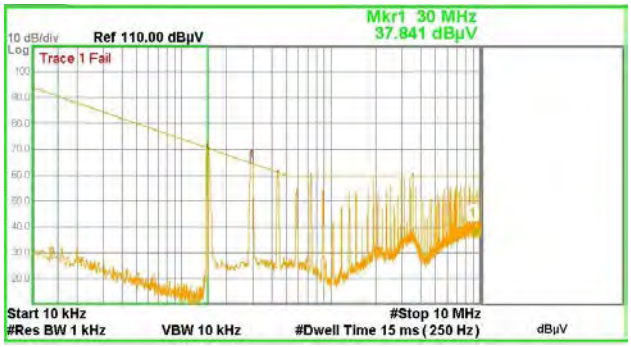

Figure 11. DM interference

4.3.2 CM component measurement

Equipment setup was changed according to Figure 7, power supply was on, load on EUT was om maximum, state CE102 was recalled and CM interference level was measured Figure 12.

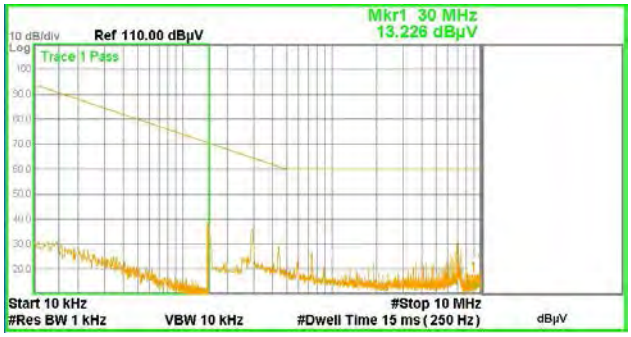

Figure 12. CM interference

4.3.3 Measurement data analysis and filter proposal

According to measurement results, on Figure 10, is shown that ambient interference is far below threshold curve for CE102 standard, so obtained measurement results are valid.

From Figure 11, is concluded that dominant interference, that EUT generate is DM, and EUT didn't passed test, its obvious that threshold curve for CE102 standard is exceeded, and in upper left corner of measurement data, Figure 11, is shown "Trace 1 Fail", so filter is needed to correct this type of interference.
On Figure 12, is shown that CM interference is significantly lower, for above 30 dB compared to DM interference, and this type is significantly below threshold curve for CE102, so this component type passed test, and for this component type, filter is not needed.

4.4 Filter proposal

For suppression of DM type of interference EMI filter is used, while for suppression of CM type of interference Choke filter is used.

As explained in privies chapter, for DM type of interference filter is needed.

The idea is to find EMI filter, with attenuation of DM type of interference, at least of 25dB or greater, according to Figure 11, and Figure 12. Also chosen EMI filter should be capable sustain maximum current capacity of EUT.

For purpose of explanation, filter FN409-6.5-02 is chosen. According to datasheet of this filter, filter have satisfying current capacity. Next, from datasheet, is analyzed attenuation chart Figure 13.

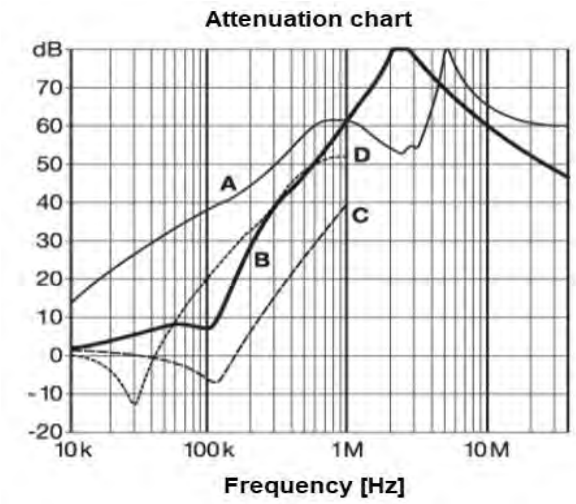

Figure 13. Typical Filter Attenuation [8]

Per CISPR 17 standard [9], each curve represents:
A = 50 Ω/50 Ω sym,
B = 50 Ω/50 Ω asym,
C = 0.1 Ω/100 Ω sym,
D = 100 Ω/0.1 Ω sym.
For calculating attenuation of DM type of interference, curve B is used.
and for calculating of CM type of interference, curve D is used. According to attenuation chart, Figure 13, measured value of DM and CM, Figure 11 and Figure 12, respectively, level of DM noise should be below 50dBµV, and level of CM noise should be at background noise level, after implementation of selected filter. Selected filter is installed on power line, between power supply and EUT, on the side of EUT. If the filter has ground connection, it connects to the chassis.

4.5 Verification

After filter implementation, as described in previous chapter, the tests, as shown on Figure 6 and Figure 7 were performed. Measurement results are showed on Figure 15 and Figure 16, respectively.

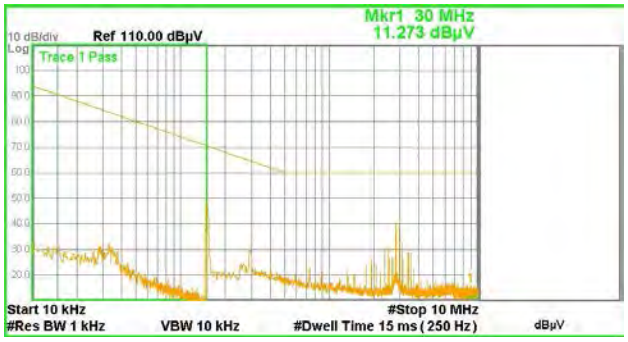

Figure 14. DM interference after filter implementation

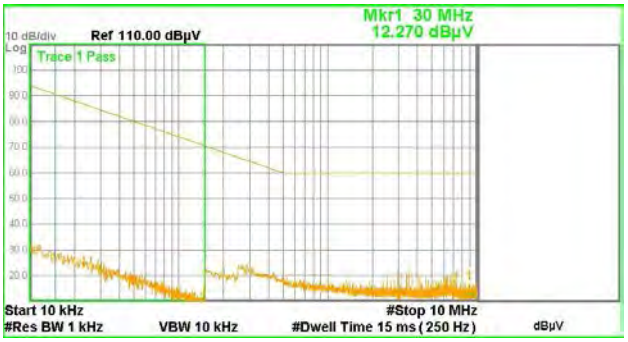

Figure 15. CM interference after filter implementation

Figure 14 and Figure 15, shows that analysis and calculation from previous chapter was correct.

Last test, that was carried out, for demonstration, that this methodology was correct, was test as shown on Figure 5, after a filter.

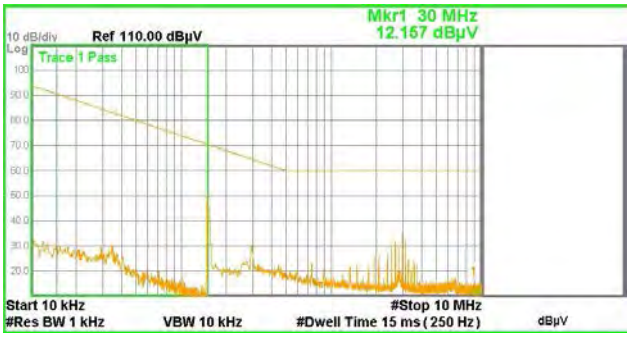

Figure 16. Conducted interference after filter implementation

On Figure 16, was shown that, also methodology proposed by MIL-STD-461, Figure 5, verified results. Only with expanded methodology, as proposed in this paper, and as showed on Figure 6 and Figure 7, is possible to manage each type of conducted interference separately.

5. CONCLUSION

This paper presents a measurement based methodology for the analysis of conducted electromagnetic interference, starting from the appropriate configuration of measurement equipment acquisition of conducted emission data, followed by spectral analysis and separation of the measured interference into DM and CM components. The obtained results are used to identify the dominant noise mode over investigated frequency range to determine required level of suppression. Further, based on required level of suppression and the dominant type interference, appropriate filter for implementation was selected. Finally, after the implementation of the filter, a final verification was performed to confirm that that the interference is within the limits defined by standard.

The future extension of this paper would include the design of filter, according to the data obtained by the methodology and measurement in order to optimize the filter for a specific device. Generic filters are usually not optimal, they cover wider frequency ranges, with certain suppression that could be much greater then is needed and because of that are certainly larger in size, heavier in mass and in higher price range. The designed filter would represent an optimal solution, would have required suppression, would be smaller in size, lighter and in lower price range.

Abstract: *Assessing the level of development of local government units (LGUs) represents one of the key instruments for understanding spatial disparities and supporting evidence-based regional policy. The methodological framework of this study integrates statistical and geospatial analyses to assess the level of development of LGUs in the Republic of Serbia. The analysis uses relevant socio-economic indicators. The Development Index of LGUs was calculated based on the following indicators: unemployment rate, income per capita, own revenue per capita, educational attainment, and population growth or decline rate. The highest development index was detected in Stara Pazova with 182.04 index points (i.p.), which means that the development of this LGU is 82.04 % above the republic average. Belgrade, as the largest city, is in the second place with 158.92 i.p., followed by Novi Sad (154.6 i.p.). Niš, as the third largest city in the Republic of Serbia, with 98.62 i.p. belongs to the second development group. In the fourth, the lowest development group, three LGUs detected development index lower than 50 % of the republic average – Rekovac (47.49 i.p.), Bojnik (49.19 i.p.), and Sjenica (49.62 i.p.). These findings highlight the need to reform the methodological framework, as well as the necessity of introducing new indicators that would more adequately reflect contemporary social, economic, and demographic challenges.*

Keywords: *Geospatial analysis, GIS, Local Government Units, development index, Republic of Serbia.*

1. INTRODUCTION

Assessing the level of development of local government units (LGUs) represents one of the key instruments for understanding spatial disparities and supporting evidence-based regional policy. Such assessments enable the identification of developed and underdeveloped areas, the allocation of development funds, and the implementation of measures aimed at achieving balanced regional growth.

The concept of territorial development is relatively recent and has evolved from earlier notions of regional and local development, as well as top-down and bottom-up approaches. Although these terms are often used interchangeably in practice, each represents a theoretical advancement over its predecessors. Local development, while frequently positioned within broader regional policy, remains insufficiently defined, yet is closely linked to key pillars such as capital and infrastructure policies, migration, and growth center strategies [1].

Development strategies have traditionally been framed through two contrasting approaches: top-down models based on industrialization and centralized planning, which often exacerbate inequalities, and bottom-up approaches that emphasize local resources, small-scale initiatives, and community participation [2].

More recently, the concept of territorial development has emerged as an integrative framework that encompasses local and regional development while incorporating notions such as place, clusters, and ecosystems [3]. Contemporary perspectives further highlight the role of both production processes and governance structures as

Corresponding author: Z. Kričković;
E-mail: zoran.krickovic@vs.rs
DOI: 10.5937/OTEH26098K

key drivers of territorial development, alongside broader forms of innovation, including social and institutional change, often shaped through both cooperation and conflict [4].

Regional disparities in Serbia remain a significant development challenge [5]. Although a legal and institutional framework exists, anchored in the Constitution and the Law on Regional Development [6], its implementation is constrained by outdated strategic documents and limited policy updates. The classification and measurement of LGU development levels represent a key instrument of regional policy [7], yet no revised regulatory framework has been adopted in recent years. This underscores the need for updated methodologies and policies to support more balanced and sustainable territorial development.

In Serbia, as in many other countries of Central and Eastern Europe, significant regional inequalities persist, both in terms of economic potential and quality of life [8]. The use of geospatial analysis in this context enables a more detailed examination of spatial patterns of development, revealing the spatial concentration of more or less developed municipalities. By applying GIS tools and statistical methods, it becomes possible to visualize the spatial distribution of indicators of socio-economic development and to detect LGUs that share similar development characteristics. This approach contributes not only to a better understanding of spatial disparities, but also to the formulation of more targeted and efficient development policies.

The methodological framework of this study is based on the integration of statistical and geospatial analyses aimed at assessing the level of development of LGUs in the Republic of Serbia. The analysis includes the use of relevant socio-economic indicators that reflect the demographic, economic, and infrastructural characteristics of municipalities and cities.

2. METHODOLOGY

The study area encompasses the entire territory of the Republic of Serbia, including its LGUs. According to the data of the Statistical Office of the Republic of Serbia (SORS), there are 197 municipalities, city municipalities, and cities that constitute the LGUs [9], [10], [11]. Out of the total number of LGUs, 29 are located in the region of Kosovo and Metohija, for which statistical data are not available in the official databases of SORS. Consequently, these LGUs were excluded from this research.

Spatial data used in this analysis were obtained from the open data platform of the Republic Geodetic Authority (RGA) [12]. As the results of this study are presented at the level of cities and municipalities, it was necessary to adjust the available RGA datasets accordingly. Figure 1 presents an overview of the research workflow applied in this study.

In this process, the city municipalities of Belgrade, Niš, Vranje, Požarevac, and Užice were merged into single city polygons, thereby forming 145 LGUs analysed in total across the Republic of Serbia. The spatial processing and aggregation were conducted in ArcGIS Pro 3.0. During the research, Microsoft Excel was used for the initial processing and cleaning of open datasets obtained from SORS. This step included the identification, extraction, and preparation of relevant data to be used for further analysis. According to the Official Gazette [13], the Development Index of LGUs is calculated based on the following indicators:

– Unemployment rate, calculated as the ratio between the number of unemployed persons and the sum of employed and unemployed persons within an LGU;
– Income per capita, representing the ratio of the total taxable income earned in a given calendar year (by the place of residence of the income recipient) and the total population of the LGU;
– Own revenue per capita, calculated as the ratio between the total realized own revenues of an LGU and its total population;
– Educational attainment, expressed as the share of the working-age population with completed secondary, post-secondary, or higher education in the total working-age population (according to the most recent census); and
– Population growth or decline rate, calculated as the ratio between the population size in the observed year and that recorded in the 2002 census at the LGU level.

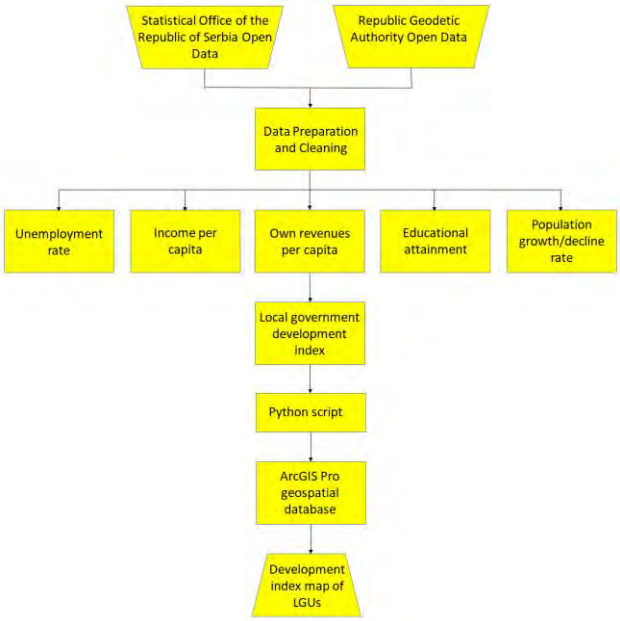

Figure 1. Schematic process of the research.

After calculating all indicators that reflect the level of development of a given territory or region, they were used to prepare an updated Unified Development List of LGUs in Serbia. According to the Official Gazette [13], each indicator is assigned a specific weight coefficient within the composite Development Index:

– Unemployment rate – 30%,
– Income per capita – 25%,
– Own revenue per capita – 10%,

– Educational attainment – 15%,

– Population growth or decline rate – 20%.

For the calculation of unemployment, income, and own revenue per capita, data for the three years preceding the year of calculation were used. In this study, that period covered 2022-2024. Additionally, a correction factor of -10 points was applied for LGUs in the fourth development group, whose working-age population density is lower than 30 persons per square kilometre. The calculation of the unemployment rate indicator was performed using the following equation:

$$I_{j,i} = \frac{R_i}{P_{j,i}} \times 100 \quad (1)$$

where I is the relative index (the national average equals 100), j represents the LGU, i the indicator, R the national average, and P the value of the indicator for the given LGU. For other indicators, the inverse proportion was applied, as higher values indicate better performance. According to these proportions, for the unemployment rate, values greater than 100 indicate results above the national average, while values below 100 indicate below-average performance. For all other indicators, higher values denote better results relative to the national average.

A review of the STAT database of the SORS and the publications Municipalities and Regions in the Republic of Serbia ([9], [10], [11]) revealed that data on income per capita at the municipal level are not available. Following direct communication with the Communication and Information Department of the SORS via email, it was confirmed that the SORS does not possess such data, but only data on the average wages of employees by municipality of residence and on household income at the regional level. The use of regional-level income data was considered inappropriate, as disaggregation to the level of LGUs would likely result in significant inaccuracies. Therefore, this study employs data on the average wages of employees by municipality and the number of employees as indicators of the economic status of the population, enabling an approximate estimation of income per capita. The Tax Administration of the Republic of Serbia undoubtedly collects such data, as clearly outlined in its Tax Guide [14], which specifies the categories of taxable income, including wages, taxable income from self-employment, copyright and related rights and industrial property rights, real estate, the rental of movable property, from the provision of hospitality services, taxable income of athletes and sports professionals, seafarers, and other taxable income [14].

In this context, foreign income refers to income earned and taxed in another country by taxpayers who are residents of the Republic of Serbia. Therefore, average wages represent only one of nine income categories that would be relevant for calculating the income per capita indicator. Consequently, this indicator, when estimated solely on the basis of average wages at the level of LGUs, does not fully reflect the actual socio-economic conditions of the population within a given territory or region. However, due to the lack of publicly available data, it is not possible to calculate income per capita in a precise and comprehensive manner. Data for the next indicator, own-source revenue per capita, were used on current revenues data from the SORS. The reason is the same as for the previous indicator – official publications of the SORS do not provide data on own-source revenues of LGUs, but only on current revenues.

The level of education, as the following indicator of territorial or regional development is defined as the ratio between the working-age population with completed secondary, post-secondary, or higher education and the total working-age population. During the analysis of this indicator certain inconsistencies were identified. Specifically, if the working-age population is assumed to comprise individuals aged 15 to 64, and the number of individuals with the aforementioned levels of education is aggregated based on the 2022 census data [15], the resulting share of the education level exceeds 100% in some LGUs. This clearly represents an unrealistic depiction of the actual educational structure of the population. It is established that the publications of the SORS do not present the number of working-age population by educational structure, but rather only data for the population aged 15 and over. For this reason, the total population aged 15 and above was used for the purposes of this research, in order to ensure that differences in educational structure remain positive and suitable for further analysis.

Based on the SORS data on 2002 census [15] and the projection of the population number at the end of 2024 [11], the population growth or decline rate by LGU is calculated. After applying the assigned weights, the final Development Index (N) for each LGU (j) was calculated using the following equation:

$$N_j = \omega_1 I_{j1} + \omega_2 I_{j2} + \omega_3 I_{j3} + \omega_4 I_{j4} + \omega_5 I_{j5} \quad (2)$$

The correction factor mentioned above was then applied to the final index values for the fourth development group. As data on Kosovo and Metohija region for some indicators were not available, therefore the development index for this region couldn't be calculated.

As a link between the data and the obtained results in MS Excel, a script written in the Python programming language was used. The open-source software PyCharm, a popular Integrated Development Environment (IDE) for Python, served as the main development platform. Today, Python offers a large number of libraries applicable to various fields. In this research, in addition to the core libraries, two additional libraries were used: openpyxl and arcpy.

The openpyxl library is used for working with Excel files in the .xlsx format. It enables reading, creating, editing, and saving Excel files without requiring MS Excel itself. Its key functionalities include reading and writing data to cells, formatting (colours, fonts, styles), working with multiple sheets, creating formulas, charts, and tables, as well as manipulating rows and columns [16].

The second library, arcpy, was developed by Esri for use with ArcGIS Pro (and formerly ArcMap). It allows for the

automation of GIS workflows – including spatial analysis, geospatial data processing, management of raster and vector data, and the administration of geodatabases. The key advantage of this library lies in its ability to automate spatial analyses [17]. Arcpy serves as the foundation for the integration of ArcGIS Pro within the Python environment and provides a vital link between various data sources and geospatial databases.

3. RESULTS AND DISCUSSION

According to the Official Gazette [13], out of the five regions that constitute the second level of the Nomenclature of Statistical Territorial Units (NUTS 2) of the Republic of Serbia, two (Belgrade and Vojvodina regions) are classified as developed, while the remaining three, located in the southern part of the country (Šumadija and Western Serbia, Southern and Eastern Serbia, and Kosovo and Metohija regions), are considered underdeveloped. It is evident that the northern part of the Republic is more developed than the southern part. Of the total territory of the Republic of Serbia, 28% is classified as developed, whereas the remaining 72% is underdeveloped. Thus, the developed area accounts for less than one-third of the country's total territory. The geographical distribution of development clearly reflects the inequality in the territorial development of the Republic of Serbia.

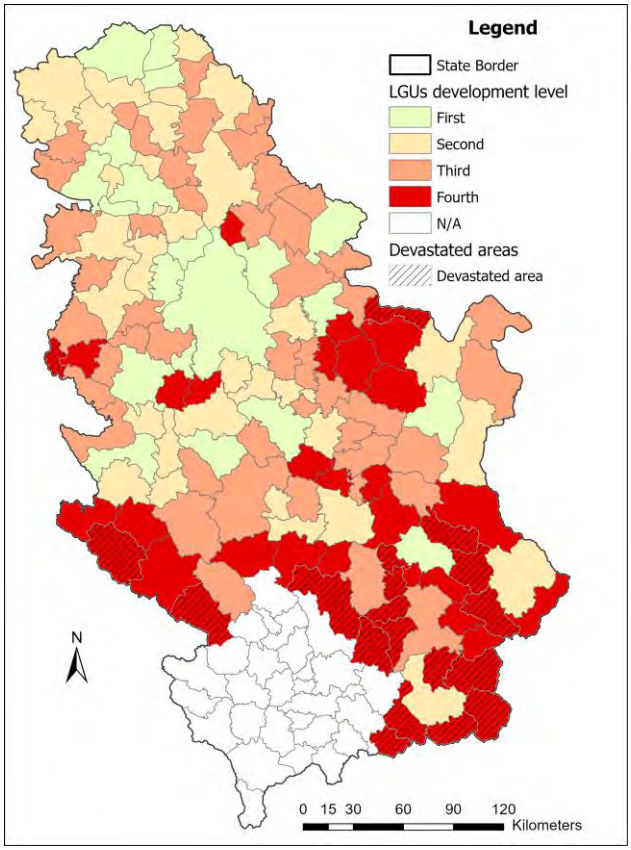

Figure 2. Spatial LGUs development according the Unified List of Development Levels of Regions and LGUs for 2014 [13].

Spatial distribution of the development of cities and municipalities within the territory of the Republic of Serbia is compiled according to the Regulation on the Determination of a Unified List of Development Levels of Regions and LGUs for 2014 (Figure 2). According to this overview, out of a total of 145 cities and municipalities, 20 belong to the first, most developed group, 34 to the second, 47 to the third, and 44 to the least developed, fourth group. Of these 44 LGUs from the least developed group, 19 are classified as devastated areas. Only 13.78% of LGUs have a development level above the national average, while nearly one-third (30.35%) have a development level below 60% of the national average. Devastated areas account for 13.1% of the total number of LGUs in the Republic of Serbia. It is evident that the least developed LGUs and the most devastated areas are located in the southern part of the Republic of Serbia, indicating significant regional disparities in territorial development.

As the first indicator of the development index, the unemployment rate shows a clear spatial disparity in the unemployment rate across the territory of the Republic of Serbia can be observed, with the highest levels recorded in the southwestern and southeastern parts of the country. The highest unemployment rates, exceeding 50%, were registered in Tutin (64.39%) and Novi Pazar (53.05%), while the lowest rates were observed in Stara Pazova (4.18%), Žagubica (6.53%), and Bački Petrovac (6.9%). Belgrade, as the capital city, follows closely with an unemployment rate of 7.01%.

The second indicator, Income per capita, calculated according to the method described above, also clearly highlights the higher level of development in major urban centres such as Belgrade and Novi Sad. An exception is observed in Bor, where the highest income per capita was recorded. In contrast, LGUs in the south-western and southern parts of Serbia, including Novi Pazar, Sjenica, Tutin, Preševo, and Bujanovac, exhibit the lowest levels of this indicator.

Due to the use of the aforementioned data, the results are somewhat overestimated for the third indicator – own revenue per capita, as the current revenues exceed own-source revenues. This indicator clearly reveals differences in relation to LGUs with smaller populations, where the highest own-source revenues per capita were recorded, such as in Čajetina (194.37 thousand RSD), Crna Trava (169.38 thousand RSD), Trgovište (148.12 thousand RSD), and Bor (142.5 thousand RSD), which thus represent the LGUs with the highest values of this indicator.

In contrast, LGUs with larger populations exhibit lower own-source revenues per capita, as observed in Bujanovac (27.14 thousand RSD), Preševo (28.15 thousand RSD), and Tutin (30.58 thousand RSD). As illustrated on the map, the majority of LGUs fall within the lowest category of own-source revenues (70 LGUs), followed by 56 LGUs in the second group and 19 LGUs in the third group, which includes the City of Belgrade as the largest urban center in the Republic of Serbia.

The aforementioned inconsistencies in the calculation of the following indicator of the development index – educational attainment, can be illustrated by the example

of the capital city, Belgrade. The SORS 2022 census data of the population between 15-64 years old for this city is 1,086,113. When the number of the population older than 15 years with completed secondary, post-secondary, or higher education is added, the result is 1,235,175 population. This is negative difference and this calculation is impossible to use. The uneven development of LGUs is clearly visible, with more populous cities generally exhibiting higher educational attainment, such as Novi Sad (86.68 %), Belgrade (86.55 %) and Niš (84.80 %). Unlike these, cities in Braničevo District have the lowest educational attainment – Malo Crniće (38.55 %), Žabari (43.38 %), and Petrovac na Mlavi (44.7 %).

The last indicator – population growth shows that population growth was detected in only four LGUs – Novi Pazar (126.75 %), Novi Sad (124.59 %), Tutin (111.13 %), and Belgrade (106.72 %). Unlike these, in the remaining 97% of LGUs population decline was detected, with the highest percentage detected in Crna Trava, with only 37.22 % of the population from 2002.

After all indicators calculated, the development index is calculated according earlier mentioned methodology. The geospatial distribution of LGUs according to the calculated Development Index is shown in Figure 3. It is clear the development progress of the LGUs, as in the lowest group are 13 LGUs, in the second, most number of the LGUs was detected – 62, in the third 42 and in the first group, in which development is above republic average, are 29 LGUs. Also, uneven territorial development of the Republic of Serbia is visible.

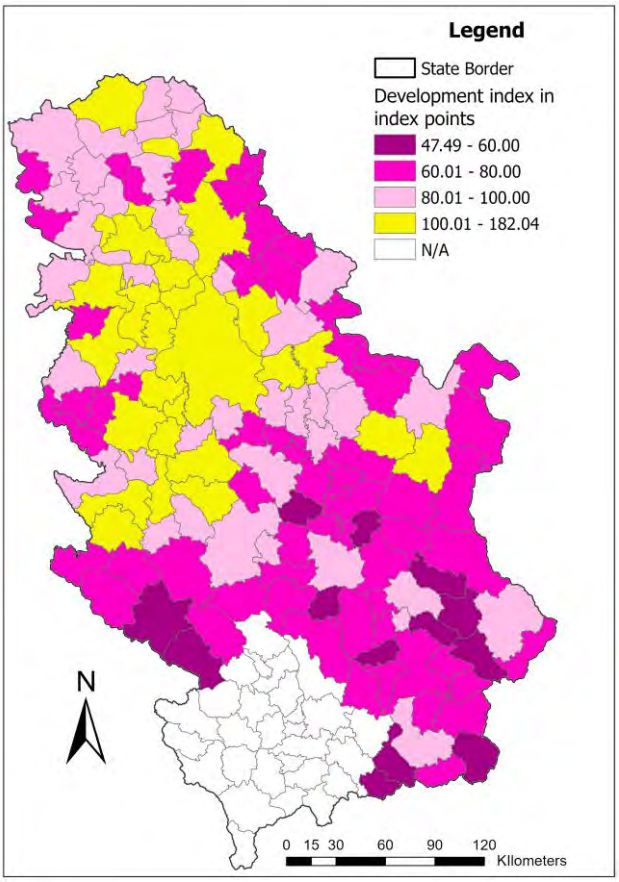

Figure 3. Development index for 2024 year according to publicly available SORS data.

The highest development index was detected in Stara Pazova with 182.04 index points (i.p.), which means that the development of this LGU is 82.04 % above republic average. Belgrade, as the largest city is in the second place with 158.92 i.p. followed by Novi Sad (154.6 i.p.). Niš, as the third largest city in the Republic of Serbia, with 98.62 i.p. belongs to the second development group. In the fourth, the lowest development group, three LGUs detected development index lower then 50 % of the republic average – Rekovac (47.49 i.p.), Bojnik (49.19 i.p.), and Sjenica (49.62 i.p.).

If these results are visually compared with the new methodologies proposed in [7], in which the authors identified two variants that, in terms of all structural performance indicators, provide the most realistic representation of the level of development of municipalities in the Republic of Serbia [7], it can be concluded that they yield broadly similar results with regard to the territorial distribution of the development index, although individual outcomes differ significantly. This is particularly evident in the case of Žagubica, which, according to this study, belongs to the first group of developed LGUs (108.77 i.p.), whereas in [7] it is classified within the fourth group, comprising devastated areas. Other LGUs do not exhibit such pronounced differences in the development index between this study and the results presented in [7].

In the context of the Republic of Serbia, the analysis indicates significant regional disparities. Although a well-developed legal and institutional framework for monitoring the level of development of LGUs exists [6], and [13], the continued application of a unified classification list from 2014 points to issues related to insufficient updating and the limitations of existing mechanisms, as also discussed in [7]. The results of this study, based on the most recent statistical data, confirm pronounced inequalities, particularly between the northern and southern parts of the country, furthermore that more than one-third of LGUs fall into the category of underdeveloped or devastated areas.

The assessment of local self-government development in Serbia, based on the official development methodology and the most recent statistical indicators, provides valuable insights into the spatial distribution of demographic, economic, infrastructural, and public service capacities across municipalities. The results of this research can significantly support the identification and prioritization of safe helicopter landing zones within the Project in the Military Geographical Institute “The use of geospatial data within a multicriteria analysis for the identification of safe helicopter landing zones in the territory of the Republic of Serbia”, as these development indicators may provide useful contextual information for future multicriteria analyses of transport accessibility, healthcare infrastructure, emergency response capacity, and public-space availability. Integrating development indicators with geospatial criteria may therefore contribute to a more efficient and equitable planning of helicopter landing networks, particularly in areas requiring rapid access to emergency medical and disaster response services.

Furthermore, these findings highlight the need to reform the methodological framework, as well as the necessity of introducing new indicators that would more adequately reflect contemporary social, economic, and demographic challenges. Furthermore, strengthening the role of local communities in the formulation of development policies is essential, in order to enable the inclusion of specific local resources and potentials.

4. CONCLUSION

The comparative analysis of the development index has shown that Serbia is still characterized by a high degree of inequality in the level of regional and LGU development, which significantly limits the possibilities for balanced and sustainable development. Although the existing institutional and legal mechanisms are well established in theory, in practice they are not sufficiently updated or adequately implemented, as reflected in the continued use of the 2014 Regulation. The data obtained in this study indicate the need to develop a new, up-to-date unified classification of LGU development levels, which would provide a more realistic representation of the current situation and serve as a basis for more effective regional policy planning.

In the future, it is necessary to design a model that would align the interests of local communities with national development strategies and introduce modern indicators that reflect the complexity of territorial development, as also proposed in the Study of the Republic of Serbia and its collaborators. Only through the integration of economic, social, and demographic dimensions, together with the active participation of all stakeholders, can a more equitable distribution of resources and a more balanced territorial development of the Republic of Serbia be achieved.

Abstract: *The development of Python-based algorithms has enabled the automation of selected processes in digital topographic map production at the Military Geographical Institute – "General Stevan Bošković" (MGI). In this study, automation is presented as a broader strategy for improving efficiency, consistency, and sustainability in GIS-supported map production workflows. Algorithm development was moved from ArcMap to ArcGIS Pro in order to support the transition from Python 2 to Python 3 and to provide a more modern, maintainable, and extensible software environment. Only algorithms that depend on specific ArcMap functionality, such as legacy representation features, were retained in the ArcMap environment. Implemented as native GIS tools, the algorithms incorporate institutional cartographic rules into modular geoprocessing procedures that can be used by both developers and GIS operators. As an illustrative example, the paper highlights the automation of content alignment along adjacent map sheet boundaries in ArcGIS Pro, a traditionally labor-intensive task requiring detailed visual inspection and manual correction. Particular attention is given to the Python-based processing pipeline and to the formulation of the functions used for geometry refinement, consistency control, and operator-guided validation of remaining discrepancies. The migration to ArcGIS Pro also improved compatibility with current GIS technologies and established a stronger foundation for future upgrades, including adaptation to different cartographic products and scales. The results show that Python GIS algorithms can significantly reduce manual intervention, improve workflow consistency, and provide a transferable framework for the modernization of digital map production processes.*

Keywords: *GIS, Python, Geoprocessing Automation, Digital Topographic Maps.*

1. INTRODUCTION

Digital topographic map production is no longer limited to the visual design and reproduction of cartographic content. In modern production systems, topographic maps are created from complex geospatial databases in which geometric accuracy, attribute consistency, topological correctness, and repeatability of procedures are equally important. This has increased the importance of automated and semi-automated GIS workflows, especially in institutions responsible for systematic map production [1].

At the same time, the growing volume of geospatial data has made purely manual cartographic procedures increasingly difficult to maintain. Tasks that were traditionally performed through visual inspection and manual editing often require repeated execution on large numbers of features. Such procedures are time-consuming and may lead to inconsistent results, since repetitive manual editing increases operator fatigue and the possibility of overlooked error. For this reason, automation has become an important element of digital cartography, contributing to reduced processing time, standardized production rules, and improved quality of the final geospatial database.

Python has become one of the most widely used programming languages for GIS automation because it provides a flexible environment for processing spatial data and building customized geoprocessing workflows. In GIS applications, Python is commonly used for data conversion, spatial analysis, topology control, batch processing, and the integration of multiple geoprocessing operations into repeatable procedures. Through libraries such as ArcPy, PyQGIS, GDAL/OGR, GeoPandas, Shapely, and PyProj, Python enables the development of tools for practical production procedures in which institutional production guidelines are directly

Corresponding author: M. Simić;

DOI: 10.5937/OTEH26099S

implemented [2, 3].

The role of Python in geospatial applications is not limited to conventional geoprocessing automation. Python-based workflows are also increasingly employed for the integration of GIS and remote-sensing data, automated spatial analysis, and machine- and deep-learning applications [4–6].

Within the ArcGIS environment, Python has an important role because it allows users to transform individual geoprocessing operations into structured tools that can be used directly from the program interface. Depending on the complexity of the task, Python code can be implemented as standalone scripts, script tools, or Python toolboxes. These approaches make it possible to automate repetitive procedures, define user parameters, control input data, and integrate developed tools into existing production workflows [7, 8]. Therefore, Python-based automation represents a practical bridge between software development and everyday cartographic production.

In the production of digital topographic maps at the Military Geographical Institute – "General Stevan Bošković" (MGI), Python-based algorithms have been developed to support selected cartographic and geoprocessing procedures. These algorithms are designed to incorporate institutional cartographic rules into repeatable GIS tools, while still allowing operator supervision where full automation is not appropriate. This is particularly important in topographic map production, where the final result must satisfy both geometric and cartographic requirements. Earlier automation procedures were primarily developed in the ArcMap environment and were based on Python 2. Although these tools provided practical benefits in production, the long-term sustainability of such workflows depends on their modernization and adaptation to current GIS technologies [9]. The transition from ArcMap to ArcGIS Pro and from Python 2 to Python 3 requires the revision of existing algorithms, adaptation of geoprocessing procedures, restructuring of code, and evaluation of which functions can be transferred to the new environment and which must remain connected to legacy ArcMap functionality.

An analysis of Python GIS algorithms is conducted within the broader framework of modernizing digital topographic map production. The focus is placed on the organization of automated workflows, the migration of algorithm development toward ArcGIS Pro, and the use of modular geoprocessing procedures. Content alignment along adjacent map sheet boundaries is used as an example of this approach because it represents a complex and traditionally labor-intensive procedure that combines geometry refinement, consistency control, and operator-guided validation. More broadly, the migration to Python 3 and ArcGIS Pro establishes a sustainable framework for the automation of additional production tasks, such as cartographic generalization in the derivation of smaller-scale maps from the 1:25,000 digital topographic map (DTM25).

2. MIGRATION FROM PYTHON 2 TO PYTHON 3

The migration from Python 2 to Python 3 represents an important step in the modernization of GIS-supported cartographic production. Earlier automation procedures were developed in the ArcMap environment which relied on Python 2. Although these tools were functional and useful in production, their long-term use is limited by software obsolescence, reduced compatibility with modern libraries, and the gradual transition of GIS platforms toward Python 3 [10]. ArcGIS Pro uses Python 3 and represents the current development environment for Python-based GIS automation in the Esri ecosystem.

This migration is not only a technical update of programming syntax, but also a transition toward a more sustainable production framework. Maintaining algorithms in an outdated software environment can create several practical problems, including limited support for new geoprocessing tools, difficulties in integrating updated Python libraries, reduced compatibility with new data formats, and increased dependence on legacy workflows. Since ArcGIS Desktop, including ArcMap, has reached the end of its product life cycle, migration to ArcGIS Pro is also necessary for ensuring the continuity of institutional GIS workflows.

One of the main advantages of migration to ArcGIS Pro is the use of a modern Python 3 environment managed through Conda. This enables better control of Python packages, easier management of project-specific environments, and access to updated scientific and geospatial libraries. This environment contains ArcPy and additional Python libraries used for geoprocessing, data analysis, and automation [11].

However, migration from Python 2 to Python 3 also requires careful revision of existing algorithms. Certain changes in syntax, string handling, dictionary behavior, module organization, and library compatibility can require modification of older code. Automated conversion tools can assist in this process, but they do not fully replace manual inspection and testing. For this reason, migration represents a controlled redesign of the workflow rather than a simple conversion of scripts from one Python version to another [12].

In the context of digital topographic map production at the MGI, this process involved analysing the existing ArcMap-based algorithms and determining how their logic could be transferred to the ArcGIS Pro environment. For the workflow presented in this study, complete migration was possible because the procedure did not depend on legacy cartographic representation mechanisms specific to ArcMap. The algorithms were therefore redesigned for Python 3 and ArcGIS Pro while preserving the original cartographic logic. In this way, an established production task was transferred into a modern software environment, improving maintainability, compatibility with current GIS technologies, and the potential for future expansion.

By adapting the tools to a modern GIS environment, the code becomes easier to update, document, test, and extend. This is especially important in institutional cartographic

production, where tools are not created for one-time use, but must remain operational across multiple production cycles. A modernized Python 3 workflow also makes it easier to introduce additional automated procedures, connect different processing stages, and gradually reduce repetitive manual work.

3. MATERIALS AND METHODS

DTM25 production at the MGI includes several interconnected phases, such as editorial preparation, aerial photogrammetric survey, photogrammetric mapping, field verification and completion, cartographic processing, and reproduction [9]. This paper focuses on the cartographic processing phase, which includes numerous repetitive geoprocessing operations that require consistency, precision, and repeatability across different production tasks.

The selected production procedure used for methodological demonstration is the alignment of content along adjacent DTM25 map sheet boundaries. This procedure was selected because the alignment of adjacent map sheets requires a combination of interrelated operations, including the detection of features near sheet boundaries, geometric refinement of line and polygon features, control of topological continuity between neighbouring sheets, and identification of remaining discrepancies for operator review. In manual workflows, this task requires detailed visual inspection of all feature vectors located near the map frame. Small geometric offsets, gaps, or overlaps may remain unnoticed at the standard display scale, especially in areas with dense content such as contour lines, hydrography, or communication networks.

The automated workflow is organized around three production scenarios. The first scenario refers to the case in which the adjacent sheet has already been completed, so the active sheet is adjusted according to the finalized geometry of the neighbouring sheet. The second scenario refers to the simultaneous processing of two adjacent sheets, where both sheets are adjusted in a coordinated manner. The third scenario refers to the preparation of an active sheet when the neighbouring sheet has not yet entered the cartographic processing phase. These scenarios correspond to unidirectional, bidirectional, and preparatory alignment procedures.

The input data consist of DTM25 feature classes stored in production geodatabases, together with the sheet index polygon layer used to define the boundaries of adjacent map sheets. The procedure processes line and polygon feature classes separately because these geometry types require different correction logic. Line features include contour lines, roads, railways, flowing water, communication objects, and other linear cartographic elements. Polygon features include vegetation areas, water bodies, marshland, and other surface elements (Figure 1.).

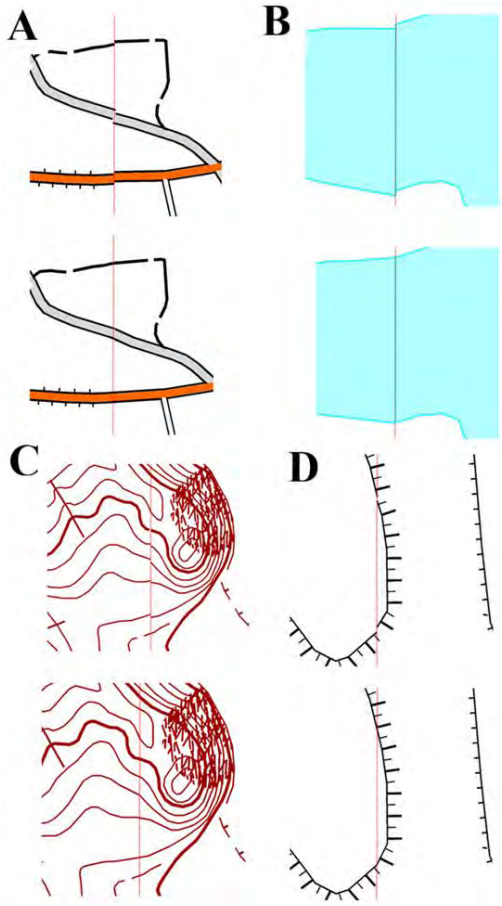

Figure 1. Examples of communication networks (A), hydrology (B), contour lines (C), and relief (D) at TK25 sheet boundaries (red line) before (top image) and after (bottom image) automatic vector processing

Point features are used as control outputs, marking locations where automatic processing detected unresolved or potentially problematic geometry (Figure 2.).

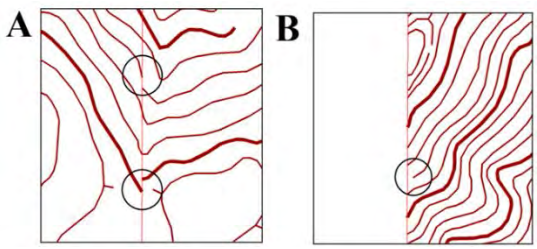

Figure 2. Point indicators (displayed as circles) marking unresolved contour-line geometry in bidirectional alignment (A) and preparatory alignment (B)

The workflow was implemented in ArcGIS Pro using Python 3 and ArcPy geoprocessing functions. The tools were designed as modular GIS procedures that can be executed from the ArcGIS Pro interface, allowing operators to use them without direct interaction with the source code. Before running the procedure, the operator defines the relevant input geodatabases, the map sheet pair, the feature classes to be processed, and the tolerance values for geometry correction. Repetitive and rule-based operations are performed automatically, while the operator remains responsible for parameter selection and validation of marked discrepancies making the workflow semi-

automated.

The general processing sequence consists of four main steps. First, user-defined parameters are read and assigned to internal variables. Second, the polygons of the selected DTM25 sheet pair are extracted from the sheet index layer and used as spatial references for selecting features along the boundary zone. Third, separate processing objects are initialized for line and polygon feature classes. Fourth, the tool performs hierarchical processing. It first iterates through each selected sheet pair and then through the selected feature classes within that pair. This structure allows the same logic to be applied to multiple sheets and multiple cartographic layers without rewriting the procedure for each individual case.

To make the processing logic more explicit, the workflow can be represented as a Python pipeline composed of reusable geoprocessing functions. This functional representation separates the algorithm into elementary operations. Formulating the process in this manner is useful because it shows the order of execution, and how the same functions can be reused in different production scenarios.

If F_L is defined as the function for processing line features, F_G as the function for processing polygon features, and P_L as the function for creating point features that indicate changes or unresolved discrepancies, the procedures can be represented as follows.

Active and Passive Replic

For line features, the active sheet is adjusted according to the passive, already finalized neighbouring sheet:

$$F_L(e) = (S_2 \circ L \circ S \circ I_2)(e) \quad (1)$$

$$P_L(e) = \big(P \circ M(I, I_2)\big)(e) \quad (2)$$

For polygon features, the algorithm first selects the relevant polygon elements on both sheets and then applies snapping and densification along the boundary zone:

$$G(e) = (L_A \circ L_1)(e) \quad (3)$$

$$G_2(e) = (L_A \circ L_2)(e) \quad (4)$$

Two Active Replicas

In the case of two active replicas, the alignment is performed in two phases because both neighbouring sheets are still in production.

For line features, the first phase prepares and adjusts selected features from both sheets:

$$B(e) = (I \circ L_1)(e) \quad (6)$$

$$B_2(e) = (I_2 \circ L_2)(e) \quad (7)$$

$$F_{L1}(e) = (S_2 \circ L \circ S_3(B_2, L_1))(e) \quad (8)$$

In the second phase, the corresponding features are adjusted in the opposite direction and point indicators are created for operator verification:

$$F_{L2}(e) = S_3(B, L_2)(e) \quad (9)$$

$$P_L(e) = \big(P \circ M_2(B, B_2)\big)(e) \quad (10)$$

For polygon features, the first phase selects and adjusts the relevant polygon elements:

$$G(e) = (L_A \circ L_1)(e) \quad (11)$$

$$G_2(e) = (L_A \circ L_2)(e) \quad (12)$$

$$F_{G1}(e) = (S_b \circ G_2)(e) \quad (13)$$

The second phase performs boundary refinement using snapping, densification, and intersection-based correction:

$$F_{G2}(e) = Sp(D \circ Sp(L_F \circ G, PP), IP(G_2))(e) \quad (14)$$

Active Replica Only

When only the active sheet is available, the procedure prepares its boundary content for later integration with the neighbouring sheet.

For line features:

$$F_L(e) = S_4(e) \quad (15)$$

$$P_L(e) = (H \circ C)(e) \quad (16)$$

For polygon features:

$$F_G(e) = S_b(e) \quad (17)$$

Definition of Pipeline Functions

The pipeline formulas use the following variables:

– e and f represent the features that are being processed;
– ω represents an auxiliary or intermediate feature used as an additional input to an operation;
– $TK25_1$ represents the polygon of the first sheet;
– $TK25_2$ represents the polygon of the second sheet;
– b represents the distance from the sheet frame in meters;
– c represents the feature type code used for selecting specific polygon features.

The line-feature functions used in the pipeline are defined as follows:

– $I(f)$ = intersect $(f, TK25_2)$
– $I_2(f)$ = intersect $(f, TK25_1)$
– $S(f)$ = snap $(f, I_2(f))$
– $L(f)$ = select_fc_that_isnt_snaped $(f, TK25_1)$
– $S_2(f)$ = snap $(f, TK25_2)$
– $M(f, \omega)$ = merge (f, ω)
– $P(f)$ = create_changes (f)
– C = create_parallel_line_to_frame $(TK25_1, TK25_2, a)$ – where $a = b - 3$.

– $H(f)$ = create_correction_lines (f, $TK25_2$, C)
– $L_1(f)$ = select_fc_on_replica (f, $TK25_1$)
– $L_2(f)$ = select_fc_on_replica (f, $TK25_2$)
– $S_3(f, \omega)$ = snap (f, ω)
– $M_2(f, \omega)$ = merge (f, ω)
– $S_4(f)$ = snap $(f, TK25_2)$

The polygon-feature functions used in the pipeline are defined as follows:

– $L_1(f)$ = select_fc_on_replica $(f, TK25_1)$
– $L_2(f)$ = select_fc_on_replica $(f, TK25_2)$
– $L_A(f)$ = select_features (f, c)
– PP = create_parallel_line_to_frame $(TK25_1, TK25_2, b)$
– $IP(f)$ = create_intersection_fc_with_polygon (f, $TK25_1$)
– $L_F(f)$ = select_fc_on_frame_border (f, PP)
– $S_p(f,\omega)$ = snap (f, ω)
– $D(f)$ = densify_fc (f)
– $S_b(f)$ = snap $(f, TK25_1)$

The python class methods used in these functions represent the elementary geoprocessing operations from which the complete workflow is composed. In the following method definitions, *a*, *b*, and *c* are used as generic input arguments:

– intersect *(a, b)* – performs the intersection of line object *a* with polygon *b* and creates intersection points.
– snap *(a, b)* – snaps points of object *a* to standalone points, points within a line object, or boundary lines of polygon object *b*.
– select_fc_that_isnt_snapped *(a, b)* – selects line objects *a* that touch the boundary of the adjacent sheet polygon *b*.
– merge *(a, b)* – merges objects *a* and *b* into a new object.
– create_changes *(a)* – creates a point object indicating lines of object *a* that require operator verification.
– create_parallel_line_to_frame *(a, b, c)* – creates a line at distance *c*, parallel to the frame of polygon *b*, and located on sheet polygon *a*.
– create_correction_lines *(a, b, c)* – creates a point object indicating lines of object *a* that cross the auxiliary line *c*, but do not touch the boundary of the adjacent sheet polygon *b*.
– select_fc_on_replica *(a, b)* – selects line or polygon objects *a* located on sheet polygon *b*.
– select_features *(a, b)* – selects polygon objects *a* with attribute code *b*.
– create_intersection_fc_with_polygon *(a, b)* – creates intersection lines between polygon object *a* and sheet polygon *b*.
– select_fc_on_frame_border *(a, b)* – selects polygon objects *a* that intersect line *b*.
– densify_fc *(a)* – increases the number of vertices in polygon object *a*, improving the precision of subsequent snapping and boundary refinement.

This formulation presents the workflow as a structured sequence of reusable geoprocessing functions rather than as a simple execution of individual GIS tools. Such an approach makes the logic of the algorithm more transparent and provides a basis for applying the same principle to similar cartographic production tasks. This structure can also be presented through workflow diagrams, as shown in Figures 3 and 4.

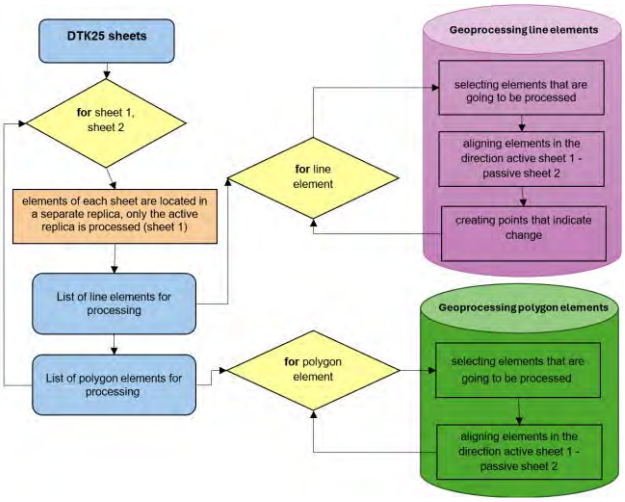

Figure 3. Diagram illustrating the content alignment workflow in the Active & Passive Replica tool

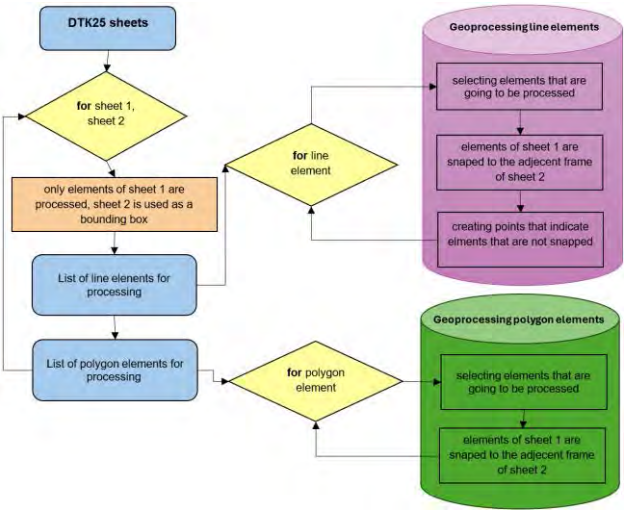

Figure 4. Diagram illustrating the content alignment workflow in the Active & Passive Replica tool

4. RESULTS AND DISCUSSION

The developed Python GIS workflow was tested on a series of adjacent DTM25 sheet pairs produced at the MGI. The main purpose of testing was to evaluate whether the developed workflow could correctly identify, refine, and control boundary geometries in different production scenarios.

The results showed that the automated processing successfully resolved most geometric inconsistencies that occurred within the defined tolerance values. In the case of line features, offsets and interruptions along sheet boundaries were corrected. The most visible improvement was observed for contour lines and road features, where manual correction is usually time-consuming because of

the number and density of elements along the map frame.

For polygon features, the workflow reduced unwanted gaps and overlaps between neighbouring boundary elements. This was especially important for large surface features that extend across sheet borders, such as vegetation areas, water surfaces, marshland, and similar polygonal elements.

The generated point control layers also proved to be useful. Instead of visually inspecting the entire sheet boundary, the operator was directed to specific locations where unresolved discrepancies or potentially problematic geometries remained. As a result, the operator's work was concentrated on complex cases that required expert assessment, while repetitive geometric corrections were performed automatically.

The effect of automation was also evaluated through the time required for sheet-boundary alignment. According to production records, the conventional manual procedure required approximately 5 working hours to align the content between two adjacent DTM25 sheets. Since one DTM25 sheet may need to be aligned with four neighbouring sheets, the total time for a complete sheet could reach approximately 20 working hours. After applying the Python GIS workflow, the average processing time was reduced to approximately 40 minutes per adjacent-sheet operation, or about 2.7 working hours for a complete sheet, including script execution, preliminary sheet analysis, and subsequent correction of marked discrepancies. This represents a time saving of more than 85% compared with the conventional procedure and an efficiency increase of more than seven times.

Overall, the results indicate that the developed Python GIS workflow provides a practical basis for semi-automated cartographic processing. The tested functions showed repeatable applicability across different feature classes and production scenarios. This confirms that the selected procedures can be performed in ArcGIS Pro while preserving the original production logic, making the workflow suitable for use in a real cartographic production environment. These results also show that the same principle can be extended to other DTM25 production tasks in which repetitive geoprocessing operations are present.

Expressing the workflow through clearly defined reusable geoprocessing functions makes the algorithm easier to analyse, test, modify, and extend. It also allows individual parts of the workflow to be adapted for other production tasks without redesigning the entire procedure.

5. CONCLUSION

Python GIS algorithms provide an effective basis for modernizing procedures in digital topographic map production. By transferring the workflow to ArcGIS Pro and Python 3, the developed solution was adapted to a current software environment while preserving the cartographic logic, production rules, and operator-guided validation procedures.

The workflow enables automatic correction of most inconsistencies in line and polygon features located along sheet borders. Generated control points allow the redirection of manual work from complete detail visual inspection of the sheet boundary to targeted verification of remaining problematic cases. In this way, automation did not remove cartographic judgement from the process. Instead, it reduced repetitive editing and focused operator attention on situations where expert control is necessary. This resulted in a substantial reduction in processing time and an efficiency increase of more than seven times.

The developed workflow establishes a methodological and practical knowledge base for applying Python programming to the automation of other processes within the production of geotopographic materials. The same logic can be adapted to other cartographic tasks, such as generalization. The results also indicate that semi-automation is an appropriate model for complex cartographic workflows. Full automation is limited by the variability of mapped content and the need for cartographic interpretation, but a carefully designed semi-automated workflow can significantly reduce manual work, improve consistency, and support a more sustainable digital topographic map production system.

Abstract: *Security Information and Event Management (SIEM) platforms are essential for centralized security monitoring in Security Operations Centers (SOCs), yet they continue to face a persistent challenge: high volumes of false positive alerts that impair analyst efficiency and delay incident response. This paper presents a comparative evaluation of three SIEM platforms—Wazuh, IBM QRadar, and Splunk Enterprise Security—in detecting selected MITRE ATT&CK techniques. Several attack scenarios, including brute force authentication, network reconnaissance, and malicious command execution, were executed to assess detection accuracy, latency, false positive rates, and alert precision. Results reveal notable differences between open-source and commercial solutions. Enterprise platforms demonstrated superior correlation capabilities and lower false positive rates, while open-source Wazuh offered competitive detection performance at significantly reduced deployment costs. These findings provide practical insights into SIEM performance when detecting adversary behaviors mapped to the MITRE ATT&CK framework, offering guidance for organizations balancing cost, accuracy, and operational efficiency in their security stack selection.*

Keywords: *SIEM, MITRE ATT&CK, False Positives, Threat Detection, Security Monitoring*

1. INTRODUCTION

The increasing complexity of modern information systems and the continuous growth of cyber threats have significantly increased the importance of centralized security monitoring solutions. Organizations generate large volumes of security-related logs originating from endpoints, servers, authentication services, and network devices, making manual analysis of security events increasingly difficult. In such environments, Security Information and Event Management (SIEM) systems have become essential components of Security Operations Centers (SOC), enabling centralized collection, correlation, and analysis of security events in real-time [1].

Despite the widespread adoption of SIEM technologies, one of the major operational challenges remains the high number of false positive alerts generated during event correlation and threat detection processes. Excessive false positives may lead to alert fatigue, increased workload for SOC analysts, and delayed response to legitimate security incidents. Consequently, evaluating the balance between detection capability and false positive generation has become an important aspect of SIEM performance assessment.

In recent years, the MITRE ATT&CK framework has emerged as a standardized knowledge base for modeling adversarial behavior and evaluating defensive mechanisms. ATT&CK-based testing allows researchers and security analysts to simulate realistic attack techniques and objectively measure the detection capabilities of security platforms [2].

Recent SOC studies additionally emphasize that excessive alert volume may contribute to analyst fatigue, operational inefficiency, and delayed incident prioritization. Consequently, modern SIEM evaluation increasingly includes not only detection capability, but also alert quality and operational usability within SOC environments [3].

This paper presents a comparative evaluation of the Wazuh, IBM QRadar, and Splunk Enterprise Security SIEM platforms through the analysis of selected MITRE ATT&CK techniques and false positive events. The research is conducted in a controlled laboratory environment using simulated attack scenarios mapped to ATT&CK techniques, including brute force attacks, network reconnaissance, and suspicious command execution.

The primary contributions of this research are:

1) a controlled ATT&CK-based comparative evaluation of three widely used SIEM platforms under identical attack conditions;

Corresponding author: M. Premovic;
E-mail: marko.premovic@vs.rs;
DOI: 10.5937/OTEH26100P

2) quantitative assessment of false positive generation and detection effectiveness using standardized evaluation metrics;

3) operational analysis of alert quality through Precision-based evaluation of actionable alerts within SOC environments.

The paper is organized as follows. After the introduction, the second chapter presents the theoretical background on SIEM systems, the MITRE ATT&CK framework, and false positive alerts, while the third chapter describes the experimental environment, attack scenarios, and evaluation metrics. The fourth chapter presents the detection results and false positive analysis, followed by the conclusion and directions for future work.

2. THEORETICAL BACKGROUND

2.1 Security Information and Event Management Systems

Security Information and Event Management (SIEM) systems are designed to provide centralized collection, normalization, correlation, and analysis of security events generated within enterprise infrastructures.

Modern SIEM platforms utilize rule-based analytics, behavioral analysis, and threat intelligence integration to identify suspicious activities and generate alerts for SOC analysts [4].

Modern enterprise SIEM platforms additionally support integration with external threat intelligence feeds, enabling improved contextual analysis and prioritization of high-risk events during correlation processes.

However, improperly configured detection rules may generate excessive false positive events, reducing the operational efficiency of security monitoring processes.

Recent comprehensive surveys of SIEM adoption trends confirm that organizations continue to prioritize false positive reduction as a key operational challenge, with correlation rule tuning remaining one of the most resource-intensive SOC activities [13].

2.2 MITRE ATT&CK Framework

The MITRE ATT&CK framework represents a structured knowledge base used for the classification of adversarial tactics and techniques observed during cyber attacks.

One of the primary advantages of the ATT&CK framework is its applicability in detection engineering and security evaluation. By mapping attack scenarios to ATT&CK techniques, security analysts can evaluate the effectiveness of defensive mechanisms and identify potential detection gaps within monitored environments.

The ATT&CK techniques used in this research are presented in Table 1.

Table 1. Selected MITRE ATT&CK Techniques Used in the Experimental Evaluation

Technique	ATT&CK ID
Brute Force	T1110
Network Service Scanning	T1046
Command and Scripting Interpreter	T1059

2.3 False Positive Events

False positive alerts represent security events incorrectly classified as malicious activities by detection systems. High false positive rates may negatively impact SOC operations by increasing analyst workload and reducing the visibility of legitimate threats [5]. Consequently, reducing unnecessary alerts while maintaining high detection accuracy is considered one of the major challenges in SIEM optimization and detection engineering. In practical SOC environments, false positive reduction is commonly achieved through correlation rule tuning, contextual enrichment, and event prioritization mechanisms. Proper rule optimization may significantly improve analyst efficiency without reducing detection coverage [6].

3. EXPERIMENTAL ENVIRONMENT

3.1 Laboratory Setup

The laboratory environment was designed to emulate a small enterprise network consisting of approximately 50 endpoint systems. The infrastructure included Windows workstations, Linux servers, centralized authentication services, and network devices generating routine operational logs. Endpoint activity included user authentication events, administrative operations, file access events, process execution records, and network communications in order to simulate realistic enterprise workloads.

A dedicated Kali Linux system was used for attack execution, while Windows and Ubuntu hosts acted as monitored targets. Security events were collected through native operating system logging mechanisms and forwarded to the evaluated SIEM platforms. Log sources included authentication logs, process creation events, command execution records, and network connection events.

The laboratory topology was intentionally configured to generate both legitimate administrative activity and malicious behavior. This approach enabled observation of SIEM detection performance under conditions that more closely resemble operational SOC environments, where benign and malicious events coexist within the same monitoring infrastructure. Laboratory parameters are shown in Table 2.

Table 2. Laboratory Configurations Parameters

Parameter	Value
Simulated Endpoints	50
Windows Systems	Multiple
Linux Systems	Multiple
SIEM Platforms	Wazuh 4.8, QRadar 7.5, Splunk ES 7.3.2
Attack Workstation	Kali Linux
Log Sources	Auth, Process, Network, System
ATT&CK Techniques Tested	3
Repetition per Scenario	5

To ensure result comparability, all SIEM platforms received identical log streams generated from the same attack scenarios and background network activity. Platform-specific detection rules were configured according to vendor-recommended practices while maintaining comparable monitoring coverage across all evaluated solutions.

3.2 Attack Scenarios

Several attack scenarios mapped to selected MITRE ATT&CK techniques were executed during the experimental phase of this research. The scenarios were designed to represent common adversarial activities frequently encountered in enterprise environments and SOC operations. Each scenario was executed five times under identical laboratory conditions in order to evaluate detection consistency, alert generation behavior, and correlation effectiveness across the analyzed SIEM platforms.

The first scenario simulated credential access attempts using the Hydra tool and was mapped to ATT&CK technique T1110 (Brute Force). Multiple SSH authentication attempts were generated against Linux systems within the laboratory environment using valid and invalid credential combinations. The objective of this scenario was to evaluate the ability of SIEM platforms to detect repeated authentication failures and identify potential brute-force activity while minimizing unnecessary alerts generated by legitimate authentication events.

The second scenario focused on network reconnaissance activities corresponding to ATT&CK technique T1046 (Network Service Scanning). Reconnaissance was performed using the Nmap tool [8] against multiple hosts within the monitored network segment. Various scanning techniques were executed in order to generate network discovery events and service enumeration activity. This scenario was selected because reconnaissance activities often produce event patterns that resemble legitimate administrative operations, making accurate detection particularly challenging for SIEM platforms.

The third scenario simulated malicious command execution behavior associated with ATT&CK technique T1059 (Command and Scripting Interpreter). PowerShell commands commonly observed in attack investigations were executed on Windows systems in order to generate process creation events, command execution logs, and related security telemetry. The objective was to evaluate the capability of each SIEM solution to identify suspicious command execution activity while maintaining acceptable alert precision.

To provide realistic operating conditions, attack execution was performed while legitimate background activity was simultaneously generated throughout the laboratory environment. Authentication events, file access operations, system administration tasks, and normal network communications were continuously produced by the simulated endpoints. This approach enabled evaluation of SIEM performance under conditions that more closely resemble operational enterprise networks rather than isolated attack demonstrations.

Each attack scenario was repeated five times for every evaluated SIEM platform. During every execution, detection events, generated alerts, false positive occurrences, and detection latency were recorded. The collected observations were subsequently aggregated and used for the calculation of the evaluation metrics presented in this study.

3.3 Evaluation Metrics

The performance evaluation of the three SIEM platforms (Wazuh, IBM QRadar, Splunk Enterprise Security) was based on quantitative metrics derived from controlled attack simulations mapped to MITRE ATT&CK techniques T1110 (Brute Force), T1046 (Network Service Scanning), and T1059 (Command and Scripting Interpreter). Each attack scenario was repeated five times per platform, with simultaneous generation of legitimate background activity across 50 simulated endpoints to emulate realistic SOC conditions.

3.3.1 Determination of Event Classification Outcomes

For each executed attack instance and each background activity event, security events generated by the SIEM platforms were classified into four mutually exclusive categories:

True Positive (TP) -- An alert was generated, and the event corresponded to an actual executed attack technique (e.g., a Hydra brute-force SSH attempt correctly detected as T1110).

False Positive (FP) -- An alert was generated, but the event was not part of any attack; it originated exclusively from legitimate administrative or background activity (e.g., a scheduled PowerShell script flagged as suspicious command execution).

True Negative (TN) -- No alert was generated, and the event was indeed benign (e.g., a normal user login or routine file access).

False Negative (FN) -- No alert was generated, although an attack was successfully executed (e.g., an Nmap network scan that remained undetected).

Classification was performed by correlating SIEM alert logs with ground truth attack logs collected from the Kali Linux attack workstation and from target endpoints (Windows and Linux system logs). Each event was manually verified by the research team to eliminate ambiguity.

The total event set for each SIEM platform consisted of approximately 1000 benign background events (authentication, process creation, file access, network connections) and 120 attack related events (5 repetitions × 3 techniques × approximately 8 individual attack actions per technique). Thus, the total number of evaluated events per platform was 1120, distributed as TP + FP + TN + FN = 1120.

3.3.2 Detection Time Measurement

Detection Time (detection latency) was defined as the interval between the moment an attack action was completed on the target system and the moment the SIEM platform generated a corresponding alert in its console.

Detection latency was measured as the elapsed time between attack execution and alert generation within the corresponding SIEM platform. Measurements were collected for all true positive detections and averaged across all attack scenarios. The final "Avg Detection Time" reported in Table 4 represents the arithmetic mean value per platform.

3.3.3 Calculation of Accuracy and False Positive Rate (FPR)

Detection Accuracy was calculated using the standard formula:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

Accuracy represents the proportion of all evaluated events (both malicious and benign) that were correctly classified by the SIEM.
False Positive Rate (FPR) was defined as:

$$FPR = \frac{FP}{FP + TN} \quad (2)$$

FPR measures the ratio of benign events that were incorrectly flagged as malicious relative to all actual benign events. A lower FPR indicates better alert precision and reduced analyst fatigue.
Alert Relevance Ratio (ARR) is proposed as a complementary SOC-oriented metric:

$$ARR = \frac{TP}{TP + FP} \quad (3)$$

Precision represents the proportion of generated alerts that correspond to actual malicious activity. Higher Precision values indicate a greater proportion of actionable alerts requiring analyst investigation.

From an operational SOC perspective, Precision is additionally discussed in this paper as the Alert Relevance Ratio (ARR), emphasizing the practical value of alert quality and analyst workload reduction.

3.3.4 Raw Detection Statistics

Based on the classification methodology described in Section 3.3.1, the raw counts of TP, FP, TN, and FN were aggregated for each SIEM platform across all attack repetitions and background events. Table 3 presents these raw values.

Table 3. Raw Detection Statistics

Platform	TP	FP	TN	FN	Total Events
Wazuh	84	196	804	36	1120
QRadar	90	88	912	30	1120
Splunk	93	67	933	27	1120

Approximately 1000 benign events were generated through routine administrative activity, authentication operations, process execution, and normal network communications across the laboratory environment.

3.3.5 Derived Performance Metrics

Using the raw data from Table 3 and the equations (1) - (3), the following performance metrics were calculated for each SIEM platform.

Avg Detection Time – mean latency in seconds (measured only for TP events).

Table 4. Comparative Performance Metrics Across SIEM Platforms

Platform	Recall	(ARR)	F1	(FPR)	Accuracy	Avg Detection Time (s)
Wazuh	70%	30%	0.42	19.6%	79.3%	4.3 ± 1.2
QRadar	75%	50.6%	0.60	8.8%	89.5%	2.1 ± 0.5
Splunk	77.5%	58.1%	0.66	6.7%	91.6%	1.8 ± 0.4

Values represent the arithmetic mean across five attack repetitions. Standard deviations for detection time were as follows: Wazuh ±1.2 s, QRadar ±0.5 s, Splunk ±0.4 s, indicating consistent detection latency across attack repetitions.

The obtained metrics indicate that enterprise SIEM platforms (QRadar and Splunk) demonstrated significantly higher detection accuracy, substantially lower false positive rates, better alert relevance, and lower detection latency compared to the open-source platform Wazuh. However, Wazuh maintained acceptable detection performance with considerably reduced deployment costs, making it a viable option for organizations with limited resources.

High false positive rates were observed primarily during reconnaissance-related activities (T1046) due to the

similarity between legitimate administrative network scans and malicious scanning behavior. Such conditions may negatively affect SOC workflows by increasing alert fatigue and reducing analyst efficiency. The Alert Relevance Ratio (ARR) further highlights that in the case of Wazuh, only 30% of generated alerts were truly malicious, whereas Splunk achieved nearly 60% relevance.

4. RESULTS AND ANALYSIS

4.1 MITRE ATT&CK Detection Results

Detection performance is reported primarily using recall, precision, and their harmonic mean, since these metrics more faithfully reflect the operational reality of a SOC than accuracy under the present class distribution. The evaluation set contains 120 attack events against approximately 1000 benign events, so accuracy is dominated by the correct classification of benign traffic and overstates platform effectiveness. Splunk Enterprise Security achieves 91.6% accuracy, yet its recall is 77.5%, meaning roughly one in five attack events is missed. Recall follows the same ordering across platforms, at 70.0% for Wazuh, 75.0% for QRadar, and 77.5% for Splunk, indicating that detection coverage is broadly comparable and that the platforms separate far more sharply on alert quality than on raw coverage. Precision, reported here as the Alert Relevance Ratio, exposes that separation directly. Only 30.0% of Wazuh alerts correspond to genuine attacks, against 50.6% for QRadar and 58.1% for Splunk, so the open-source configuration imposes a substantially heavier triage burden for a similar level of coverage. The F1 score summarises both axes as 0.42, 0.60, and 0.66, respectively, confirming that Splunk dominates QRadar, which in turn dominates Wazuh, since each platform achieves both higher recall and higher precision than the platform below it. This ordering reinforces the central observation of this study, that alert relevance rather than detection coverage is the dimension on which these platforms most clearly diverge.

This finding is consistent with the base-rate fallacy problem in intrusion detection, which Axelsson [10] demonstrated nearly two decades ago, yet it remains a persistent challenge in SOC operations.

The performed experiments demonstrated that all analyzed SIEM platforms were capable of detecting the majority of executed ATT&CK techniques. However, differences were observed regarding correlation quality, alert precision, and detection latency.

Similar ATT&CK-based SIEM evaluation approaches have recently been adopted in enterprise threat detection studies [9].

In Table 5, "Partial" detection for Wazuh against T1046 (Network Service Scanning) indicates that while the platform successfully detected certain Nmap scan types (e.g., TCP SYN scan), other scan variants (e.g., UDP scan) remained undetected due to the absence of specific correlation rules in the default Wazuh configuration. In contrast, QRadar and Splunk demonstrated comprehensive detection across all scan types.

Table 5. Detection Results of MITRE ATT&CK Techniques Across Analyzed SIEM Platforms

Technique	Wazuh 4.8	QRadar 7.5	Splunk Enterprise Security 7.3.2
T1110	Detected	Detected	Detected
T1046	Partial	Detected	Detected
T1059	Detected	Detected	Detected

The obtained results indicate that enterprise platforms demonstrated improved event correlation and lower alert redundancy compared to the open-source solution [7].

4.2 False Positive Analysis

False positive analysis showed notable differences between the analyzed SIEM platforms. During network scanning scenarios, the open-source platform generated a larger number of low-priority alerts, while enterprise platforms applied more precise correlation mechanisms that reduced unnecessary event generation.

The Precision-Recall curves in Figure 1 illustrate the trade-off between detection precision and recall across different classification thresholds. Splunk Enterprise Security consistently achieves higher precision than QRadar for the same recall level, while Wazuh exhibits the lowest precision across the entire recall range. This confirms that commercial platforms provide better alert quality, which directly reduces the number of false positives requiring analyst review.

High false positive rates were observed primarily during reconnaissance-related activities due to the similarity between legitimate administrative operations and suspicious scanning behavior. Such conditions may negatively affect SOC workflows by increasing alert fatigue and reducing analyst efficiency.

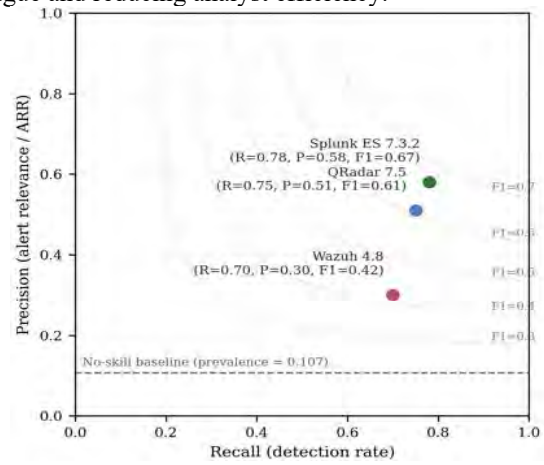

Figure 1. Precision-Recall Curves for the Evaluated SIEM Platforms

The operational impact of false positive rates can be illustrated through a typical SOC scenario. Assuming a daily volume of 1,000 benign events requiring analysis, Wazuh's FPR of 19.6% would generate approximately

196 false positive alerts per day, whereas Splunk's FPR of 6.7% would generate only 67 false positives. This difference of 129 additional alerts per day contributes directly to analyst fatigue and may delay the investigation of true positive incidents. Consequently, the choice of SIEM platform has measurable implications for SOC staffing requirements and mean time to respond (MTTR). The operational impact of false positive alerts on SOC workflows has been extensively documented in recent studies [11].

Beyond the numerical false positive rate, an important observation was the operational impact of alert clustering. Some reconnaissance-related false positives appeared as isolated events, while others triggered multiple correlated alerts for the same activity. Although this did not directly affect detection accuracy, it increased the number of events requiring analyst review. This observation aligns with recent qualitative research by Alahmadi et al. [12], who found that SOC analysts perceive the majority of security alerts as non-actionable, contributing to alert fatigue and operational inefficiency.

4.3 Performance Evaluation

Performance analysis included resource utilization and average detection latency during attack execution. The enterprise platforms demonstrated improved scalability and faster event correlation under higher event volumes, while the open-source platform required lower deployment costs and hardware resources.

The comparative analysis indicates that the selection of a SIEM platform strongly depends on organizational requirements, available infrastructure, and operational priorities.

It should be noted that the presented results were obtained within a controlled laboratory environment with a limited number of attack scenarios and endpoints. Real-world enterprise infrastructures may introduce additional variables, including encrypted traffic, heterogeneous logging formats, and significantly larger event volumes.

Another limitation of the presented evaluation is the relatively small number of ATT&CK techniques included in the testing process. While the selected techniques represent commonly observed adversarial behaviors, modern attack campaigns often combine multiple tactics across different stages of the intrusion lifecycle. Consequently, the obtained results primarily reflect platform performance under focused attack scenarios rather than full attack-chain simulations. Future evaluations may benefit from incorporating multi-stage attack emulation in order to assess SIEM correlation capabilities under more complex operational conditions.

5. CONCLUSION

This paper presents a comparative evaluation of the Wazuh, IBM QRadar, and Splunk Enterprise Security SIEM platforms through the analysis of selected MITRE ATT&CK techniques and false positive events. The conducted experiments demonstrated that all analyzed platforms were capable of detecting common adversarial activities, including brute force attacks, network reconnaissance, and suspicious command execution.

The obtained results showed that enterprise SIEM solutions provided improved event correlation and reduced false positive rates, while the open-source platform offered competitive detection capabilities with significantly lower deployment costs. Furthermore, the research highlighted the operational impact of false positive alerts on SOC workflows [9] and emphasized the importance of correlation rule optimization in modern security monitoring environments [3][6].

ARR is proposed as a complementary indicator for future SIEM benchmarking studies.

The study also indicates that alert relevance and correlation quality may represent equally important evaluation criteria as traditional detection metrics when assessing SIEM effectiveness in operational SOC environments.

Based on the obtained results, organizations with limited budgets and smaller infrastructures may benefit from Wazuh's competitive detection performance at reduced costs, while large enterprises requiring high precision and low latency should consider commercial solutions such as Splunk Enterprise Security or IBM QRadar.

Future research may include larger-scale infrastructures, additional ATT&CK techniques, and integration of machine learning approaches for adaptive SIEM correlation and false positive reduction.

The findings suggest that alert quality metrics may provide greater operational insight than detection accuracy alone. This is consistent with the base-rate fallacy problem identified by Axelsson [10], who demonstrated that accuracy becomes misleading when attacks constitute a small fraction of total events, as is typical in enterprise environments.

Abstract: *Hierarchical agents that delegate long-horizon planning to a large language model (LLM) and low-level control to a learned execution module have recently been shown to solve sparse-reward tasks that defeat monolithic reinforcement learning (RL) agents. Two distinct designs of the execution module have been proposed independently for the same environment: a mixture-of-experts (MoE) architecture that retains one specialized policy per sub-task and routes between them, and a single network obtained by distilling several expert policies into one. Both were reported to outperform an end-to-end baseline, but they have never been compared to each other, and the published numbers were obtained under different expert-training procedures, which makes a direct reading of them unsafe. This paper places both designs in a single architectural framework, re-analyses the published results under a common notation, and identifies precisely which comparisons the existing evidence does and does not support. We find that the two execution modules are separated by 0.02 average reward, far below the resolution of single-seed experiments, while the expert policies they were built from differ by up to 18 percentage points on identical sub-tasks purely because of how they were initialized. We further show that under both designs the planner contributes essentially no errors, so the execution module is the binding constraint in both systems.*

Keywords: *reinforcement learning, hierarchical agents, mixture of experts, policy distillation, large language models, MiniGrid, sparse reward*

1. INTRODUCTION

Reward sparsity remains one of the practical limits on applying reinforcement learning (RL) to tasks of realistic length [1], [2]. When the environment returns a scalar reward only after a long sequence of interdependent actions has been executed correctly, the credit-assignment problem becomes intractable for a single monolithic policy, and training either stagnates or converges to a policy that solves only the shortest missions. The difficulty compounds with horizon: the probability of a randomly explored trajectory completing every required sub-task falls off geometrically with the number of sub-tasks.

A family of recent architectures attacks this problem by refusing to learn planning and control in the same network. Planning, which requires abstract reasoning over a long horizon, is delegated to a large language model (LLM) that is queried once per episode and returns an ordered list of sub-goals. Control, which requires short-horizon navigation and manipulation, is left to an execution module trained by standard RL on individual sub-tasks, each of which carries a sufficiently dense reward to be learnable. Because the LLM never participates in training and is not queried at every step, the training pipeline remains a conventional RL procedure, and the inference cost of the language model is amortized over an entire episode.

Within this shared skeleton, two different designs of the execution module have been proposed independently and evaluated in the same extended MiniGrid environment. The first keeps the specialists separate: one PPO policy is trained per sub-task, and a gating network performs hard routing, selecting exactly one expert whose output is forwarded as the system action [3]. The second compresses the specialists: the trained experts act as teachers, generate a dataset of state-policy pairs, and a single student network is trained by supervised policy distillation to reproduce their behaviour across all sub-tasks [4]. One design proposes that capacity should stay partitioned, and the other that it can be shared without loss.

Both were reported to outperform an end-to-end PPO agent on multi-step missions, and both used the same planner, the same environment generator, the same reward

Corresponding author: I. Ciganović;
E-mail: iciganovic217d@raf.rs
DOI: 10.5937/OTEH26101C

function, and the same PPO implementation. Neither study set out to compare the two against each other, and neither had reason to: each was answering whether its own design beat a flat baseline. Having built both, we are now in a position to ask the question that neither could. The two designs imply opposite engineering decisions about memory footprint, inference cost, and the effort required to extend the agent with a new skill, and a practitioner choosing between them currently has no evidence to consult.

This paper does not report new training runs. Its contribution is to make the existing evidence legible and to establish what it can and cannot support. Concretely, we (i) express both architectures in one notation and identify the exact point at which they diverge, (ii) re-tabulate all published results under a common metric and flag the confounds that prevent a direct reading, (iii) show that the two execution modules are separated by an effect far smaller than the experimental resolution that produced them, (iv) demonstrate that in both systems the planner is not the limiting component.

2. RELATED WORK

2.1. Sparse reward and hierarchical control

Deep reinforcement learning handles dense-reward control well [5]; the difficulty here is specific to sparse reward. Classical remedies for reward sparsity include curriculum learning, which orders sub-tasks from easy to hard while retaining a single policy [6], and temporal abstraction, which introduces explicitly represented sub-policies. The options framework [7] and its differentiable successor, the option-critic architecture [8], learn both the sub-policies and the termination conditions end to end. FeUdal Networks [9] and h-DQN [10] instead separate a manager that emits goals from a worker that reaches them. These methods share the ambition of the present work, but they learn the decomposition jointly with the policy, which reintroduces a difficult optimization problem precisely where the reward is sparsest.

2.2. Mixture of experts

The mixture-of-experts formulation dates to Jacobs et al. [11], where a gating network combines the outputs of specialized sub-networks. Modern large-scale variants use sparse gating to activate a small subset of experts per input, yielding conditional computation at constant cost [12], [13]. The architecture considered here occupies the extreme of that spectrum: gating is hard, exactly one expert is active, and the experts are complete policies trained in isolation rather than sub-networks of a jointly optimized model.

2.3. Knowledge and policy distillation

Distillation transfers the behaviour of one or more teachers into a student by supervised regression on the teachers' outputs [14]. In the RL setting, policy distillation [15] and actor-mimic [16] showed that several task-specific agents can be compressed into a single network, often with improved stability, because the student learns from a fixed target distribution rather than from non-stationary environment interaction. The variant used in the system studied here is multi-teacher distillation with an important additional degree of freedom: the student may be initialized either randomly or from a policy already trained by RL on all sub-tasks simultaneously.

2.4. Comparing modular and monolithic policies

Direct comparisons between modular and compressed policies are rare, partly because the two are usually proposed as answers to different questions: mixtures of experts for capacity scaling, distillation for deployment efficiency. Where both appear in one study, the comparison is typically incidental. The RL literature also lacks agreed conventions for equalizing the training budget of a modular system against a monolithic one, since the natural unit of accounting, environment steps, is consumed per policy rather than per system. This paper treats that accounting question as a first-class obstacle rather than a detail.

2.5. Language models as planners

Following the emergence of instruction-following language models [17], [18], several systems have used them to decompose tasks for embodied agents. Zero-shot planners extract action sequences directly from an LLM [19]; SayCan grounds the language output in learned affordances [20]; ReAct interleaves reasoning and acting [21]; Voyager maintains a growing skill library in an open-ended environment [22]. Systems that query the model at every step incur an inference cost proportional to episode length, and systems that place the model inside the training loop inherit that cost multiplied by the number of training episodes. The architecture examined here queries the model exactly once per episode, before the first action.

3. UNIFIED ARCHITECTURE

We describe both systems as instances of a single three-stage architecture, which allows the point of divergence to be stated precisely. Figure 1 shows the shared pipeline and the two execution variants.

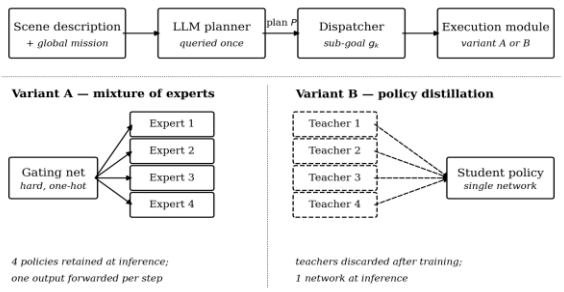

Figure 1. The unified three-stage architecture. Planner and dispatcher are shared; the two systems differ only in the execution module, which either routes between retained specialists (variant A) or replaces them with a single distilled student (variant B).

3.1. Formal setting

The environment is a partially observable Markov decision process. At step t, the agent receives an observation consisting of a 7x7x3 egocentric view, a scalar direction, and a tokenized mission string, and emits an action a_t from the discrete MiniGrid action set. A mission M is solvable by an ordered plan P = (g_1, ..., g_K) of sub-goals drawn from a fixed vocabulary G = {go to goal, go to <object>, toggle <object>, pick up <object>}. The reward is granted only on completion of the global mission and is discounted by the number of steps taken,

$$R = 1 - 0.9\frac{num_steps}{max_steps} \quad (1)$$

so that a perfect score of 1.0 is unattainable and all reported values are bounded well below it.

3.2. Stage 1: planner

A structured textual description of the scene, generated by the environment during scene construction, is combined with the global mission and submitted once to a locally hosted LLM. The model returns an ordered list of sub-goals from G. The planner is not queried again for the remainder of the episode. It takes no part in training, and its parameters are frozen.

3.3. Stage 2: dispatch

Sub-goals are issued to the execution module one at a time as the current mission string. Control returns to the dispatcher when the execution module emits the done action, at which point the next sub-goal in P becomes active. No external oracle verifies that the sub-goal was in fact achieved; the module's own done signal is the only completion event. If the plan is exhausted or the step budget expires, the episode terminates.

3.4. Stage 3: execution, variant A (mixture of experts)

Variant A maintains four independent policies, one per sub-goal type in G, each trained by PPO in isolation on episodes whose entire mission is that sub-goal. A gating network, consisting of an embedding layer, a GRU, and a linear layer, consumes the current mission string and emits a one-hot vector selecting the active expert. Formally, the module computes

$$f(x) = sum_i(w_i(x)f_i(x)) \quad (2)$$

With w_i representing the weight corresponding to the i-th expert, and f_i the output of the said expert. w(x) is constrained to the vertices of the simplex, so exactly one expert's output survives. The gating network is trained by supervised learning on the fixed vocabulary.

3.5. Stage 3: execution, variant B (policy distillation)

Variant B trains the same four experts, then discards them at inference time. Each expert is rolled out in the environment to produce a dataset of pairs (o, p_i_expert(o)), the datasets are pooled, and a single student network with the architecture of one expert is trained by supervised learning to reproduce the pooled action distributions. Two initializations are considered: a randomly initialized student, and a student initialized from a PPO policy previously trained on all sub-tasks simultaneously, referred to below as the all model. Parameter count is constant in the number of skills, and no routing decision is made at inference time.

3.6. Cost model

The two variants differ in a way that is visible before any experiment is run. Let θ denote the parameter count of one expert policy, γ that of the gating network, and N the number of skills. Variant A stores N*θ + γ parameters and must keep all N policies resident, since the identity of the next sub-goal is not known until the dispatcher issues it. Variant B stores θ regardless of N. With the network described in Section 4.2 and N = 4, variant A therefore carries roughly four times the execution-time footprint of variant B, plus a small gating network dominated by its 32 x 1024 embedding layer.

The per-step compute tells a different story. Because gating is hard, exactly one expert is evaluated per step, so the forward-pass cost of variant A equals that of variant B plus one gating evaluation, which is amortized because the gate need only be recomputed when the sub-goal changes. The asymmetry is therefore in memory, not in arithmetic. Extending the agent with a new skill costs one additional PPO training run and one additional resident policy under variant A, against one additional teacher plus a full re-distillation of the student under variant B. Neither published study measured any of these quantities, and Section 5.5 records them as open.

3.7. Baselines

The end-to-end model, denoted no LLM, is a single PPO policy trained directly on complete multi-step missions with no planner at all; it isolates the benefit of the hierarchy itself.

4. EXPERIMENTAL SETUP

Because this paper re-analyses previously published experiments, the setup below is the one common to both source studies [3], [4]. Where the two studies diverge, the divergence is stated explicitly, since it is the substance of Section 5.4.

4.1. Environment

MiniGrid v3.0.0 [23] was extended to allow control over mission complexity. The grid is fixed at 11x11, giving at most four rooms. Object placement is constrained so that generated scenes are always solvable and never obstruct the agent, the goal tile, or a doorway. Doors carry colors and may be locked, in which case a key of the same color is required; keys may be placed inside boxes, adding a level of nesting. The environment additionally emits a

structured textual description of the scene for the planner. Training and evaluation scenes were sampled from the same generator but drawn as disjoint sets.

4.2. Policy and training

All policies use the same feature extractor: a three-branch network processing the image, direction, and mission inputs, whose latent vectors are concatenated and fed to actor and critic heads. Training uses PPO [2] as implemented in Stable-Baselines3 [24], with hyperparameters obtained by population-based bandit search [25]. Each run consists of 20 million steps with 16 parallel environments, and training proceeds in consecutive runs with decreasing learning rate and epoch count until improvement stops. The number of runs was chosen per policy by that stopping rule, not fixed in advance.

4.3. Planner configuration

The planner is qwen3:30b served locally through Ollama at temperature 0.0 with a fixed system prompt describing the available instructions, objects, colors, and the key-door rule. We benchmarked alternative open models on a fixed set of scenes; the selected model matched all reference solutions, while gemma2:27b, deepseek-r1:32b, and llama3:8b matched 13, 11, and 9, respectively [4].

4.4. Metrics

Two quantities are reported. Average reward is the mean of R over an evaluation set of 1000 freshly sampled episodes. Success rate is the fraction of episodes in which the global mission was completed, computed on a manually verified subset of 100 episodes and disaggregated by the number of sub-tasks in the plan. Sub-task-level results are reported as the average reward obtained by a policy when the sub-task is the entire mission.

5. RESULTS

This section re-tabulates the published results of both systems under the common notation of Section 3.

5.1. Sub-task level

Table 1 reports the performance of individual policies on each sub-task. Two facts stand out. First, specialization is clearly beneficial: every specialist outperforms the shared all model on its own sub-task, and every specialist scores exactly zero on sub-tasks it was not trained for, confirming that the experts carry no incidental cross-task competence. Second, and more consequentially, the pick-up and toggle experts differ substantially between the two studies. In [3] they reach 0.57 and 0.47; in [4], where they were fine-tuned from the all model rather than trained from scratch, they reach 0.68 and 0.65.

Table 1. Sub-Task Performance Of Individual Policies (Average Reward)

Policy	Goal	Object	Pick	Togg
Go to goal	0.86	0.00	0.00	0.00
Go to object	0.00	0.72	0.00	0.00
Pick up [3]	0.00	0.00	0.57	0.00
Toggle [3]	0.00	0.00	0.00	0.47
Pick up [4]*	0.00	0.00	0.68	0.00
Toggle [4]*	0.00	0.00	0.00	0.65
All (shared)	0.75	0.65	0.59	0.58

* fine-tuned from the all model rather than trained from scratch.

The gap matters. On two of four sub-tasks, the distillation system started from teachers 11 to 18 points stronger than the experts the MoE system routes between. Neither paper had cause to flag this, since neither was comparing across the two, but any end-to-end comparison that ignores it inherits it as a confound.

5.2. Multi-task execution

Table 2 reports execution modules evaluated across all sub-tasks simultaneously, without a planner. The ordering is informative. Distillation from a randomly initialized student reaches 0.56, which is worse than the all model it was meant to improve upon; distillation from the all model reaches 0.67, which is better. The identity of the initialization, rather than the distillation procedure itself, accounts for a swing of 0.11.

The MoE module has no directly comparable entry in this table, because hard routing makes its aggregate multi-task performance a weighted average of the per-expert values of Table 1 rather than a separately measured quantity. Computing that average over the four sub-task types gives an implied value of approximately 0.66, but this is an arithmetic construction and not a measurement, and it is reported here only to indicate the order of magnitude.

Table 2. Execution Modules Evaluated Across All Sub-Tasks, No Planner

Execution module	Reward	Seeds
All (PPO, shared policy)	0.65	1
Distilled, random init	0.56	1
Distilled, from all model	0.67	1
MoE, hard routing	~0.66*	1

* implied weighted average of Table 1, not an independent measurement.

5.3. End-to-end performance

Table 3 reports complete systems on multi-step missions.

Both hierarchical systems improve substantially on both baselines: against the end-to-end no-LLM agent the margin is 0.12 to 0.14 average reward, and against a non-hierarchical PPO agent it is 0.22 to 0.24. The benefit of delegating planning is therefore not in question.

The comparison between the two execution modules, however, is. The MoE system reports 0.57 and the distilled system 0.55, a difference of 0.02. All figures come from single runs at a fixed seed, which was a reasonable choice when the comparison of interest was against a flat baseline separated by 0.12 or more. It is not enough resolution for a 0.02 gap. RL training at fixed hyperparameters varies across seeds, and [3] reports exactly such a spread in final expert performance over four seeds. We read Table 3 as saying the two execution modules are indistinguishable on the evidence available, rather than as a narrow win for MoE.

Table 3. End-To-End Performance On Multi-Step Missions (1000 Episodes)

System	Reward	Seeds
PPO	0.33	1
End-to-end, no LLM	0.43	1
LLM + distilled [4]	0.55	1
LLM + MoE [3]	0.57	1

5.4. Complexity and the location of failure

Table 4 disaggregates success rate by plan length for the MoE system and its baselines. Performance degrades sharply with horizon: from 98.44 percent on single-sub-task missions to 28.57 percent at three sub-tasks and 14.29 percent at four. The end-to-end agent, by contrast, collapses to near zero as soon as more than one sub-task is required, solving one three-sub-task episode only through an incidental behaviour in which an object lying on the path happened to be the required key.

Crucially, manual verification of 100 planner outputs found no invalid plans in either study; every plan was a correct, if not always optimal, solution to the global mission. Since the planner introduced no failures, all observed degradation is attributable to the execution module. This holds for both variants and is the single most important shared finding: the two systems differ in how they organize execution, and execution is exactly what limits them.

A rough consistency check supports this. Treating sub-task failures as independent, the expected success rate of a three-step pick up, toggle, go-to-goal sequence under the MoE expert rates of Table 1 is 0.57 x 0.47 x 0.86, or about 0.23, against 0.2857 observed. The estimate is close enough to make execution failure the plausible dominant mechanism, though the independence assumption is untested and the observed value exceeds the prediction, which suggests failures are in fact mildly correlated with scene difficulty rather than independent.

Table 4. Success Rate By Plan Length (Percent) calculated on the first 100 episodes

System	1 sub	3 sub	4 sub
PPO	68.75%	0.00%	0.00%
End-to-end, no LLM	68.75%	4.76%	7.14%
LLM + distilled [4]	89.06%	23.81%	14.29%
LLM + MoE [3]	98.44%	28.57%	14.29%
sample size	64	21	14

5.5. Planner accuracy and cost

Because the planner is shared, its properties bound both systems equally. Table 5 reports the model-selection benchmark from [4]. The selected model matched every reference solution on the benchmark set, and two of the three alternatives were close behind, which indicates that on 11x11 scenes the planning task is near saturation for models of this size. That is convenient for the present comparison, since it holds the planner constant, but it also means the benchmark cannot discriminate between planners and gives no evidence about behaviour on larger scenes.

Planning cost, by contrast, is substantial. Reported inference time is 3 to 15 minutes per episode on a single consumer GPU, dominated by the thinking phase of the model, against a per-step execution cost measured in milliseconds. The hierarchy therefore trades a large fixed cost at the start of each episode for a much cheaper trajectory, and any deployment argument that turns on latency must account for this term, which is identical for both execution modules and larger than either.

Table 5. Planner Model Selection Benchmark [4]

Model	Matched	Params
qwen3:30b (selected)	14 / 14	30B
gemma2:27b	13 / 14	27B
deepseek-r1:32b	11 / 14	32B
llama3:8b	9 / 14	8B

Benchmark set of 14 reference scenes. Near-saturation at this scene complexity limits the discriminative power of the benchmark.

5.6. What the evidence does not support

Table 6 summarizes the comparisons required to choose between the two execution modules, together with their current status. Of seven, three are settled by published data, and four are open. None of the published runs report either module at a matched step budget, at matched parameter count, over multiple seeds, or with latency and memory figures. That is not an oversight so much as a consequence of scope: those quantities only become interesting once the two designs are placed side by side, which is what we are

doing here for the first time.

Table 6. Status Of The Comparisons Required To Choose A Module

Comparison	Status
Beats end-to-end baseline	Settled, both
Planner error contribution	Settled, both
Success by plan length	Settled, both
Matched step budget	Open
Matched parameter count	Open
Multi-seed with CIs	Open
Inference latency, memory	Open

6. DISCUSSION

Three things come out of this.

The hierarchy is settled. The execution module is not. Delegating planning to a language model queried once per episode produces a large and consistent improvement over end-to-end RL on multi-step missions, reproduced independently in both studies with different execution modules. We take that as settled. The choice between routing specialists and compressing them rests on a single 0.02 difference measured once, and we would treat it as open.

Initialization matters more than the distillation procedure does. The gap between distilling from random weights and distilling from a trained policy is 0.11, five times the gap between the two architectures. A randomly initialized student ends up worse than the model that would have supplied its initialization. That points to imitation of expert action distributions not being enough on its own to build the representation, and suggests distillation works here as a consolidation step on an already competent policy rather than as a way of training one from nothing.

Execution is what binds in both designs. Across the two studies, the planner produced no errors in 100 manually verified episodes, so every route to a better system runs through the execution module. That changes the question worth asking. Not which module scores higher today, but which improves faster per unit of extra training, and which degrades more gracefully once the planner starts making mistakes. A planner with no observed errors on 11x11 grids will not stay error-free on larger scenes.

The two designs are not just different implementations of the same capability. They fail differently, and that is testable. A routed mixture degrades sub-task by sub-task, since a weak expert damages only the plans that invoke it, and the remaining experts are untouched. A distilled student shares parameters across all skills, so degradation is expected to be diffuse, and a poorly represented sub-task may be compensated or overwritten by the others. The published data are consistent with this reading.

The published evidence supports a weak recommendation, and it follows from the architecture rather than from the reward numbers. Where the skill set is fixed and small, memory is not constrained, and skills are added rarely, MoE architecture is preferable because a new skill costs one training run and cannot disturb existing ones. Where the agent must run on constrained hardware, or where the skill set is large enough, a distilled network is preferable, provided the student is initialized from a multi-task policy rather than randomly. The 0.11 penalty for random initialization is the one effect in this analysis large enough to act on with confidence.

Resolving the comparison needs nothing conceptually new. Both modules should be trained under a declared step-accounting rule, reported under both conventions, since a four-expert MoE granted the same per-expert budget as a single student consumes four times the total experience. Both should be evaluated over at least five seeds with confidence intervals, on at least 200 episodes per complexity bracket, and reported alongside parameter count, memory footprint, and per-step inference latency.

7. REPRODUCIBILITY

All numbers re-analysed in this paper originate from the two source studies [3], [4], both of which published their source code and a video demonstration of the resulting agents. The environment is a modified MiniGrid v3.0.0, the RL implementation is Stable-Baselines3 v2.7.0, and the planner is served through Ollama v0.30.0 with the configuration reproduced in Section 4.3. Training was performed on a single consumer GPU, with each 20-million-step run requiring between four and seven hours of wall-clock time.

We note one obstacle to exact reproduction that affects both studies equally. The number of consecutive training runs per policy was determined by an improvement-based stopping rule applied during training rather than fixed in advance, so the total number of environment steps consumed by each published policy is a function of the observed learning curve. Reproducing the published numbers therefore requires reproducing that decision process, not merely the hyperparameters.

8. CONCLUSION

We have placed two independently proposed execution modules for LLM-planned hierarchical agents, a hard-routed mixture of experts and a multi-teacher distilled policy, into a single architectural framework and re-analysed their published results under common notation. The hierarchical design itself is well supported: both variants improve on an end-to-end PPO agent by 0.12 to 0.14 average reward on multi-step missions, and in both the planner was found to contribute no failures, making the execution module the binding constraint.

The comparison between the modules, however, is not supported. They are separated by 0.02 average reward from single-seed runs, while the experts underlying them differ by up to 18 percentage points on identical sub-tasks

solely because of initialization, and the effect of initialization on the distilled student is itself five times larger than the architectural difference. We conclude that the choice between modularity and compression remains open.

AI-ASSISTED DECISION SUPPORT IN COMMAND-AND-CONTROL SYSTEMS: APPLYING THE SENSE–UNDERSTAND–DECIDE–ACT (SUDA) CYCLE

Vlatacom Institute of High Technologies, Milutina Milankovića 5, Belgrade, Serbia

Abstract: *Modern command-and-control (C2) systems face a paradox: the volume of sensor data grows exponentially while the time available for decision-making shrinks. This paper presents an architectural framework for AI-assisted decision support in C2 systems based on the Sense–Understand–Decide–Act (SUDA) cycle and demonstrates it on a deployed system: the Vlatacom C7ISTAR solution, in which the ORAO command platform carries the ARES (Algorithmic Reconnaissance and Execution System) three-tier AI core, in operational service protecting national critical infrastructure since 2024. Each phase is mapped to a technology layer and characterized by measured quantities: a panoramic thermal sensor covering the full circle in 2.3 s; an edge-AI stage above 100 TOPS with sub-100 ms inference latency, reducing about fifty raw detections per second to approximately one plausible target; and an agile electro-optical turret classifying a cued object in under two seconds. We argue that decision advantage arises not from replacing the human decision-maker but from restructuring the C2 information flow around the SUDA cycle, so that the path from sensor to decision-maker, and from decision to effect, becomes short, traceable and measurable.*

Keywords: *command and control, decision support, artificial intelligence, SUDA cycle, counter-UAS.*

1. INTRODUCTION

Sensors have proliferated across every domain of the modern battlefield—radar, electro-optical and infrared imaging, radio-frequency and acoustic sensing, unmanned platforms, and networked reporting—so a contemporary command post receives orders of magnitude more data than any human staff can assimilate in the time available. At the same time the velocity of the threat has increased: unmanned systems in large numbers, loitering munitions, electronic attack and cyber effects compress the interval between first detection and required response from hours to minutes, and in terminal defense to seconds.

Hence the central paradox of this paper: commanders have never had more information, and never less time in which to use it. The side that resolves it obtains decision advantage — the ability to close its own decision cycle faster, and with better judgment, than the adversary. The classical articulation is Boyd's observe–orient–decide–act (OODA) loop [1], refined for C2 analysis by Brehmer [2]; Endsley's theory of situation awareness [3] captures the quality dimension. Command-support terminology has evolved in step: from C2 through C4ISR — within which geographic information systems first brought spatial decision support to the operational picture [4] — to the extended C5ISR, C6ISTAR and C7ISTAR designations that successively admit cyber defense, combat systems, and collaboration and interoperability [5]; C7ISTAR, the fullest of these, is adopted here as the designation of the unified sovereign command-and-mission portfolio that the described solution implements.

Artificial intelligence can now materially contribute to both the speed and the quality of the cycle, yet its integration into C2 raises questions as much doctrinal as technical — how much authority may be delegated to a machine, how a recommendation is explained to the operator who must act on it, how models operating on classified data are kept under sovereign control — and recent scholarship agrees that acceleration is valuable only while human judgment remains authoritative within the loop [6]. Beneath these lies the practical question this paper takes as its organizing principle: how long is the path from sensor to decision-maker, what happens to the information along the way, and how much of the journey can be entrusted to a machine.

The paper defines the SUDA cycle and positions it against the OODA loop, situation-awareness theory and the JDL data-fusion model (Section 2); maps each phase onto a technology layer (Section 3); instantiates the framework on the deployed Vlatacom C7ISTAR solution, with measured quantities per phase (Section 4); analyses human–machine teaming and the constraints of edge inference and sovereignty (Sections 5 and 6); and traces a complete engagement with its cycle-time budget (Section 7). Section 8 concludes.

2. THE SUDA CYCLE AS A C2 FRAMEWORK

The SUDA cycle structures a C2 system's information flow into four continuously repeating phases. In Sense, data are acquired from all available sources. In Understand, they are fused into a single coherent representation — the common operational picture (COP) — and enriched with machine-derived interpretation: classification, anomaly detection, and short-term prediction. In Decide, the system generates feasible courses of action (COA), evaluates them against constraints, and presents them to the human decision-

maker. In Act, the selected course is translated into tasking of effectors and sensors, execution is monitored, and observed effects feed the next iteration; Figure 1 summarises the cycle.

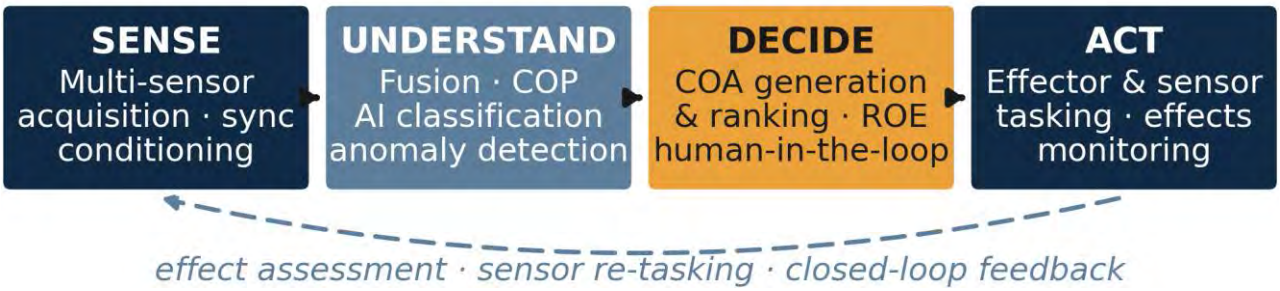

Figure 1. The SUDA decision cycle with the technology layer associated with each phase

SUDA deliberately restates Boyd's loop in system-engineering form: Observe maps to Sense; Orient — the phase Boyd considered decisive — to Understand, where fusion and machine learning are concentrated; Decide and Act retain their names. The gain is mapping discipline: each phase becomes an identifiable set of services with interfaces and latency budgets, and cycle time — from a change in the real world to a completed response — becomes a key performance indicator, decomposable into per-phase terms that Section 4 measures on a deployed system.

The framework aligns with established theory and doctrine. Endsley's three levels of situation awareness [3] span Sense and Understand; the JDL data-fusion model [7] structures the Understand phase—historically the bottleneck of the C2 cycle and therefore where AI offers the greatest compression —the central design thesis of this paper. The Joint All-Domain Command and Control (JADC2) concept likewise organizes capability around sense, make sense, and act — matching Sense, Understand, and the combined Decide–Act — and requires machine analysis to be explainable, confidence-tagged, and accessible only to authorized users [8], [5]. SUDA is thus not a competitor to these formulations but their engineering expression.

3. MAPPING SUDA PHASES TO TECHNOLOGY LAYERS

Figure 2 presents the functional architecture resulting from mapping the SUDA phases onto technology layers: read upwards from the base, it is the sensor-to-decision-maker path drawn as a stack, with the cryptographic rail protecting the observation at every station.

3.1. Sense — multi-sensor acquisition

The Sense layer comprises the heterogeneous sensor set — radar, electro-optical and infrared imaging, radio-frequency and acoustic sensors, unattended ground sensors — together with structured reporting from deployed units and, increasingly, open-source (OSINT) feeds. Three engineering requirements dominate. First, time synchronization and geo-registration: fusion is only as good as the spatial and temporal alignment of its inputs, so every observation must carry a trusted timestamp and position reference. Second, standardized metadata: sensor identity, mode, confidence, and provenance must accompany every detection so the evidence can be weighed correctly; that trust begins with authenticating the sensors themselves, for which the authors' earlier Internet-of-Battlefield-Things model provides a basis [9]. Third, data conditioning at the edge, so that constrained links carry information rather than raw redundancy. The layer must also degrade gracefully: losing individual sensors or links should reduce coverage, not collapse the picture.

3.2. Understand — fusion, the COP and AI services

The Understand layer transforms conditioned observations into shared meaning. Its foundation is multi-sensor fusion in the sense of the JDL model [7]: associating detections into tracks, correlating tracks across sensors, and maintaining a single consistent COP that all echelons consume. Fusion may occur at the detection level or the track level; practical systems combine both, trading communication load against fusion gain [10], and at the semantic end of this range the Institute has applied fuzzy-relational methods to fuse heterogeneous surveillance data [11]. The integrity of the COP's geospatial foundation must be protected in its own right [12].

On top of the fused picture, AI services operate: classification models assign object types; anomaly-detection models learn an area's pattern of life and flag deviations that escape threshold-based rules; predictive models project track behavior, supporting projection in Endsley's sense [3]. Two properties are essential: every machine-derived statement carries explicit uncertainty — confidence and provenance, surfaced to the user — and the services are modular and retrainable, components with a lifecycle.

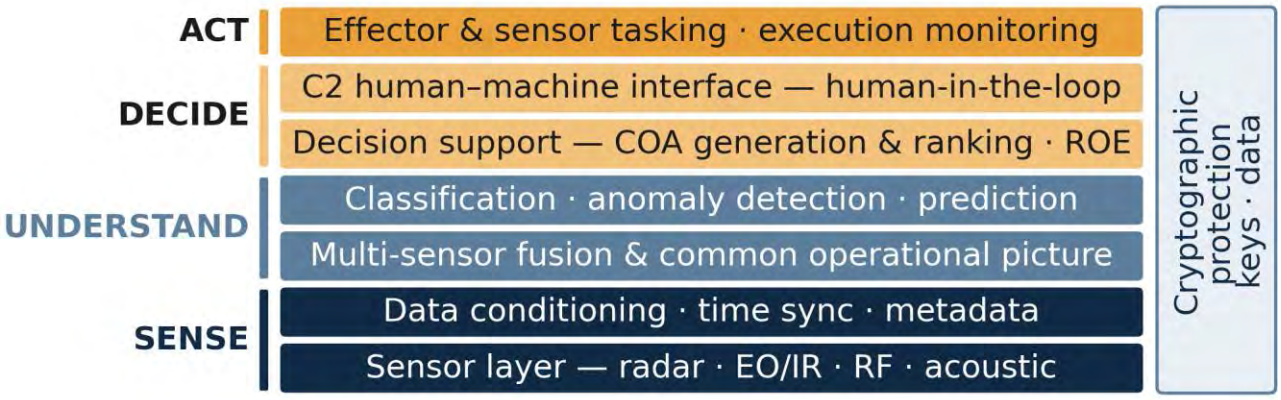

Figure 2. Functional architecture of AI-assisted C2, organized by SUDA phase, with cryptographic protection as a cross-cutting layer

3.3. Decide — decision support with the human in the loop

The Decide layer converts understanding into options: threat evaluation, COA generation, and ranking against explicit criteria — effectiveness, resource consumption, risk, deconfliction and, critically, compliance with the rules of engagement (ROE), encoded as machine-readable constraints so that no proposed option violates them by construction; what-if simulation lets the operator probe an option before committing. Large language models have recently been demonstrated as generators of candidate courses of action at machine speed [13]; the same literature documents their unreliability under adversarial and escalatory conditions [14] — which is precisely why this layer is designed so that the machine proposes and the human disposes. Ranked options are presented with their rationale — factors, contributing sensors, confidence — and every recommendation and human selection is logged, creating the audit trail on which accountability and institutional learning depend.

3.4. Act — tasking, monitoring and feedback

The Act layer translates the selected course of action into tasking of effectors and, equally, of sensors: closing the loop includes directing collection where confirmation of effect is needed. Execution is monitored against the plan, and effect assessment — whether the action achieved the intended result — is fed back into Sense and Understand, updating the picture and, over time, the models themselves. In a realistic system, many SUDA cycles run concurrently, from seconds in point defense to hours at the operational level.

4. REALISATION: THE ORAO C7ISTAR PLATFORM

The framework of Section 3 is realized in ORAO, the command-and-control platform of the Vlatacom Institute (the name is proper to this software platform, unrelated to the aircraft): a scalable micro-services system that integrates remote sensing equipment, maintains a common operational picture and lets the operator act in the field remotely. ORAO has been in operational service since 2024, protecting a national critical energy-infrastructure installation against small commercial and FPV drones — the class current counter-UAS surveys identify as hardest to counter at such sites [15], [16]. It rests on a decade of the Institute's research across the SUDA layers: electro-optical platforms and video processing [17], [18], object tracking and AI-based detection [19], [20], [21], fusion of heterogeneous sensor data [11], and cryptographic protection of operational data [22], [23].

ARES, the Algorithmic Reconnaissance and Execution System, supplies the platform's intelligence— a modular AI core conceived as a software brain over the existing sensor base, organized in three tiers that map almost one-to-one onto the SUDA phases. ARES Edge infers on a processing module at the sensor itself, classifying targets in under a second without transmitting a high-bandwidth video stream — the transition from Sense to early Understand, viable on constrained or intermittent networks. ARES Core is the operational tier: it fuses encrypted telemetry of the order of ten thousand events per second from several sites into a single COP and applies a unified ontology that recognizes behavioral patterns rather than isolated events, carrying Understand and preparing Decide. ARES Strategic is the command tier, coupling the picture to large-language-model agents through which a commander obtains reports and candidate courses of action by voice or text — the pattern demonstrated by [13], here on an operational picture rather than a simulation, under the human authority and audit trail of Section 3.3. Across all tiers, AI is combined with rule-based events and actions in a supervised autonomous mode — responses deployed automatically or manually per configuration and countermeasure type — and, being microservice-based, the platform adds sensors, effectors, and functions without altering the core, spanning fixed and vehicle-mounted configurations alike. Figure 3 shows the platform fusing radio-frequency detection with electro-optical tracking of the same target while displaying sensor and effector coverage on the map.

Each SUDA phase carries measured figures, summarised in Table 1 — engineering values read from the system's own instrumentation and logs during commissioning and routine operation, quoted to characterize the architecture, not as contractual guarantees. The Sense layer illustrates the data-volume problem concretely: a thermal panoramic sensor of 1280 × 1024 pixels, driven by a high-end video-

processing platform developed at the Institute [18], covers the full circle in 36 sectors every 2.3 s. The Understand layer illustrates the compression AI achieves: the raw flow of about fifty candidate detections per second, dominated by clouds and birds, is reduced to approximately one plausible target per second by tracking, cloud and bird filtering, and direct referral of close targets to AI classification — techniques building on the Institute's robust tracking and learned detection in thermal and short-wave-infrared imagery [19], [20], [21] — a fifty-to-one reduction before any human sees the picture: the difference between an operator who is overwhelmed and one who is informed.

Figure 3. The ORAO platform in operation at a demonstration site: the live optical stream with telemetry, the map with bearing lines from RF spectrum sensing, and the zone and sector overlay of sensors and effectors on a single console (identifying details redacted)

Table 1. SUDA phases instantiated on the ORAO platform, with characteristic measured quantities

SUDA phase	Function	Realisation	Characteristic figures
Sense	Multi-sensor acquisition, conditioning, time reference	Thermal panoramic head; RF spectrum sensing; vMSIS3 EO/IR turret with laser rangefinder; a dedicated passive acoustic sensor; X-band radar where permitted	Full circle in 2.3 s; RF spectrum 20 MHz–6 GHz
Understand	Track fusion, COP, AI classification	ARES Edge and ARES Core on current-generation GPU; classes: drone, bird, aircraft, helicopter; ontology layer; Kalman filtering with deep-learning re-identification	Above 100 TOPS; inference latency below 100 ms; four parallel video streams; 50 raw detections/s reduced to about 1/s
Decide	Threat evaluation, option preparation, ROE constraints	ORAO decision services with ARES Strategic: AI and rule-based events and actions; LLM-generated COA; supervised autonomous operation	Operator authority by default; automatic response only where explicitly configured
Act	Effector and sensor tasking, monitoring, feedback	Cueing of the vMSIS3 turret; RF jamming with selective radiation and coverage control; effect assessment returned to the COP	Turret classifies a cued object in under 2 s from any previous position

The Decide and Act layers are equally concrete. Rules of engagement appear as configuration: the protected installation applies selective control of jammer radiation power and coverage zones so that countermeasures do not reach the surrounding populated area — an ROE constraint compiled into system behavior exactly as Section 3.3 requires — and safeguards prevent countermeasures from triggering without authorization unless a fully automatic mode has been explicitly enabled. The Act layer closes the loop within the electro-optical turret's two-second verification window, automatically directed to coordinates supplied by another sensor and returning a classified, ranged, and geo-located object to the picture that cued it; the Institute has reported this turret's optical platform and pointing performance [17].

5. HUMAN–MACHINE TEAMING

Whether AI-assisted C2 delivers value depends less on model accuracy than on the quality of the human–machine team; three requirements structure the problem. The first is a deliberate allocation of function. The taxonomy of Parasuraman, Sheridan and Wickens [24] distinguishes automation of information acquisition, analysis, decision selection and action implementation, each at graded levels. In the SUDA framing, high automation is appropriate in Sense and much of Understand, where machines outperform humans in throughput and vigilance — the fifty-to-one reduction of Section 4 is no human task at all. In Decide, automation prepares and ranks options, but authority over the use of force remains with the human commander; delegation beyond that point must be explicit, bounded, and reversible—the standard allied policy now codifies autonomy in weapon systems [25]. Autonomy is not fixed: control tightens when time permits, and narrowly defined responses are pre-authorized where reaction times make deliberation impossible — supervised autonomous operation in ORAO is precisely a graduated setting of this parameter.

The second is explainability. A recommendation that cannot be explained will in practice be either ignored or blindly followed — both failure modes. The field systematized in the DARPA XAI program [26] offers

many techniques, but the operational requirement is specific: explanations in the operator's terms — which evidence, from which sensors, drove this ranking; what the confidence is; what would change the conclusion — delivered at the moment of decision and honest about uncertainty, the transparency recent work identifies as the foundation of operator situation awareness in human-AI teams [27]. A classification shown on the console with its confidence value alongside the imagery behind it is a modest but real instance of the principle.

The third is trust calibration: over-trust produces automation bias — operators accepting machine output uncritically, a failure mode documented across military decision-support deployments [28] — while under-trust wastes the machine's contribution. Calibration is built through transparency of confidence, training in the system's characteristic strengths and failure modes, and consistent logging. Responsibility is not transferred to software: the commander remains accountable, and the system must be designed so that this accountability is real, traceable, and fair.

6. IMPLEMENTATION CONSIDERATIONS

6.1. Edge and central inference

A practical architecture distributes intelligence between the sensor edge and the center: latency-critical inference (detection, first-line classification, data conditioning) at the edge, where it also relieves communication links; resource-intensive functions (model training, large-scale fusion, long-horizon analytics) centrally. In the deployed system, all AI processing occurs locally, in the field or vehicle, so the system remains operational without a network connection, and the edge platform is retrained locally on newly collected data. The edge–center connection assumes contested communications: edge nodes continue autonomously on locally cached models when links fail, the COP degrades gracefully, and synchronization resumes when connectivity returns. Adoption in an existing C2 system is likewise incremental: the layer first enters as an advisory overlay through standardized interfaces — including NATO STANAG and legacy national formats — and services migrate to integrated status as confidence and accreditation mature, building the doctrinal and trust foundations of Section 5.

6.2. Security and sovereignty

AI-assisted C2 operates on data whose confidentiality, integrity and availability are matters of national security. Data in transit and at rest are therefore protected by cryptographic means under national control — centralized key management, an interoperable public-key infrastructure and secure key distribution [29]; the chain's trustworthiness rests on key generation, hence hardware true-random generation as the foundation — the Institute's research on autonomous symmetric ciphering and key distillation [22], [23] addresses exactly this chain. The C2 network also defends itself with the same family of methods it offers the commander: machine-learning detection of anomalies in the network's own behavior [30]. Models are assets: provenance known, training data controlled, updating performed within the national security perimeter — models trained on classified operational data cannot depend on external infrastructure — the deeper reason why local retraining at the edge is an architectural requirement, not merely a latency optimization. Emission security is addressed through hardware design and accreditation. Sovereign control over data, models and cryptography is thus a precondition of operational trust.

7. CYCLE-TIME ANALYSIS OF AN ENGAGEMENT

Consider a protected critical-infrastructure site of the kind described in Section 4 — roughly one square kilometer, observed by a thermal panoramic head, RF spectrum sensing and an agile electro-optical turret, with a countermeasure tower under selective radiation control, integrated through ORAO; the objective is to stop small drones before they approach within 500 m of the perimeter. In Sense, the panoramic head sweeps the full circle every 2.3 s while the RF layer listens across the spectrum; a drone entering the outer zone is registered by one or both — an emitter by its control link, a silent one by its thermal signature against the sky. In Understand, the raw flow is compressed before an operator sees anything: detections are bound into tracks, cloud and bird returns rejected, and the surviving track fused with the RF bearing into one object in the COP, carrying position, classification, confidence, and contributing sensors. ORAO cues the turret; its edge-AI returns a class — drone rather than bird, aircraft or helicopter — with a confidence value in under two seconds, while the laser rangefinder converts bearing and range into coordinates: a few seconds after first detection, the operator has one identified, located, ranked object instead of fifty ambiguous stimuli per second.

In Decide, the platform prepares the response: which countermeasure applies, which zone it may radiate into, whether the rules permit automatic action or require approval—and, because the ROE are compiled into the configuration, it offers no option that would radiate into the prohibited sector. The operator, alerted by a single track rather than a continuous stream, reviews the classification and supporting imagery, then authorizes the measure. In Act, the jammer radiates its selective pattern, the turret observes, and the outcome — the drone descending, returning or landing — is recorded as effect assessment, refining both the picture and the models. The same discipline scales beyond soft-kill: with layered gun-based and directed-energy effectors from the Institute's portfolio, the chain from first radar contact with a multi-drone raid at 8 km to confirmed neutralization closes within about 45 seconds.

The interval from first stimulus to a directed, compliant response is thus compressed from the timescale of manual correlation across separate consoles to that of a supported decision, with every step transparent, logged and under human authority; and it decomposes — 2.3 s of panoramic revisit in Sense; sub-100 ms inference and under 2 s of turret verification in Understand; a human decision bounded by how well the option was prepared; a tasking latency in Act — each term a separate engineering problem with a separate owner. That is what it means to say that

SUDA turns cycle time from a metaphor into a measurable system property.

8. CONCLUSION

This paper has presented an architectural framework for AI-assisted decision support in C2 systems, organized around the SUDA cycle and demonstrated on a system in operational service. Its central claim is that decision advantage arises not from replacing the human decision-maker but from restructuring the C2 information flow so that machines do what they do best — acquire, fuse, classify, detect anomalies, prepare and rank options — while human judgement is applied, deliberately and accountably, where it matters most. The Vlatacom C7ISTAR realisation, in which the ORAO platform carries the ARES three-tier AI core, substantiates the claim phase by phase with the measured figures of Table 1. Together those figures describe a single object — a short, instrumented and accountable path from sensor to decision-maker and from decision to effect — and it is that path, not any individual algorithm, that modern command support has to engineer. The sovereign, end-to-end integration of sensors, intelligence and effectors within one platform is becoming the defining requirement of the field.

Future work follows three lines: standard metrics and instrumentation for per-phase cycle-time measurement across heterogeneous systems; test, evaluation and accreditation of learning-based functions, including behaviour under distribution shift and adversarial conditions; and interoperability of SUDA-structured decision support across systems and coalition boundaries.

Abstract: *Laser-induced synthesis of ε-Fe_2O_3 thin films via pulsed laser deposition (PLD) involves complex energy transfer processes, impacted by coupled exciton–spin solitons in the precursor α-Fe_2O_3 lattice. This paper is continuation of our previous work, presenting a combined analytical and numerical investigation of soliton decoupling thresholds and the resulting magnetization in ε-Fe_2O_3. A soliton-based model describes energy transfer from laser photons to exciton and spin–spin solitons, allowing derivation of threshold photon energies for decoupling, as a function of laser fluence, exposure time, and exciton–spin coupling. Numerical simulations using a MATLAB-based solver produced two-dimensional and three-dimensional plots, revealing nonlinear and saturating dependencies of soliton stability on laser parameters. Furthermore, a Magnetization Calculator was developed to quantify the normalized magnetization, incorporating additional factors, such as: damping, pulse duration, and soliton amplitude. The combination of analytical thresholds and numerical modeling provides a framework for exploring PLD synthesis conditions and their potential influence on the magnetic response of ε-Fe_2O_3 thin films.*

Keywords: *ε-Fe_2O_3, exciton–spin soliton, soliton decoupling, pulsed laser deposition, magnetization modeling*

1. INTRODUCTION

ε-Fe_2O_3 thin films are of interest because of their strong magnetic anisotropy, high coercivity, and high-frequency ferromagnetic resonance, making them promising for high-frequency magnetic and electromagnetic applications [1–5]. However, the metastable ε-phase is difficult to stabilize during synthesis, and its magnetic properties depend sensitively on growth conditions [6–8]. Pulsed laser deposition (PLD) provides a route for controlling these conditions, but the laser-induced energy-transfer processes underlying the formation and magnetic response of ε-Fe_2O_3 remain insufficiently understood.

Various approaches have been proposed to improve ε-Fe_2O_3 thin film synthesis, particularly using pulsed laser deposition (PLD) [9–11]. In our previous study, theoretical optimization of PLD synthesis parameters was performed, to improve the properties of ε-Fe_2O_3 thin films. Ref. [12] investigated the impact of laser choice on the magnetization of the final product. Using soliton theory, the study analyzed the coupling between exciton solitons and spin-spin solitons, induced by laser irradiation of the α-Fe_2O_3 target during PLD. This paper is continuation of the study, presented in Ref. [12], providing deeper insight in the laser-induced energy-transfer pathway, for which is assumed that impact the magnetic ordering and stability of the final product phase of the PLD synthesis. Performed numerical computations and MATLAB simulations illustrate the applicability of the model and provide a software tool to assist experimental design in PLD synthesis, facilitating the production of ε-Fe_2O_3 thin films with improved magnetization and functional properties.

Consequently, it has potential 2.THEORETICAL MODEL

In Ref. [12], a theoretical model based on soliton theory [13], was proposed to describe energy transfer from the laser-excited α-Fe_2O_3 precursor to the ε-Fe_2O_3 product. According to this model, exciton solitons are formed through interactions between laser photons and the electron subsystem, while spin-spin solitons arise due to spin interactions in the ferromagnetic chains of the hematite crystal lattice.

Solitons are localized energy packets capable of carrying information through the lattice. Consequently, a coupled pair of exciton and spin-spin solitons can transfer energy from the precursor to the final ε-Fe_2O_3 lattice.

To gain deeper insight into the amount of laser photon energy, which is required for decoupling of the coupled pair of exciton soliton and spin-spin soliton, and building on the exciton soliton amplitude provided in Ref. [12], in this study is introduced the corresponding exciton soliton energy. Based on the cubic-quintic nonlinear Schrödinger equation (CQNLSE) considered in Ref. [12], the standard soliton energy can be expressed as the integral of the Hamiltonian density over the spatial coordinate z:

Corresponding author: V. Nikolić;
E-mail: violeta@vin.bg.ac.rs
DOI: 10.5937/OTEH26103N

$$E_{\text{exciton}} = \int_{-\infty}^{\infty} \left[M_L \left(\frac{\partial \rho}{\partial z}\right)^2 - \frac{G_L}{2}\rho^4 - \frac{F_L}{2}\rho^6 \right] \mathrm{dz} \quad (1)$$

where is E_{exciton}=$\mathrm{M}_L \left(\frac{\partial \rho}{\partial z}\right)^2$ – gradient energy (analogue to the kinetic-like term), and $\frac{-G_L}{2}\rho^4 - \frac{F_L}{2}\rho^6$ – cubic and quintic nonlinearities (analogue to the potential-like term) [14].

This integral can be solved analytically, resulting in an expression relating soliton energy to amplitude, showing that higher amplitudes correspond to higher energies—reflecting stronger energy transfer under higher laser excitation [14, 15], eq. (2):

$$E_{\text{exciton}} \sim \mathrm{M}_L \frac{\rho_0^2}{L} - \frac{G_L}{2}\rho_0^4 L - \frac{F_L}{3}\rho_0^6 L \quad (2)$$

where is soliton width given by expression: L=$\frac{4M_L}{G_L \rho_{0^2}(1+\mathrm{B}_L)}$.

Considering eq. (10) from Ref. [12], and eq. (2), the energy of the coupled pair of exciton soliton and spin-spin soliton is given by eq. (3):

$$\tilde{H}_{coupled} = \tilde{E}_{exc} + \tilde{E}_{spin} + \lambda \tilde{E}_{exc} + \tilde{E}_{spin} \quad (3)$$

where is: $\tilde{H} = \frac{H}{E_0}$, and $\tilde{E} = \frac{E}{E_0}$. To maintain dimensional consistency, the energies in eq. (3) are expressed relative to a characteristic energy scale, E0, in order to perform dimensional normalization. The exciton-spin-soliton coupling coefficient (describing the nonlinear coupling between the excitonic and spin-soliton contributions), λ, is consequently dimensionless, and describes the strength of the nonlinear energetic interaction between the exciton-soliton and spin-soliton contributions. The coupled Hamiltonian illustrates the total energy of the exciton soliton and spin-spin soliton system, including their mutual energy transfer.

Efficient magnetic energy transfer requires that the two soliton subsystems remain coupled during transfer from precursor to product. If the exciton soliton energy exceeds a characteristic coupling energy, decoupling occurs, limiting magnetization transfer. This defines a threshold condition separating regimes of effective and ineffective energy transfer.

Let us recall that the exciton soliton energy is described by eq. (4):

$$E_{\text{exciton}} \approx \eta \mathrm{N}_a \hbar\omega \quad (4)$$

where is $\hbar\omega$ - photon energy (laser wavelength), N_a - number of absorbed photons (dependent on fluence and exposure time of laser), η<1 - energy-transfer factor (losses to photons, heat, defects). Considering the fact, that decoupling begins when $\eta \mathrm{N}_a \hbar\omega \geq E_{\text{spin-spinsoliton}}$, the threshold laser energy is given by eq. (5):

$$\hbar\omega_{\text{th}} \sim \frac{E_{\text{spin-spinsoliton}}}{\eta \mathrm{N}_a} \quad (5)$$

Decoupling of exciton and spin-spin solitons is expected when the accumulated exciton soliton energy (determined by photon energy, laser fluence, and exposure time), becomes comparable to, or exceeds, the characteristic energy threshold for soliton decoupling. Higher photon energies reduce the required exposure and fluence to reach this regime.

Since laser excitation generates exciton solitons in the α-Fe_2O_3 precursor (which are coupled to spin–spin solitons), it is considered that the energy, transferred through this coupled soliton system, represents additional parameter, by which the absorbed laser energy can influence the magnetic state of the material during formation of the ε-Fe_2O_3 phase. For this reason, given study proposes that the calculated soliton energy and decoupling threshold can be used as indicators of the energy-transfer process, and its potential influence on the magnetic ordering of the resulting ε-Fe_2O_3 phase.

Although an analytical threshold condition for soliton coupling is derived, the effective coupling is dependent on laser photon energy, laser fluence, exposure time (number of pulses), material-dependent coupling strength, and dissipative energy-loss channels. Therefore, the obtained analytical result could be further probed using numerical simulations.

To perform numerical application of the postulated theoretical basis, here is important to notice that numerical computational basis of the model is relied on the probing of the laser excitation threshold, sufficient to induce decoupling of the exciton and spin-spin solitons. Afterwards, two complementary phenomenological descriptions (representing two complementary parameterizations, probing relation between different synthesis parameters and normalized magnetization (M_{norm})) were introduced. First parameterization approach investigate the response of the Mnorm to photon energy, and other controllable parameters. Second parameterization approach (representing PLD cumulative-energy formulation) enable monitoring of the impact of the accumulated laser energy, relative to the effective threshold, on the M_{norm}. Different parameterization formulations relies on various phenomenological expressions for M_{norm}, introduced in order to consider different aspects of M_{norm} behavior.

2.1. Numerical methods for laser-induced decoupling and magnetization estimation

To investigate the effect of laser irradiation on the stability of coupled exciton–spin solitons in α-Fe_2O_3 and the resulting magnetization of the synthesized ε-Fe_2O_3 phase, a numerical solver was developed in MATLAB [16]. This solver is based on the analytical expressions derived for the total soliton energy and the critical energy required for decoupling. It allows systematic variation of the key parameters influencing soliton coupling, including: photon energy of the laser, effective laser exposure time (t_{exp}), or energy-transfer efficiency factor (η), describing the fraction of the relevant absorbed photon energy transferred to the exciton-soliton excitation.

For each set of parameters, the algorithm evaluates whether the absorbed laser energy exceeds the threshold for decoupling the coupled soliton state. If the threshold is surpassed, the program estimates the corresponding reduction in M_{norm}, based on the proportionality between spin–spin soliton energy and the quantized magnetization.

All input parameters are constrained to experimentally relevant ranges, and energy calculations follow the semi-classical quantization framework outlined in Ref. [12] (eq. (9)–(11)).

This approach provides a computationally efficient method to assess the influence of laser parameters on the magnetic properties of ε-Fe_2O_3, without requiring full time-dependent PLD simulations. It also serves as a predictive tool for optimizing synthesis conditions in experiments.
Further, to perform numerical magnetization modeling, in order to quantify the effect of laser-induced soliton decoupling on the magnetization of ε-Fe_2O_3 thin films, a MATLAB-based Magnetization Calculator was developed.

A MATLAB-based solver and Magnetization Calculator were developed to evaluate the analytical threshold relations and the resulting normalized magnetization. The program systematically varies photon energy, exposure time, energy-transfer efficiency, coupling strength, damping, and soliton amplitude, allowing individual and combined parameter effects to be examined without full time-dependent PLD simulations.

3. RESULTS AND DISCUSSION

To visualize the threshold photon energy for decoupling of the exciton-spin-spin soliton system, chosen parameters were systematically varied, such as: spin-spin soliton energy ($E_{\text{spin-spin soliton}}$ [eV]), number of adsorbed photons (N_a), laser fluence [J/cm^2], and exposure time [s]. These variations were modeled, using eq. (6):

$$N_a = \frac{F_p A_{ill}(1-R) A_{absorp} f_{rep} t_{exp}}{E_{ref}} = F_p t_{exp} \alpha_{eff} \qquad (6)$$

where F_p is the laser fluence per pulse, t_{exp} is the total irradiation/deposition duration corresponding to the pulse number, N_{pulses} ($N_{pulses} = f_{rep} t_{exp}$), A_{ill} – illuminated area, R – reflectivity, A_{absorp} – absorptance, f_{rep} – pulse repetition rate, and E_{ref} is reference photon energy. Accordingly, eq. (6) represents a phenomenological estimate of the effective number of absorped photon excitations, during PLD. The effective photon-absorption factor, α_{eff}, incorporates the illuminated area, optical losses, target absorptance, pulse repetition rate, and a reference photon-energy scale; its value is treated as an adjustable model parameter ($\alpha_{eff} = 10^{18} cm^2 J^{-1} s^{-1}$).

The numerical simulations yield the results shown in Fig. 1 and Fig. 2. Since eq. (3) is phenomenological energy-coupling relation, Fig. 1 and Fig. 2 appears as a result of phenomenological threshold/decoupling calculation, providing deeper insight in the conditions, under which laser excitation become sufficient for decoupling. Fig. 1 presents the dependence of the threshold photon energy on laser fluence, for different energy-transfer efficiencies at a fixed exposure time.

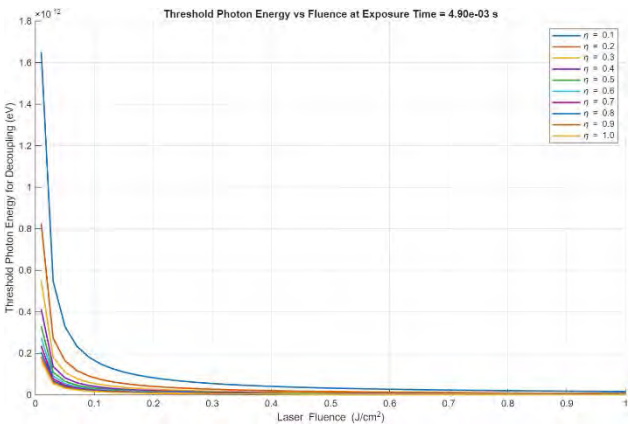

Figure 1. Dependence of threshold photon energy on laser fluence at a fixed exposure time (4.90×10^{-3} s) for various energy-transfer factors (η).

Each curve represents the threshold photon energy required to initiate soliton decoupling as a function of fluence, with different colors, corresponding to different values of η. The plot illustrates impact of the increasing fluence on the lowering of the threshold energy, and highlighting the nonlinear interplay between laser parameters and soliton stability. Fig. 1 shows an inverse dependence of threshold photon energy on fluence: increasing fluence increases the number of absorbed photons and therefore lowers the photon energy required for decoupling. The convergence of the curves at higher fluence indicates diminishing sensitivity to further fluence increases.

Fig. 2 provides a complementary view through a three-dimensional color map, illustrating the variation of the threshold photon energy with both fluence and exposure time, for a fixed energy-transfer factor: η=0.5.

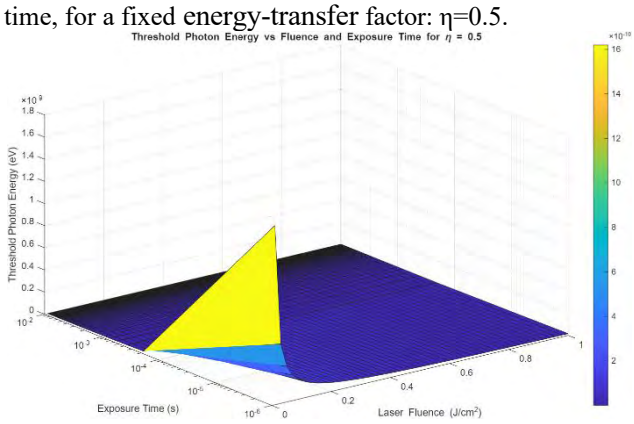

Figure 2. Dependence of threshold photon energy on fluence and exposure time, for a fixed energy-transfer factor: η=0.5.

Fig. 2 shows the corresponding dependence on fluence and exposure time. At low fluence and short exposure, higher photon energies are required for decoupling, whereas increasing either parameter lowers the threshold because of cumulative energy absorption. The surface gradually approaches saturation, indicating diminishing sensitivity at higher fluence and exposure. These trends are consistent with the analytical behavior of the model reported in Ref. [12].

To directly link soliton decoupling to magnetic response, a

Matlab-based Magnetization Calculator was employed. This tool computes the total soliton energy, evaluates the decoupling condition, and outputs the normalized magnetization as a function of laser photon energy and additional synthesis parameters. For this purpose, it is introduced the simplified phenomenological expression (eq. (7)) for evaluation of the M_{norm}, in order to facile interactive visualization (shown in Fig. 3). Thus, eq. (7) represents phenomenological parameter-sensitivity response of M_{norm}, proposed considering first parameterization approach:

$$M_{\text{norm}} = \exp\left(-\gamma \frac{E_{\text{threshold}}}{E_{\text{photon}}} \frac{t_{\text{ref}}}{t_{\text{pulse}}} \frac{T_{\text{ref}}}{T_{\text{target}}} \frac{\rho_{\text{ref}}}{\rho_0}\right) \quad (7)$$

where $E_{threshold}$ denotes the laser energy required to initiate exciton–spin soliton decoupling, as determined from the analytical model. The quantities t_{ref}, T_{ref}, and ρ_{ref} are reference values introduced for normalization, ensuring that the resulting magnetization is expressed as a dimensionless quantity between 0 and 1. The parameter γ represents a dimensionless phenomenological damping parameter ($0 \leq \gamma \leq 1$), with larger values corresponding to stronger damping. The damping coefficient is introduced to account for energy-loss mechanisms present during laser irradiation and soliton propagation, including phonon scattering, thermal dissipation, lattice defects, and non-radiative recombination. These processes reduce the fraction of absorbed laser energy that effectively contributes to soliton coupling and magnetic ordering, making γ an essential parameter for realistic modeling of experimental conditions. Consequently, eq. (7) enables estimation of the effective M_{norm}, incorporating both energy input and dissipative effects.

Higher photon energy, longer pulse duration, lower damping, or higher soliton amplitude, result in increased M_{norm}, reflecting more efficient energy transfer and stronger magnetic ordering in the synthesized thin films.

The resulting dependence of M_{norm} on photon energy is shown in Fig. 3. Accordingly, Fig. 3 shows response of the M_{norm} on the photon energy, and other controllable parameters.

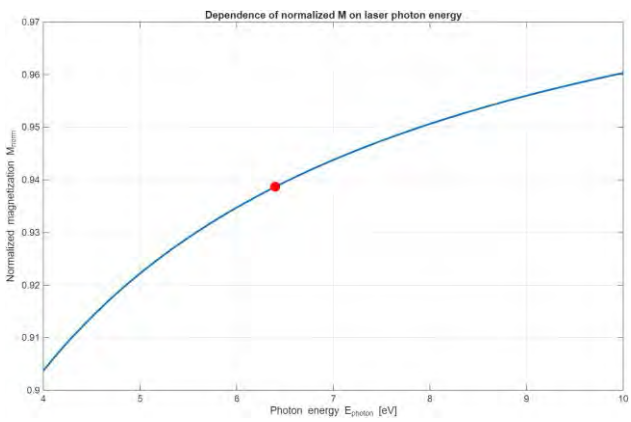

Figure 3. Dependence of normalized magnetization on laser photon energy.

Fig. 3 demonstrates a pronounced threshold-like behavior: at low photon energies, the normalized magnetization remains low, indicating insufficient energy to sustain exciton–spin–spin soliton coupling. As photon energy increases, the magnetization rises steeply, approaching unity when the photon energy reaches or exceeds the coupling threshold. This confirms that higher-energy photons more efficiently preserve magnetic ordering during the phase transformation from α-Fe_2O_3 to ε-Fe_2O_3. The red marker in Fig. 3 corresponds to a specific parameter set selected interactively via Matlab Live Script sliders. Its vertical position reflects the influence of additional parameters—such as pulse duration, soliton amplitude, temperature, and damping—demonstrating that even at high photon energies, non-optimal values of these parameters can significantly reduce the resulting magnetization. This emphasizes the necessity of multi-parameter optimization, rather than reliance on photon energy alone.

Noteworthy, the PLD Magnetization Calculator enables calculation of M_{norm}, and a simultaneous assessment of multiple parameters affecting the normalized magnetization, with results summarized in tabular form (Table 1). Since Table 1 results are computed, relying on the second parameterization approach, for numerical computations are applied next eq. (8-10):

$$E_{laser} = E_{photon}\eta ln(1 + N_{pulses}) \quad (8)$$

$$E_{total} = E_{soliton} + E_{laser} \quad (9)$$

$$E_{threshold} = E_{bond} + E_{thermal} \quad (10)$$

which is resulting in the next phenomenological expression, describing M_{norm} response: $M_{\text{norm}} = \frac{1}{1+(E_{total}/E_{threshold}-1)^2}$ (11). The critical photon energy is obtained, considering condition that: $E_{total} = E_{threshold}$, resulting in the eq. (12):

$$E_{critical} = \frac{E_{threshold} - E_{soliton}}{\eta ln(1+N_{pulses})} \quad (12).$$

The calculations are performed, considering values, used as computational cases spanning a realistic deposition-time scale. In PLD synthesis, the total irradiation time is related to the number of applied laser pulses through: $N_{pulses} = f_{rep}t_{exp}$, while the pulse duration describes the width of each individual laser pulse. To reflect this distinction, the present calculations use a repetition rate of 5 Hz and consider representative pulse numbers of 5,000–20,000, corresponding to total irradiation times of 1,000–4,000 s (approximately 17–67 min), while a pulse duration of 20 ns is used as a representative PLD pulse width. The selected pulse numbers are representative computational cases, rather than experimentally reported pulse counts for a specific ε-Fe_2O_3 film. Numerical results are represented in Table 1.

Table 1. Calculated M_{norm} for representative PLD conditions, using KrF, ArF, and F_2 laser excitation.

Laser	Photon Energy [eV]	Num Pulses	Exposure [s]	Total energy	Threshold energy	Critical energy	M_{norm}
KrF	4.9	5000	1000	34.888	1.5	0	0.0020143

This tabular output facilitates rapid comparison between different laser sources and exposure conditions, offering a practical and predictive framework for optimizing PLD synthesis strategies. Table 1 proposes impact of the accumulated laser energy, relative to the effective threshold, on the M_{norm}.

The motivation for this calculator is based on the fact that published PLD studies roughly establish that laser and deposition conditions influence ε-Fe_2O_3 phase formation and magnetic properties, while the presented model explores the sensitivity of M_{norm} to photon energy.

Literature search showed that temperature and structural/growth parameters demonstrably affect the measured magnetization [17]. Also, Corbellini et al. discussed the relevance of photon energy, pulse duration, repetition rate, fluence and exposure/pulse number, as PLD parameters [1]. They listed the experimental PLD parameters explicitly: KrF, 248 nm, ~22 ns pulse duration, 5 Hz repetition rate, and ~1.8 J/cm² fluence, for the films, characterized magnetically by VSM, what demonstrated that PLD processing parameters and the resulting magnetic properties are experimentally connected, which supports the general motivation for our parameterized calculator. In 2022 is published study, where authors reported that oxygen pressure, deposition/annealing temperature, and laser beam energy significantly affect epitaxial growth of ε-Fe_2O_3; their ~20 nm films show strong magnetic anisotropy and a coercivity of about 600 Oe [18]. This is very close to what our calculator is trying to represent. Authors explicitly claimed that laser beam energy affects the epitaxial growth of ε-Fe_2O_3. That is very supporting for Fig. 3, represented in this study, because our exponential model specifically explores photon energy. We therefore have literature support for investigating laser-energy dependence, even though the literature does not validate our particular exponential formula.

Albeit, the calculator is not quantitatively calibrated against experimental values. Published PLD studies demonstrate that the magnetic properties of ε-Fe_2O_3 thin films depend on synthesis conditions, including temperature, film thickness, and laser/deposition parameters. The present model therefore provides a phenomenological parameter-sensitivity analysis, rather than an absolute prediction of magnetization.

4. CONCLUSION

In this work, a combined analytical and numerical framework was developed to investigate laser-induced exciton–spin–spin soliton interactions during PLD synthesis of ε-Fe_2O_3 thin films and their impact on magnetic properties. Building upon a previously proposed soliton-based model, analytical expressions were derived to describe energy transfer, soliton coupling, and decoupling thresholds as functions of laser photon energy, fluence, exposure time, and coupling strength.
Numerical basis of the model is given by eq. (6), which enables deeper insight in the amount of photon energy, required for decoupling, and illustrates sensitivity of the number of absorbed photons variations, on the parameters, such as fluence, exposure and coupling efficiency. Expressions for M_{norm} (eq. (7) and (11)) are obtained by two complementary phenomenological descriptions: first one provided a normalized parametric response for interactive exploration of photon energy, pulse duration, temperature, soliton amplitude and damping, and second approach is based on cumulative laser-induced energy relative to a decoupling threshold.

Numerical simulations revealed a pronounced nonlinear dependence of the threshold photon energy on laser fluence and exposure time. The resulting two- and three-dimensional representations demonstrated characteristic saturation behavior, showing that cumulative energy absorption can significantly reduce the photon energy required for soliton decoupling. These trends are fully consistent with the analytical model, validating its ability to capture the essential physics of laser–matter interactions governing phase transformation and magnetic ordering.

To quantify the magnetic consequences of soliton decoupling, a MATLAB-based Magnetization Calculator was developed. By incorporating additional physically relevant parameters—such as soliton amplitude, coupling strength, and damping effects—the tool enables estimation of normalized magnetization under realistic experimental conditions. The simulations illustrate that the dependence of normalized magnetization on photon energy depends on the adopted phenomenological parameterization, while non-optimal combinations of exposure time, damping, or coupling strength can substantially reduce the magnetic response, underscoring the importance of multi-parameter optimization.

Overall, the presented approach provides a computationally efficient methodology for exploring PLD parameter space, without the need for full time-dependent PLD simulations. The combined framework provides a computationally efficient approach for exploring the sensitivity of soliton coupling and normalized magnetization to PLD parameters. The methodology can be extended to related oxide systems in which laser-induced energy transfer influences phase stability and functional properties.

Abstract: *In this study is theoretically investigated light-driven electron transport in one-dimensional Fe–X molecular chains (X = Fe, Ni, Co) by combining Floquet band analysis with open-system transport modeling—the first framework to directly connect quasi-energy spectra under periodic driving with dissipative electron transport. Floquet calculations reveal that symmetry, orbital hybridization, and exchange splitting govern photon-assisted band mixing, while transport simulations quantify spin-resolved current enhancement. Results showed that Fe–Co motifs maximize photon-assisted conduction due to strong hybridization and high mid-band photon weight, Fe–Ni exhibits moderate enhancement, and Fe–Fe shows the least. This unified approach provides predictive guidelines for designing molecular spintronic devices optimized for light-controlled, high-efficiency electron transport.*

Keywords: *Molecular spintronics, Floquet bands, Photon-assisted transport, 1D magnetic Fe–X chains*

1. INTRODUCTION

Nowadays, molecular spintronics has attracted significant interest from the scientific community due to its potential to enable nanoscale devices with enhanced performance and novel functionalities [1]. This interdisciplinary field lies at the intersection of organic spintronics, molecular magnetism, and molecular quantum technologies. Molecular spintronic devices exploit the electron spin for data processing and storage, with applications ranging from ultrafast and energy-efficient computing to high-sensitivity sensing, which could be used in variety of potential military applications [2-5].

In this study, we combine Floquet band structure analysis (Model I) with open-system transport modeling (Model II) to investigate 1D Fe–X molecular chains, where X represents magnetic atoms (Fe, Ni, Co). The two postulated models are complementary: Model I provides the periodic-system Floquet electronic structure, while Model II uses the corresponding Fe–X motif, as an effective molecular junction to investigate photon-assisted transport. As a result, it was possible to quantify the influence of orbital hybridization and periodic driving on electron transport via photon-assisted resonances. Based on our simulations, we obtained deeper insight in the efficient electron conduction, and highlight the design principles for photon-assisted transport, which could facile optimization of the light-driven transport in molecular spintronic devices.

2. THEORETICAL MODEL AND NUMERICAL METHODS

Two complementary theoretical models are employed and combined, with the aim to investigate light-driven electron transport in a 1D Fe–X molecular system. Model I describes a periodically driven tight-binding Fe–X chain (where X denotes Fe, Ni, and Co), and it is used to analyze Floquet band formation and hybridization effects.
Model I, denoting to the periodically driven tight-binding Fe–X chain, is relied on the static tight-binding Hamiltonian, constructed by considering a 1D periodic chain, composed of alternating Fe and X sites, within a single unit cell.

It is important to note that we begin calculations from a tight-binding Hamiltonian formulated in a localized orbital basis, where on-site energies describe Fe and X atomic orbitals and hopping terms, represent nearest-neighbor coupling and hybridization. This Hamiltonian initially written in real space. For the periodic one-dimensional Fe–X chain considered in the band-structure analysis, translational symmetry allows the application of Bloch's theorem. By performing a Fourier transform to momentum space, the real-space tight-binding Hamiltonian is recast into a k-dependent Bloch Hamiltonian H(k). The Bloch Hamiltonian is therefore not a different physical model, but rather the momentum-space representation of the same tight-binding Hamiltonian under periodic boundary conditions. This representation enables calculation of the band structure and, subsequently, its Floquet extension under time-periodic driving.

Consequently, discussed Model I provided band-structure level understanding of orbital hybridization, Floquet sideband formation, resonance conditions. To perform full Matlab numerical simulating, Model I was considered in combination with Model II. In order to discuss electron transport under applied bias, an open quantum system, representing an effective Fe–X dimer, coupled to electronic reservoirs, was considered. For the quantitative transport analysis, the effective Fe–X dimer is coupled to left and right electronic reservoirs within a Floquet nonequilibrium Green's-function (Floquet-NEGF) formulation. This allows the bias-dependent driven and static currents to be evaluated consistently, with the same Fe–X parameter sets used in Model I.

Numerical procedure, performed in order to apply Model I on a considered system, was based on the construction of $H_0(k)$, for each value of k. Afterwards, it was builded truncated Floquet matrix, which diagonalization was performed numerically, and quasi-energies and orbital weights were extracted, for each vlaue of k. All calculations were performed, using standard matrix diagonalization routines in MATLAB (R2024a) [8].

Below is given theoretical postulation of the model, relying on two complementary modeling approaches. In order to construct appropriate static tight-binding Hamiltonians, few model premises were introduced. In the study is considered 1D periodic chain, consisted of motif, containing two atoms per unit cell (except Fe-Fe symmetric case): Fe atom, and X-atom (where X denotes to Ni, and Co atom). Model is based on nearest-neighbor hopping, and inter-site hybridization, as well as spin splitting is also considered, since discussed atoms are magnetic.

Considered Bloch Hamiltonians, postulated for appropriate 1D Fe-X molecular chains, are shown below. In the case of Fe-Fe chain, Bloch Hamiltonians is simplified, since identical atoms are considered, eq. (1):

$$H_0^{FeFe}(k) = \begin{pmatrix} \varepsilon_{Fe} & te^{-ika} \\ te^{-ika} & \varepsilon_{Fe} \end{pmatrix} \quad (1)$$

where ε_{Fe} denotes to on-site energy, t is the nearest-neighbor hopping amplitude, and a is the lattice constant. Introduction of magnetism in the model is mathematically achieved by introducing exchange splitting: $\varepsilon_{Fe,\uparrow} = \varepsilon_{Fe} + \frac{\Delta_{ex}}{2}, \varepsilon_{Fe,\downarrow} = \varepsilon_{Fe} - \frac{\Delta_{ex}}{2}$, while for the heteronuclear chains, the same construction is applied separately to Fe and X: ↑ ↓

$$\varepsilon_{i,\uparrow/\downarrow} = \varepsilon_i \pm \frac{\Delta_i}{2}; i = Fe, X \quad (2)$$

where is Δex – term of magnetic exchange splitting. Here should be mentioned that, in the case of Fe-Fe unit cell, it was considered large value of Δex, while it is intermediate for the case of Fe-Co dimer, and finally, the smallest is for Fe-Ni dimer. Performed mathematical step provided Hamiltonian, which is block-diagonal in spin.

Accordingly, the Hamiltonian doubles in spin space (4x4 per k). Because the two sites are parametrized identically in the Fe–Fe case, the static Hamiltonian has the corresponding site-exchange symmetry and does not contain onsite-energy asymmetry.

Bloch Hamiltonian of 1D Fe-Ni molecular chain is given by eq. (3):

$$H_0^{FeNi}(k) = \begin{pmatrix} \varepsilon_{Fe} & V_{FeNi} + te^{-ika} \\ V_{FeNi} + te^{-ika} & \varepsilon \end{pmatrix} \quad (3)$$

where ε_{Fe} and ε_{Ni} represent H on-site 0 (k) = energies, t is the hoppling amplitude, V represents the Fe-Ni hybridization strength, a is the lattice constant, k is the crystal momentum. ε_{Ni} is characterized by slightly lower value compared to ε_{Fe}, since Ni is characterized by higher number of electrons in d-band, although both atoms belongs to 3d metals, which implies moderate hybridization.

Finally, Bloch Hamiltonian of 1D Fe-Co molecular chain, eq. (4):

$$H_0^{FeCo}(k) = \begin{pmatrix} \varepsilon_{Fe} & V_{FeCo} + te^{-ika} \\ V_{FeCo} + te^{-ika} & \varepsilon_{Co} \end{pmatrix} \quad (4)$$

where ε_{Fe} and ε_{Co} represent H on-site 0 (k) = energies, t is the hoppling amplitude, V represents the Fe-Co hybridization strength, a is the lattice constant, k is the crystal momentum. Since both atoms, Fe and Co, are characterized by very similar in d-band character, it is considered smaller onsite asymmetry than Fe-Ni, which consequently could be characterized by strong exchange splitting.

In order to perform numerical methods, below are given Tables, giving set of parameters for characteristic 1D Fe-X motifs. The parameter sets were selected as representative values consistent with the distinct electronic coupling, level alignment, and magnetic characteristic of the Fe-Fe, Fe-Ni, and Fe-Co configurations, reported in the literature [6, 7]. They are therefore used as model parameterizations, rather than material-specific fitted parameters. Parameter values used in the simulations are showed in Table 1-3.

Table 1. Parameters used in all numerical simulations of the 1D Fe–Fe molecular chain.

Parameter	Symbol	Typical value
Hopping amplitude	t	1.2 eV
On-site energy	ε_{Fe}	0.0 eV
Magnetic splitting exchange constant	Δ_{ex}	1.5 eV
Driving amplitude	A	0 -3 eV
Driving frequency	ω	1 – 3 eV

Given parameters are chosen, considering the fact that discussed band is metallic, and characterized by the absence of intrinsic gap, while Floquet gap opens only via driving.

Table 2. Parameters used in all numerical simulations of the 1D Fe–Ni molecular chain.

Parameter	Symbol	Typical value
Hopping amplitude	t	1.0 eV
Fe-Ni orbital hybridization	V	1.5 eV
On-site energy	ε_{Fe}	0.2 eV
On-site energy	ε_{Ni}	- 0.3 eV
Driving amplitude	A	0 -1 eV
Driving frequency	ω	1 – 3 eV

Based on chosen parameters in Table 2, it is expected appearance of moderate bonding-antibonding splitting, and asymmetric orbital weights.

Table 3. Parameters used in all numerical simulations of the 1D Fe–Co molecular chain.

Parameter	Symbol	Typical value
Hopping amplitude	t	1.1 eV
Fe-Co orbital hybridization	V	1.8 eV
On-site energy	ε_{Fe}	0.1 eV
On-site energy	ε_{Co}	- 0.1 eV
Magnetic splitting exchange constant	Δ_{ex}	1.2 eV
Driving amplitude	A	0 -1 eV
Driving frequency	ω	1 – 3 eV

Based on chosen parameters in Table 3, it is expected appearance of strong hybridization, and large exchange splitting.

Further, under periodic driving with field amplitude A and frequency ω, it is considered the time-dependent Hamiltonian. In order to incorporate time-dependent driving in a postulated theoretical model, it was used modulation given in eq. (5):

$$H(k,t) = H_0(k) + A\cos(\omega t)\hat{O} \quad (5)$$

where $\hat{O}$ is the operator coupled to the external field. Consequently, driving modulated inter-site coupling by expression: V → V + Acos(ωt).

In order to collect spin-resolved spectra by numerical simulations, it was performed Floquet extension in harmonic space: m = -N_F, …, + N_F, where N_F = 1 depicts to the 3 harmonics and 4 spin-orbital states. A first-order Floquet truncation, m = 1, 0, +1, is adopted to retain the leading photon-assisted processes, while keeping the model minimal and transparent. Higher-order multiphoton processes are not considered in the present study. So, total Floquet dimension was 4 x 3 = 12. Accordingly, Floquet matrix is constructed by using next parameters: m = -1, 0, +1, and N_F = 1, as well as 12 x 12 matrix size (for including of the spin impact). The Floquet matrix element (in Block Hamiltonian form) is given by eq. (6):

$$(H_F)_{mn} = H_{m-n}(k) + n\omega\delta_{mn} \quad (6)$$

where is $H_{\pm 1} = \frac{A}{2}\hat{O}$.

Consequently, the resulting matrix is 12 x 12, and it is diagonalized numerically, in order to obtain quasi-energies ε_α (k), spin-resolved orbital weights, and photon weights.
To combine Model I with Model II, the effective Fe–X dimer is coupled to left and right noninteracting electronic reservoirs. The transport calculation is performed within a Floquet nonequilibrium Green's-function (Floquet-NEGF) formulation. The lead Hamiltonian is given by eq. (8):

$H_{leads} = \sum \varepsilon_{k,\alpha}\, c_{k\alpha}{}^{\dagger} c_{k\alpha}$ (8), where α=L, R denotes the left or right reservoir, and k labels the lead states. The coupling to the molecular dimer is described through the corresponding lead self-energies. In the present calculations, symmetric wide-band lead coupling was assumed, with: $\Gamma_L = \Gamma_R$ = 0.20 eV.

The bias-dependent current is obtained from the Floquet transmission function by summing the contributions from the retained Floquet sectors: m = -1, 0, +1 . Both the static (A=0) and periodically driven (A = 0.6 eV) currents are calculated using the same molecular parameters and lead couplings. This provides the quantitative transport comparison presented below.

3. RESULTS AND DISCUSSION

The combined application of Model I (Floquet band engineering) and Model II (nonequilibrium open-system transport) enables a systematic comparison of light-driven transport properties in three magnetic 1D motifs: Fe–Fe, Fe–Ni, and Fe–Co. This complementary approach allows comparison of Floquet band-structure features with the bias-dependent transport response.

Results of numerical simulation are represented in Fig. 1 – 3, for the case of 1D Fe-Fe molecular chain.

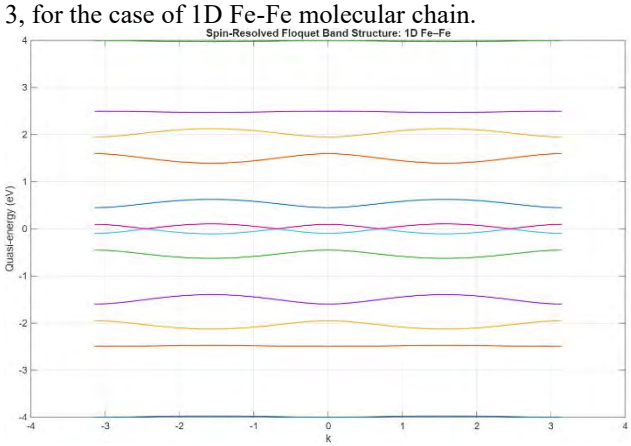

Figure 1. Spin-resolved Floquet quasi-energy band structure of a periodically driven 1D Fe–Fe molecular chain under driving (A = 0.6, ω = 2 eV).

Fig. 1 represents Floquet quasi-energy band structure of the periodically driven 1D Fe–Fe chain, obtained from the k-dependent Bloch Hamiltonian under harmonic driving (the colors of the curves are used for visual clarity to distinguish different bands and do not correspond to a particular contribution). The evolution of averaged (quasi) bands, in a system with a 1D molecular chain, consisting of two sublattices of the same atom, Fe, as a function of the crystal momentum k, in the presence of a time-periodic drive, provided visualization of band hybridization, occurred due to interaction with a photon, in the vicinity of resonance. Since Fe and Fe are characterized by d-band structures but the same electronegativities, it is also characterized by the absence of onsite asymmetry. Symmetric avoided crossings, indicating photon-induced hybridization. Recall that in a band structure, an avoided crossing occurs when two energy bands approach each other as a function of some parameter (like crystal momentum k) but do not cross because the two states are coupled (hybridized). Consequently, spin channels are balanced due to identical onsite energies.

Orbital and photon composition for selected Floquet band for 1D Fe-Fe molecular chain, is given in Fig. 2.

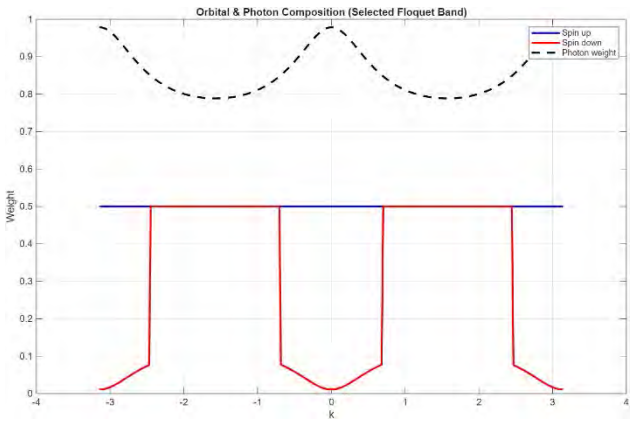

Figure 2. Harmonic composition of a selected Floquet band in Fe–Fe. Blue and red curves represent spin-up and spin-down orbital weights, respectively; black dashed curve shows the total photon weight (sum over non-zero Floquet harmonics).

Fig. 2 represents a visualization of the orbital composition (probability weights of Fe orbitals, differed in spin orientation) of a chosen Floquet band, dependent on the crystal momentum, k. It represents the Floquet band composition across the Brillouin zone, showing the spin-resolved orbital contributions and their variation with crystal momentum. Fig. 2 depict moderate, symmetric photon weight, reflecting uniform Floquet mixing.
In Fig. 3 are represented Floquet quasi-energy spectrum at k=0, for Fe-Fe molecular chain.

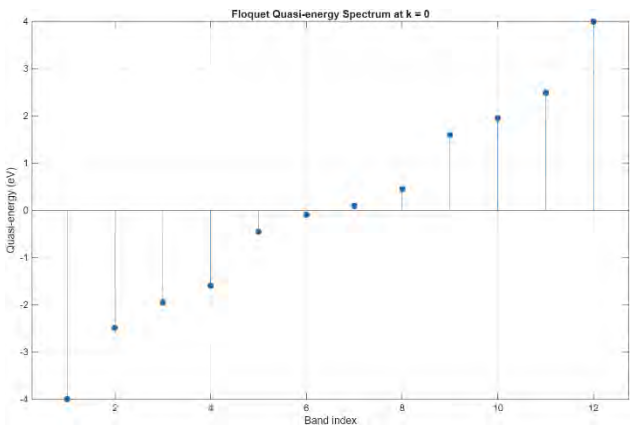

Figure 3. Quasi-energy spectrum at k = 0 for Fe–Fe, showing spin-resolved Floquet levels.

Based on the given dependence of quasi energy on band index, it could be boservable that level splitting indicates photon-mediated coupling. In other words, symmetry reflects identical atoms in the unit cell.

Considering postulated theoretical framework for numerical simulations, Fig. 4 – 6 describes behavior of 1D Fe-Ni molecular chain, modelled within the proposed theoretical frame.

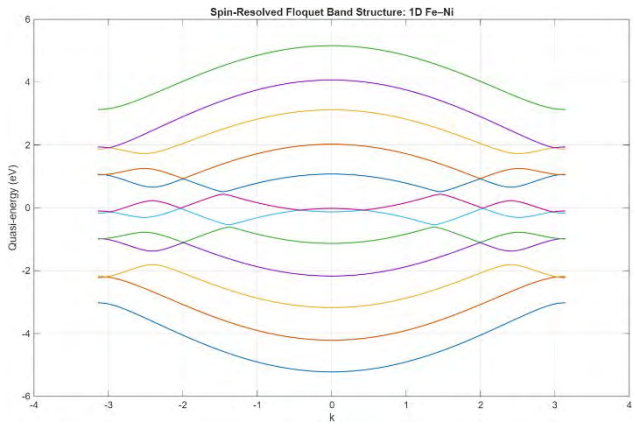

Figure 4. Spin-resolved Floquet quasi-energy band structure of 1D Fe–Ni chain under periodic driving.

Representation of spin-resolved band structure, given in Fig. 4, revealed higher degree of hybridization. Also, observed asymmetry is presented (differed from Fe-Fe chain case), due to intrinsic onsite energy difference, with momentum-dependent avoided crossings reflecting selective photon-assisted hybridization.

In Fig. 5, harmonic composition (Floquet mode weights) of the chosen quasi-energy band, illustrating the mixing of photon sectors induced by periodic driving, is represented (blue curve corresponded to spin up orbital weight, red curve to spin down orbital weight, and black dashed curve to the photon component.

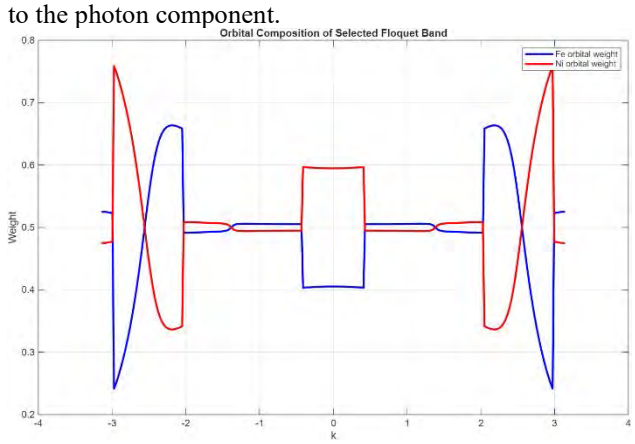

Figure 5. Harmonic composition of a selected Floquet band in Fe–Ni.

Fig. 5 showed that spin-dependent orbital weights (blue/red) highlight asymmetric Floquet mixing and inter-orbital photon coupling.

Further, Fig. 6 described Fe-Ni quasi-energy spectrum at k = 0.

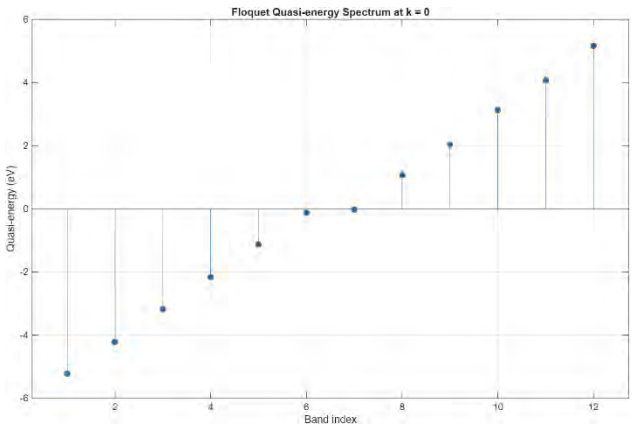

Figure 6. Quasi-energy spectrum at k = 0 for Fe–Ni.

Fig. 6 showed that it is observable uneven level spacing, reflecting intrinsic onsite asymmetry and selective photon-assisted coupling.

Finally, the results of the appropriate simulations, performed for 1D Fe-Co molecular chain, are given in Fig. 7 – 9.

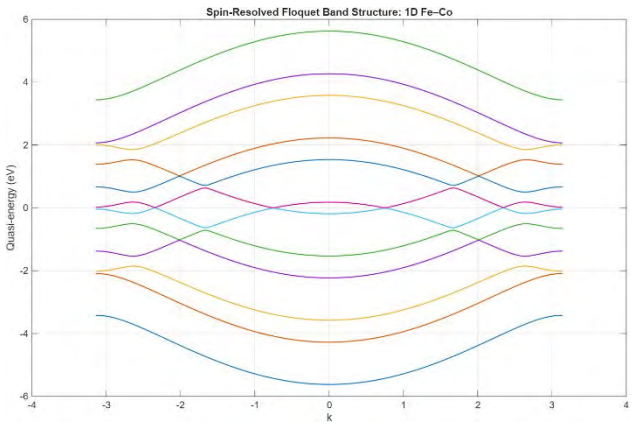

Figure 7. Spin-resolved Floquet band structure of 1D Fe–Co chain under periodic driving.

Differed from Fig. 1 and 4, in Fig. 7 could be observable pronounced avoided crossings and spin-polarized bands indicate strong hybridization and maximal photon-assisted band mixing.

Fig. 8 revealed harmonic composition of a selected Floquet band in Fe–Co. Blue/red curves depict spin-resolved orbital weights.

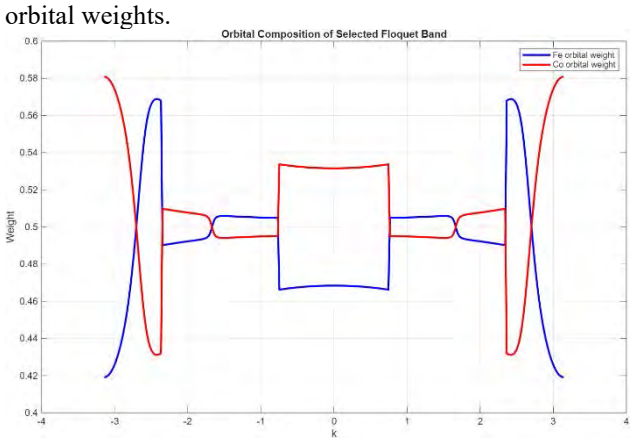

Figure 8. Harmonic composition of a selected Floquet band in Fe–Co. Blue/red curves depict spin-resolved orbital weights.

Finally, in Fig. 9 is represented chosen Fe-Co quasi-energy spectrum at k=0.

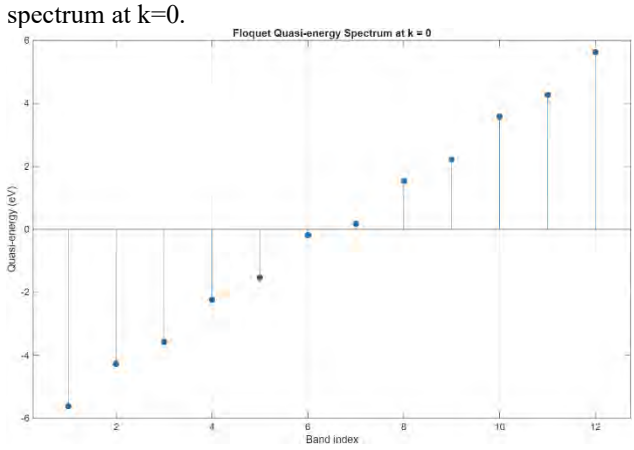

Figure 9. Quasi-energy spectrum at k = 0 for Fe–Co chain.

Fig. 9 showed largest photon-mediated level splitting among the motifs, which is consistent with stronger light-induced inter-orbital coupling within the present model.

Based on performed simulations, it was possible to derive certain conclusions regarding Floquet band structure, and impact of symmetry on hybridization.

The periodically driven Fe–Fe chain exhibits symmetric quasi-energy bands due to identical onsite energies and strong exchange splitting. In the absence of intrinsic onsite asymmetry, Floquet gaps emerge exclusively from photon-induced hybridization at resonance conditions. The resulting avoided crossings are symmetric in momentum space and spin-resolved but balanced. Consequently, light-induced band renormalization is moderate and uniformly distributed across the Brillouin zone.

In contrast, the Fe–Ni chain introduces intrinsic asymmetry ($\varepsilon_{Fe} \neq \varepsilon_{Ni}$), which leads to bonding–antibonding splitting already in the static case. Under periodic driving, this asymmetry produces momentum-dependent Floquet replicas with uneven orbital contributions. Avoided crossings become k-selective and less symmetric, indicating that photon absorption selectively enhances inter-orbital transitions rather than purely intra-sublattice processes.

Within the chosen parameterization, the case of Fe–Co chain exhibits the most pronounced avoided crossings of the orbitals. Due to strong Fe–Co orbital overlap and significant exchange splitting, the Floquet spectrum exhibits multiple pronounced avoided crossings and strong spin-dependent band renormalization. The quasi-energy dispersion reveals enhanced photon-induced coupling particularly in mid-spectrum bands, suggesting optimal resonance matching between driving frequency and intrinsic band separation.

Further, harmonic (photon) composition and Floquet mixing also could be commented. Analysis of harmonic weights reveals qualitative differences in light–matter interaction strength among the three motifs. In Fe–Fe, photon weight remains moderate and nearly symmetric between spin channels, consistent with uniform Floquet mixing. In Fe–Ni, photon weight becomes momentum-dependent and correlates with orbital asymmetry, reflecting selective hybridization between inequivalent

sites. In Fe–Co, photon weight is maximal in central quasi-energy bands and strongly spin-dependent, indicating enhanced light-induced inter-orbital coupling.

The increased photon weight in Fe–Co indicates stronger Floquet mixing associated with the chosen parameterization. The transport calculations further show that this enhanced Floquet mixing can contribute to photon-assisted transport, but does not constitute a universal predictor of current enhancement, which also depends on bias and the open-junction transport conditions.

To probe visual representation of the photon-assisted transport diagnostic for Fe-Fe, Fe-Ni, and Fe-Co pairs, numerical calculations are performed, relying on parameter set values, given in the frame of this model, Fig. 10.

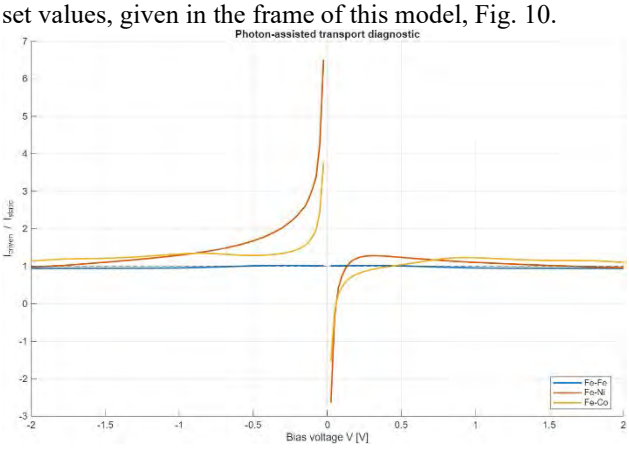

Figure 10. Photon-assisted transport diagnostic for Fe-Fe, Fe-Ni, and Fe-Co.

Fig. 10 is result of visualization of numerical calculations, representing driven/static current ratios, given in Table 4. The full transport calculations were performed over the bias range: $-2 \leq V \leq +2V$. For the statistical comparison in Table 4, the positive-bias interval: 0.1 < V < 2V, was considered, which avoids duplicating the corresponding negative-bias branch and provides a single consistent bias interval for comparing the three systems.

Table 4. Minimum, maximum, and mean driven/static current ratios, over the calculated positive-bias interval: 0.1 < V < 2 V.

Minimum ratio (Fe-Fe)	0.943988
Maximum ratio (Fe-Fe)	1.022696
Mean ratio (Fe-Fe)	0.970489
Minimum ratio (Fe-Ni)	0.952467
Maximum ratio (Fe-Ni)	1.282178
Mean ratio (Fe-Ni)	1.101671
Minimum ratio (Fe-Co)	0.587130
Maximum ratio (Fe-Co)	1.231292
Mean ratio (Fe-Co)	1.107227

Table 4 shows that the photon-assisted response is bias dependent, depicting to the fact that the Fe-Fe, Fe-Ni, Fe-Co ordering can not be asserted as universal, over the entire bias range. On the other hand, numerical calculations, probing their ordering at the representative bias of V=1, showed that the calculated photon-assisted current enhancement is 22.6% for Fe–Co, 10.4% for Fe–Ni, while Fe–Fe shows a 4.4% reduction (Table 5).

Table 5. Comparison between static current, driven current, and enhancement for Fe-Fe, Fe-Ni, and Fe-Co.

Static current (Fe-Fe)	1.677374e-05 A
Driven current (Fe-Fe)	1.602785e-05 A
Relative current change(Fe-Fe)	-0.044467 (-4.447 %)
Static current (Fe-Ni)	1.923191e-06 A
Driven current (Fe-Ni)	2.123273e-06 A
Relative current change(Fe-Ni)	0.104037 (+10.404 %)
Static current (Fe-Co)	1.330410e-06 A
Driven current (Fe-Co)	1.631574e-06 A
Relative current change (Fe-Co)	0.226369 (+22.637 %)

Thus, obtained results reproduces the manuscript's originally stated qualitative ordering at that particular bias (V = 1V), although it is bias-dependent, and given hierarchical ordering is not preserved for the all biases. At the representative bias V, the calculated enhancement follows Fe–Co > Fe–Ni > Fe–Fe. However, the full bias-dependent response demonstrates that this ordering is not universal. At V = 1.0 V, Fe–Co exhibits the largest enhancement among the three systems.

Fe–Ni exhibits moderate enhancement due to intrinsic asymmetry but weaker exchange effects.

Fe–Fe, despite strong magnetism, shows the smallest current amplification because of symmetric Floquet splitting and reduced orbital selectivity.

Finally, quasi-energy spectra at k=0, represented in Fig. 3, 6, and 9, enabled discussion about resonance structure of compared dimers. The quasi-energy spectra at k = 0 provided a compact visualization of resonance behavior. Based on Fig. 3, 6, and 9. Fig. 3, describing 1D Fe–Fe case, showed symmetric level splitting dominated by exchange effects. Fig. 6 (Fe–Ni case), exhibited uneven level spacing reflecting intrinsic onsite asymmetry. Fig. 9 (commenting Fe–Co case) displayed the largest avoided crossings, indicating strongest photon-mediated coupling.

The magnitude of level repulsion provides a qualitative indication of Floquet mixing strength, which is relevant to photon-assisted transport processes.

Accordingly, the combined Model I and Model II calculations illustrate the transport implications of Floquet mixing, orbital hybridization, exchange splitting, and open-junction transport conditions on the photon-assisted current.

4. CONCLUSION

This study demonstrates that combining Floquet band analysis with open-system transport modeling, provides a framework for examining how magnetic Fe–X motifs respond to periodic driving. The calculations show that orbital hybridization, exchange splitting, and Floquet mixing can strongly influence photon-assisted transport, while the magnitude and even the sign of the current modification depend on the applied bias. At the representative bias V = 1.0 V considered here, the Fe–Co parameterization exhibits the largest current enhancement among the three investigated motifs. The results suggests

that effective photon-assisted transport can benefit from the combination of strong hybridization, spin-dependent Floquet replicas, and appropriate resonant band matching. The unified theoretical framework offers a pathway toward rational design of light-controlled molecular magnetic junctions.

Acknowledgments

Abstract: *Modern surveillance and detection systems increasingly rely on thermal imaging cameras that detect objects based on temperature differences between the target and the surrounding environment. Military vehicles are particularly vulnerable to this type of detection due to significant heat generation from engines, mechanical friction, and exhaust systems, as well as heat transfer to external structural surfaces. As a result, these vehicles often exhibit a pronounced infrared (IR) signature, making them easily detectable under low-visibility or nighttime conditions.*

Recent research has therefore focused on natural structures exhibiting distinctive thermal behavior that may provide principles for passive infrared signature management. In this study, the hierarchical structure and thermal behavior of Morpho didius butterfly wings were investigated using scanning electron microscopy, digital holographic interferometry, differential scanning calorimetry, and infrared thermal imaging. The results revealed pronounced structural and thermal heterogeneity, including temperature-dependent heat capacity, non-uniform surface temperature distribution, and localized thermal inertia under external heating. These findings indicate that the hierarchical organization of the wing strongly influences heat storage, transfer, and spatial temperature distribution.

The identified structure–property–response relationship provides design principles for the development of bioinspired materials and surfaces capable of controlling heat distribution and delaying thermal equilibration. Such architectures may contribute to reduced infrared contrast under transient thermal conditions, providing a potential basis for passive thermal management and infrared signature reduction in military and other defense platforms.

Keywords: *IR signature reduction, thermal imaging detection, thermal masking, military vehicle protection, biomimetic material.*

1. INTRODUCTION

The continuous advancement of thermal imaging technology has greatly improved the performance of modern surveillance, reconnaissance, and target acquisition systems. In contrast to conventional optical sensors, thermal cameras detect infrared radiation emitted by objects according to their surface temperature. This capability allows reliable operation at night, in poor visibility, and under adverse weather conditions. As a result, thermal imaging has become one of the most effective methods for detecting, identifying, and tracking military vehicles on the modern battlefield [1, 2].

As thermal imaging sensors continue to improve in sensitivity and detection range, reducing the infrared (IR) signature of military vehicles has become increasingly important. [3] A vehicle's IR signature is primarily generated by heat sources such as the engine, exhaust system, tracks, and heated external surfaces, which can be detected by modern thermal sensors even under low-visibility conditions. [4] Effective IR signature reduction decreases the probability of detection, identification, and

DOI: 10.5937/OTEH26105S

tracking by enemy surveillance systems and infrared-guided weapons, thereby improving vehicle survivability on the battlefield.

A wide range of techniques has been proposed to mitigate the infrared signature of military platforms, including thermal barrier materials, low-emissivity coatings, exhaust suppression systems, active thermal management, and adaptive camouflage technologies. Although these approaches can substantially decrease the detectability of a target in the infrared spectrum, many of them introduce additional challenges related to system weight, power demand, operational complexity, and maintenance. As a result, recent research has increasingly focused on passive infrared signature management solutions based on advanced materials and engineered surface structures. [5]

Nature offers numerous examples of highly effective thermal regulation mechanisms that have evolved to help organisms survive in diverse and often extreme environments. Many biological systems possess sophisticated hierarchical structures that enable precise control of heat absorption, insulation, dissipation, and redistribution across multiple length scales. Inspired by these naturally optimized solutions, researchers have increasingly explored bioinspired design strategies for the development of advanced materials with tailored thermal properties. [6, 7] Such approaches provide valuable opportunities for creating passive thermal management and infrared camouflage materials capable of regulating surface temperature and heat transfer without external energy input.

In this work, several biological structures known for their distinctive thermal characteristics were examined to explore mechanisms that could be applied to infrared signature management. Experimental thermal analyses were conducted to evaluate their ability to influence heat accumulation, transfer, and spatial temperature distribution. By identifying the underlying principles responsible for these thermal responses, the study aims to contribute to the development of bioinspired materials and surface designs for passive thermal control. Such solutions may offer promising opportunities for reducing the thermal detectability of military vehicles and improving their survivability against modern infrared surveillance and targeting systems. [8]

2. MATERIALS AND METHODS

2.1. Biological Sample

The biological sample investigated in this study consisted of wings of the butterfly *Morpho didius*. The specimens were stored under ambient laboratory conditions in sealed glass containers, without any additional preparation prior to the experiments. The analyses were performed directly on the preserved wings.

Morpho didius was selected because of its highly ordered hierarchical wing architecture, which has been extensively recognized for its unique optical and structural properties. [9] The wing surface is covered with overlapping scales composed of complex micro- and nanoscale features, including multilayered ridge-lamella structures and air gaps. Beyond their well-known role in structural coloration, these nanostructures are expected to influence heat transfer, heat storage, and the spatial distribution of temperature across the wing surface. Their combination of geometry and material organization makes *Morpho didius* an attractive biological model for investigating passive thermal regulation mechanisms relevant to bioinspired infrared signature management.

2.2 Morphological Characterization

Standard microscopic techniques were employed as supporting methods for the characterization of the wing surface morphology (Figure 1). The microstructural features of the *Morpho didius* wings were analyzed using a scanning electron microscope (SEM), JEOL JSM-6610 LV (Japan). SEM imaging was performed in order to resolve the hierarchical micro- and nanoscale architecture of the wing surface. These observations provide a structural basis for interpreting the thermal behavior of the wing in subsequent analyses.

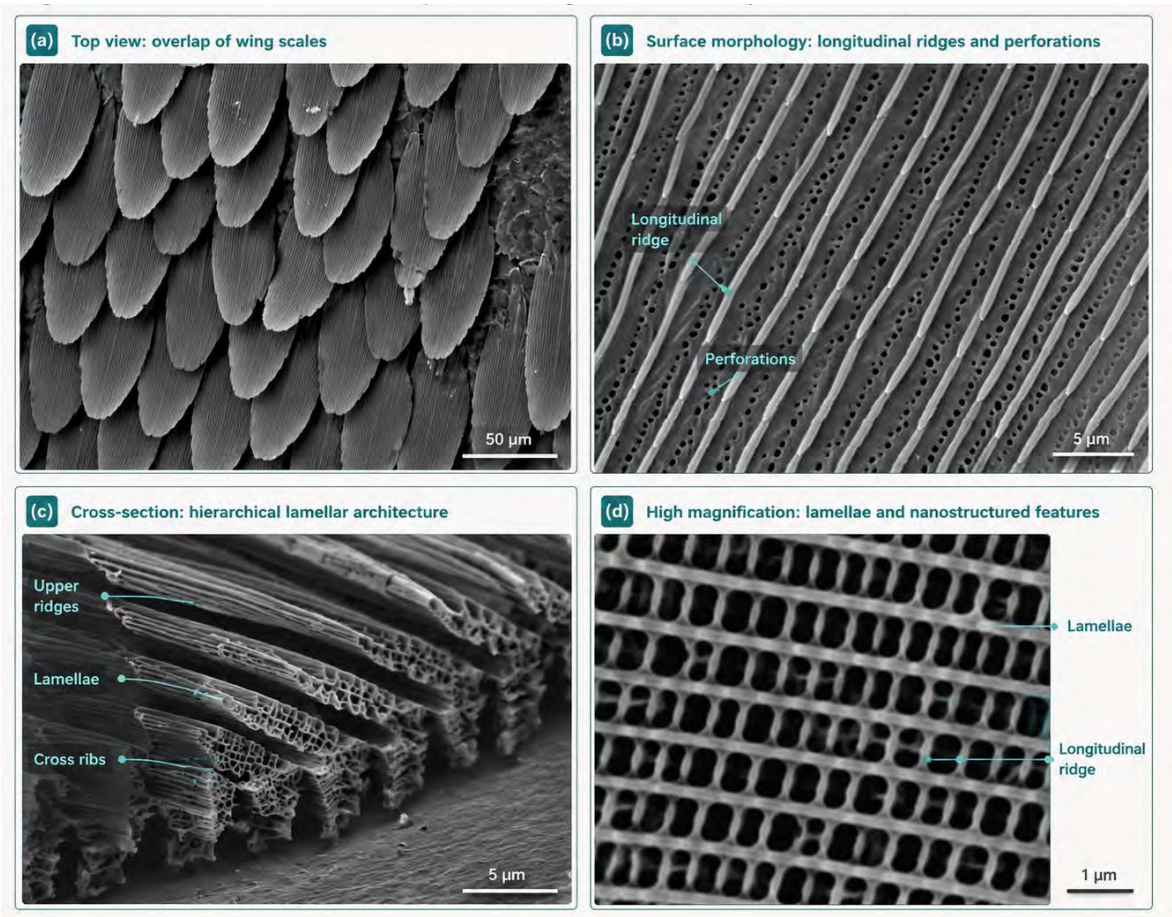

Figure 1. Scanning electron microscopy (SEM) characterization of *Morpho didius* wing scales at multiple hierarchical levels.

(a) Top-view of overlapping cover scales illustrating their roof-like arrangement.
(b) Surface morphology of an individual scale showing longitudinal ridges and perforated architecture.
(c) Cross-sectional view revealing the multilayered ridge–lamella organization responsible for the hierarchical microstructure.
(d) High-magnification image of the lamellar architecture, highlighting the periodic structural features that contribute to the wing's optical and thermal behavior.

In addition to SEM analysis, digital holographic interferometry was employed as a complementary technique for structural characterization of the *Morpho didius* wing. [9] Holography enables the recording of object deformation between two states of exposure, providing full-field, three-dimensional information about structural changes. In this study, it was used to monitor the dynamic response of the wing microstructure under external thermal stimulation. This approach allows observation of nanoscale displacements induced by heating in real time, providing insight into the mechanical and structural behavior of the hierarchical wing architecture. A simplified holographic setup was used for the measurements, while the general configuration of the system has been described elsewhere [10, 11].

2.3 Thermal Characterization

Differential scanning calorimetry (DSC) analysis was performed to determine the heat capacity of *Morpho didius* wing samples. Measurements were carried out using a DSC Q1000 instrument (TA Instruments, Delaware, USA). The samples were analyzed over a temperature range of approximately 22-140 °C, following the standard procedure provided by the manufacturer and in accordance with ASTM E1269-11. The obtained data were used to evaluate the temperature-dependent thermal response of the biological material. Particular features of the heat-capacity curve were observed in the low-temperature range of approximately 22-30 °C and in the range of approximately 86-95 °C.

Infrared thermal measurements were performed in order to observe the surface temperature response of the *Morpho didius* wing under controlled external heating. A FLIR A65sc thermal camera was positioned in front of the sample to record temperature distribution during laser irradiation. The sample was illuminated using a low-power 532 nm laser source, providing controlled localized heating of the wing surface. Thermal images were recorded with a spatial resolution of 640 × 512 pixels and a frame rate of 30 Hz. The data were processed using FLIR ResearchIR Max software (v4.40), enabling analysis of temperature distribution and temporal evolution of the thermal response.

3. RESULTS AND DISCUSSION

3.1 Morphological structure of *Morpho didius* wing

The microstructural organization of *Morpho didius* wing samples was analyzed using scanning electron microscopy (SEM), revealing a highly ordered hierarchical architecture composed of overlapping scales with well-defined micro- and nanoscale features. The surface is characterized by periodic ridge-lamella structures forming a multilayered arrangement with embedded air gaps, which together generate a complex three-dimensional morphology. Such structural organization results in a highly anisotropic surface, where geometry varies significantly across different length scales.

The observed nanoscale features are arranged in a repeating pattern that contributes to the overall structural stability and functional behavior of the wing. In particular, the combination of ridge spacing, lamella thickness, and internal voids suggests a heterogeneous medium in which local structural variations may influence both mechanical and thermal transport processes. This hierarchical organization is a key characteristic of biological photonic structures and is not limited to optical functionality alone.

In addition to static morphological analysis, digital holographic interferometry was used as a complementary technique to observe the dynamic response of the wing structure under external thermal stimulation. The results indicate that localized regions of the wing exhibit measurable nanoscale displacements when subjected to heating, suggesting that the structure is not mechanically rigid at all scales but rather exhibits subtle thermally induced deformation behavior. This dynamic response further confirms the complexity of the hierarchical architecture and its sensitivity to external energy input.

Overall, the combination of SEM and holographic observations demonstrates that the *Morpho didius* wing possesses a multi-scale structural organization with both static and dynamic characteristics. Such hierarchical complexity is expected to play an important role in governing heat distribution and energy transport within the material, providing a structural basis for the thermal behavior analyzed in the following sections.

3.2 Heat capacity behavior of *Morpho didius* wing

The thermal response of *Morpho didius* wing samples was investigated using differential scanning calorimetry (DSC), and the resulting heat capacity (Cp) as a function of temperature is presented in Figure 2. The obtained curve exhibits a pronounced non-linear behavior over the investigated temperature range (20–140 °C), indicating a temperature-dependent thermal response of the biological material.

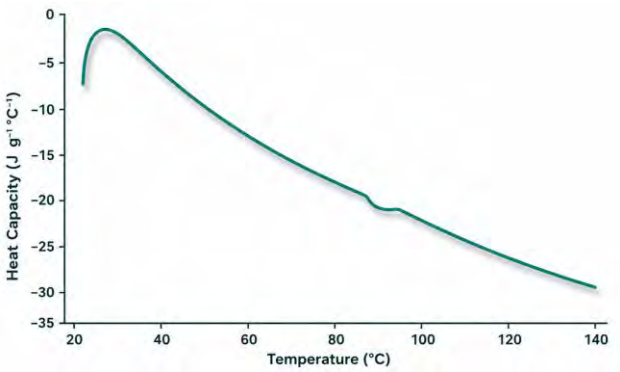

Figure 2. Heat capacity as a function of temperature for the *Morpho didius* wing obtained by differential scanning calorimetry (DSC). The observed nonlinear trend reflects the temperature-dependent thermal behavior of the hierarchical wing architecture and provides the basis for interpreting the subsequent infrared thermal response.

In the low-temperature region (approximately 22–30 °C), a pronounced change in heat capacity is observed, followed by a gradual decrease over the subsequent temperature range up to approximately 85 °C. This behavior may be associated with the relaxation of hierarchical micro- and nanoscale components within the wing architecture.

At approximately 86-95 °C, a distinct change in the slope of the curve is observed, followed by a continued gradual decrease in heat capacity toward 140 °C. This feature indicates a localized change in the thermal response of the material within this temperature range.

Overall, the non-linear temperature dependence of heat capacity indicates that the thermal response of the wing is not uniform over the investigated temperature range. The distinct changes observed in the approximately 22–30 °C and 86–95 °C regions suggest that different temperature intervals are associated with different thermal response characteristics of the biological material.

From an application perspective, such behavior is of particular interest for passive thermal regulation concepts, as temperature-dependent heat capacity may contribute to delayed heat propagation and reduced thermal contrast under transient heating conditions. These features are relevant for the design of bioinspired materials intended for infrared signature management.

3.3 Infrared thermal response

The infrared thermal response of the *Morpho didius* wing was investigated under controlled laser heating conditions using a FLIR A65sc thermal imaging camera. The recorded thermographic data provide a spatial and temporal representation of surface temperature distribution during external energy input, allowing analysis of heat propagation across the wing structure.

Upon laser irradiation, the wing exhibits a non-uniform temperature distribution, indicating heterogeneous heat absorption and dissipation across the surface. Localized regions respond differently to thermal excitation, resulting in spatial temperature gradients that reflect the underlying

hierarchical micro- and nanoscale architecture. The observed thermal behavior suggests that heat transfer within the structure is not homogeneous, but rather governed by localized structural variations.

Time-resolved thermal imaging further reveals that the cooling dynamics of the wing are non-uniform, with certain regions retaining heat for longer periods than others. This indicates the presence of localized thermal inertia, likely induced by structural complexity and air-trapped micro- and nanoscale features. Such behavior is consistent with the presence of multi-scale architectures that influence both heat storage and dissipation pathways.

The combination of spatial and temporal thermal variations observed in the FLIR measurements supports the existence of structure-dependent thermal regulation mechanisms within the wing. These findings are in agreement with the DSC results, which indicate temperature-dependent heat capacity behavior, suggesting that both macroscopic thermal response and thermodynamic properties are governed by the same hierarchical structural organization.

Overall, the infrared thermal response demonstrates that the *Morpho didius* wing does not behave as a thermally uniform material, but rather as a complex system with spatially varying heat transfer characteristics. This behavior is relevant for understanding passive thermal regulation in biological systems and may provide inspiration for the development of bioinspired materials for infrared signature management.

To integrate the morphological features, thermal properties, and observed infrared response into a unified interpretation, a schematic overview of the system behavior is presented in Figure 3.

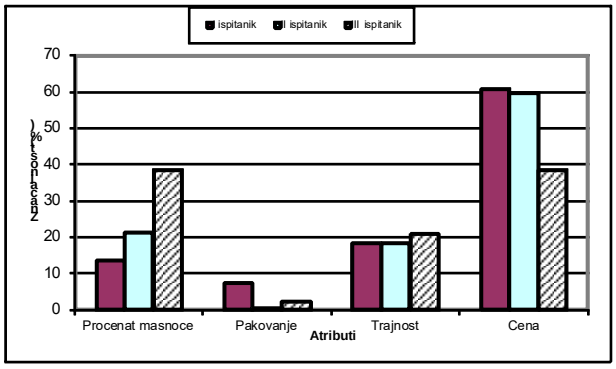

Figure 3. Structure-property-response framework illustrating how the hierarchical architecture of the *Morpho didius* wing governs its temperature-dependent thermal behavior and influences the apparent infrared response, providing inspiration for passive infrared signature management concepts.

4. ENGINEERING IMPLICATION

The observed structure–property–response relationship suggests design principles for bioinspired materials capable of advanced thermal regulation (Figure 4).

The observed thermal behavior may be particularly relevant to military platforms exposed to transient heating conditions, where infrared detectability is strongly influenced by the temperature distribution of external surfaces. The bioinspired approach proposed in this study could be translated into engineered multilayer or hierarchical surface structures designed to redistribute and temporarily store heat, thereby reducing local temperature gradients and delaying thermal equilibration. Such structures could potentially be incorporated into passive thermal-management layers, surface treatments, or camouflage-related materials applied to selected external components of military vehicles and other defense platforms. The present study does not experimentally demonstrate infrared signature reduction on a military vehicle; rather, it provides a biological model and experimentally observed structure–property–response relationships that may serve as a basis for the future design and testing of such materials under realistic military operating conditions.

Hierarchical architectures similar to those found in *Morpho didius* wings may enable a decoupling between bulk thermal properties and apparent infrared response, where the observed thermal signature is governed primarily by structural organization rather than homogeneous material behavior. Such mechanisms can lead to controlled heat storage and dissipation, resulting in reduced thermal contrast under transient heating conditions. This indicates that engineered surfaces based on similar principles could exhibit thermal behavior that is not directly representative of the overall system temperature, but instead reflects localized structural interactions with heat transfer processes. From an application perspective, such behavior is relevant for infrared signature management and the development of passive systems aimed at reducing thermal detectability of complex platforms.

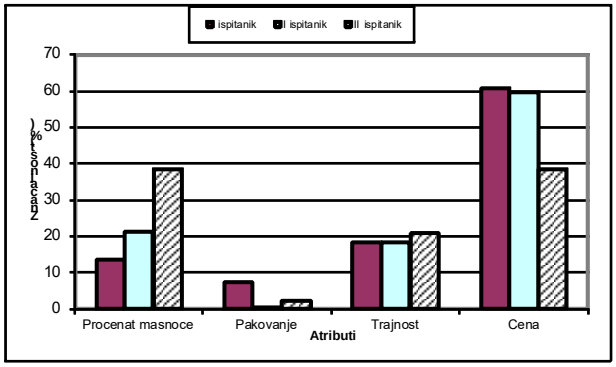

Figure 4. Bioinspired concept illustrating the relationship between hierarchical structural organization, heat redistribution, and apparent infrared response. The proposed mechanism demonstrates how structural design may govern thermal emission independently of bulk material properties, providing a framework for passive infrared signature management.

5. CONCLUSION

This study investigated the hierarchical structure and thermal behavior of *Morpho didius* butterfly wings to

identify structural principles relevant to passive thermal regulation and infrared signature management. The combined morphological and thermal analyses revealed a pronounced structure-dependent thermal response, characterized by temperature-dependent heat capacity, non-uniform surface temperature distribution, and localized thermal inertia under external heating.

The most significant finding is that the thermal response cannot be described solely by homogeneous bulk material properties. Instead, the hierarchical organization of the wing strongly influences heat storage, transfer, and spatial temperature distribution, resulting in a structure-dependent apparent infrared response. This structure–property–response relationship represents the principal functional insight obtained from the investigated biological system.

These findings provide a basis for bioinspired thermal management concepts in which hierarchical surface architectures are designed to control heat redistribution and delay thermal equilibration. Such an approach may offer a potential route toward reducing infrared contrast under transient thermal conditions and developing passive materials for infrared signature management.

Abstract: *This paper presents the results of an experimental investigation into the mechanical properties and quality assessment of welded joints and their corresponding base materials. The study focuses on high-strength armour steels, a class of steel that due to their high hardness and toughness under dynamic impact loads, are utilized in specialized protective structures. The primary objective was to evaluate the performance of the welded joints produced by a specific welding technology and MAG welding process and to compare their characteristics with those of the unaffected base metal. Tensile testing was conducted on a universal testing machine equipped with appropriate instrumentation for precise measurement of force and elongation. A total of 27 specimens were tested, including both transverse welded samples and base metal reference samples, ensuring a comprehensive dataset. The tests allowed to determine key mechanical parameters, including yield strength, ultimate tensile strength, percentage elongation after fracture, and reduction of area. Beyond the numerical results, a fractographic analysis was performed, with particular attention given to the location and morphology of the fracture. The fracture surfaces were examined to determine whether failure occurred in the weld metal, the heat-affected zone (HAZ), or the base material, providing critical insights into the weakest link of the joint. The obtained results were analysed to assess the efficiency of the welding MAG procedure.*

1. INTRODUCTION

The modern development of Infantry Fighting Vehicles (IFVs) stemmed from the continuous effort to enhance tank operational efficiency and battlefield survivability. This evolutionary requirement presented a major metallurgical and design challenge: developing armour systems capable of defeating small-arms fire and anti-tank projectiles while simultaneously maintaining optimal tactical, technical, and operational performance. Meeting these stringent criteria necessitated the development of specialized ultra-high-strength steels, commonly referred to as armour or ballistic steels, which continue to undergo active technological refinement [1-3]. Prominent among these materials is the commercial ARMOX series produced by the Swedish manufacturer SSAB Oxelösund, manufactured under strictly controlled production protocols [4]. Their primary function is to defeat kinetic energy threats such as small arms fire, armour-piercing projectiles, and explosive shrapnel while maintaining minimum structural weight to preserve vehicle mobility and operational efficiency. The superior ballistic and mechanical characteristics of ARMOX steels result directly from their tailored chemistry and manufacturing processes: ultra-low carbon content (C<0.3%) formulated specifically to improve field weldability and minimize cold-cracking susceptibility. Thermomechanical processing (TMP): utilized to achieve exceptionally high yield and ultimate tensile strengths [5,6]. However, despite these superior properties, joining armour steel plates into a coherent hull structure introduce localized material degradation. The intense heat input during the welding process inevitably alters thermo-mechanically processed microstructure, creating a localized softening zone or microstructural mismatch in the heat-affected zone (HAZ). Consequently, these welded joints represent potential critical structural vulnerabilities when exposed to dynamic or ballistic loading conditions. To address this

E-mail: vladicka@kg.ac.rs
DOI: 10.5937/OTEH26106M

challenge, this study presents a comprehensive experimental investigation into the mechanical properties, fracture behaviour, and overall quality assessment of ARMOX welded joints compared directly to the base metal.

2. MATERIALS AND METHODS

The objective of this research is to determine fundamental mechanical parameters (Re, Rm, percentage elongation A, and reduction of area Z) for different welded samples using specific welding technology. Based on obtained results, researchers investigated how welded joints perform under tensile loads, assess the technological efficiency of the applied welding procedure, and provide key insights into the structural integrity of armoured vehicles when subjected to severe mechanical stress. Testing was done by using a universal testing machine equipped with precise force and elongation instrumentation. A total of 27 specimens, comprising both transverse welded samples and base metal reference standards were tested to destruction. For testing and welding two different armour (ballistic) steels were used as well as one structural steel:

1. ARMOX 500T,
2. SWEBOR 500,
3. S355J0.

Besides armour steels, S355J0 steel was tested because in common military use the armour steels are often welded directly to structural steel, so the authors wanted to test the properties of that welded joints too.

In tables 1 and 2 the chemical composition and mechanical properties are given.

Table 1. Chemical composition of ARMOX 500T, Swebor 500 and S355J0

Steel type	Chemical composition, %									
	C	Si	Mn	Cr	Mo	P	S	Mo	Ni	B
ARMOX 500T	0.32	0.5	1.3	1.0	0.7	0.01	0.005	0.7	1.8	0.005
Swebor 500	0.30	0.5	0.4	NS	NS	0.015	0.005	NS	/	/
S355J0	0.22	0.55	1.6	/	/	0.035	0.035	/	/	/

*NS – not specified.

Table 2. Mechanical properties of G42CrMo4 cast steel [8]

Steel	R_m, MPa	$R_{p0.2}$, MPa	A, %	Z, %	Impact energy, J
ARMOX 500T	1650	1300	7-10	/	25 (R)
Swebor 500	1670	1200	9.5	/	25 (-40°C)
S355J0	510-680	355	14-18	/	27 (-20°C)

After materials selection, we approached to samples preparation. Samples were prepared in company Zastava TERVO, Kragujevac, Serbia.

For the purposes of testing and analysing the obtained results, base material samples of the selected steels were prepared, as well as test specimens for welded joints with all possible combinations. For initial testing purposes, a total of twenty-seven samples were prepared (shown in Fig. 1), according to standard SRPS EN ISO 6892-1 [7] and drawing given in Fig. 2, consisting of 9 different series with 3 samples in each series:

- Series 1 - Base material samples of S355 structural steel – 3 pcs.
- Series 2 - Base material samples of Swebor 500 high-strength steel – 3 pcs.
- Series 3 - Base material samples of Armox 500 high-strength steel – 3 pcs.
- Series 4 - Welded samples of S355 structural steel – 3 pcs.
- Series 5 - Welded samples of S355 structural steel and Swebor 500 high-strength steel – 3 pcs.
- Series 6 - Welded samples of S355 structural steel and Armox 500 high-strength steel – 3 pcs.
- Series 7 - Welded samples of Swebor 500 high-strength steel – 3 pcs.
- Series 8 - Welded samples of Armox 500 high-strength steel – 3 pcs.
- Series 9 - Welded samples of Swebor 500 and Armox 500 high-strength steels – 3 pcs.

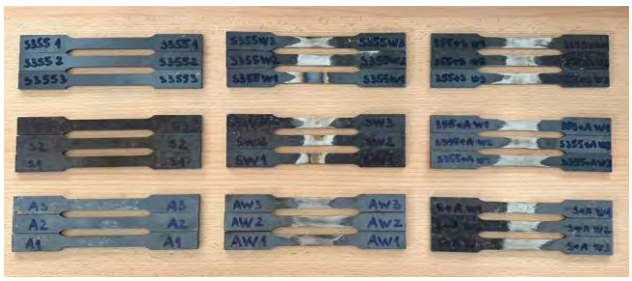

Figure 1. Prepared samples

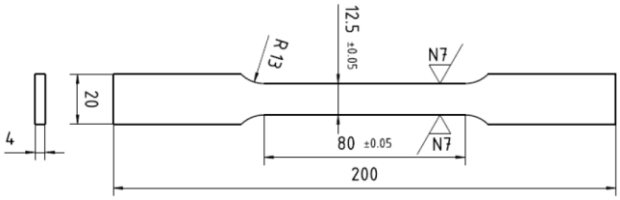

Figure 2. Drawing for samples preparation

Before testing the specimens to determine the mechanical properties of dissimilar steel welded joints, the mechanical properties of the base metals of the selected steels were determined.

The specimens for determining the mechanical properties

of dissimilar steel welded joints for all tested series were prepared through a sequence of manufacturing operations. The test specimen parts were first prepared for the welding process. Following laser cutting, the edges were bevelled so that the specimen parts could be welded. Each specimen was welded using the same method and with identical welding parameters.

Welding was performed with a runoff tab (backing tab) to prevent the formation of defects during the strike and extinction of the electric arc over such a short distance. After welding, the specimen was ground smooth at the joint location (Fig. 3). The welding was carried out using the MAG process with MIGWELD 307Si austenitic filler wire (diameter 1.0 mm) and M12 shielding gas (Ar + 0.5% CO_2). This filler wire was selected to prevent brittle fracture in the weld metal, as recommended by both the manufacturer [4] and other authors [6]. The chemical composition and mechanical properties of the filler wire are given in Table 3.

Figure 3. Appearance of welded sample

Table 3. Chemical composition of filler metal MIGWELD 307Si

Chemical composition, %				
C	Si	Mn	Cr	Ni
0.08	<1.0	7.0	18.5	9.0
Mechanical properties				
Rm, MPa	Rp0,2, MPa	A, %	KV, J	
560-660	>380	>35	32 (-196°C)	

For tensile testing, the Shimadzu servo-hydraulic testing machine (pulsator) (Fig. 4) and the MFA25 extensometer (MF Mess & Feinwerktechnik GmbH, Velbert, Germany) with a gauge length of 50 mm (Fig. 5) were used. Direct integration with the Servo 4830 controller and software enables automated data acquisition and real-time graphical visualization throughout each test. Following specimen mounting, the extensometer was positioned at the midpoint of the gauge length to measure real deformation. The device was carefully attached to prevent slippage during testing..

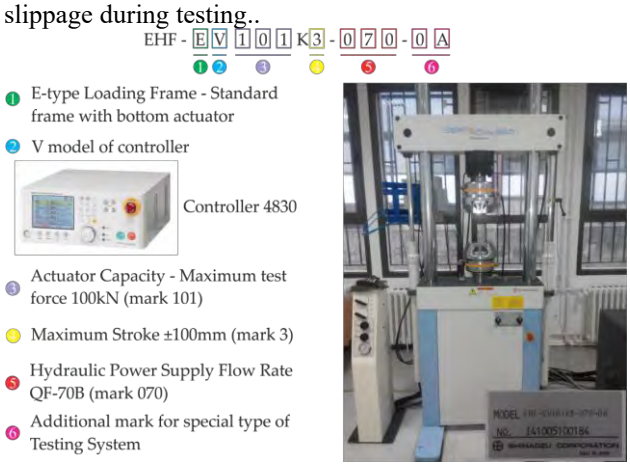

Figure 4. SHIMADZU servo-hydraulic machine

Figure 5. MFA25 extensometer

Tensile testing of the specimens was conducted at room temperature (23±5°C) at a constant displacement rate of 0.9 mm/min (Fig. 6). Prior to each test, zeroing of all measurement channels on both the testing machine and within the Servo 4830 software was carried out to ensure the accuracy and reliability of the recorded data.

Figure 6. Sample during testing

3. RESULTS AND DISCUSSION

Based on the tests performed on the specimens, an analysis of the obtained results was conducted. Following data processing using the DataViewer 4830 software, engineering stress–displacement curves were generated for each uniaxial tensile test. Furthermore, engineering stress–engineering strain curves along the A50 extensometer gauge length can also be plotted, as extensometer opening—and thus strain—was recorded continuously throughout all experiments.

For result analysis and comparison, engineering stress–displacement curves are presented for each tested specimen (Fig. 7). This approach was adopted because fracturing and necking did not consistently occur within

the extensometer gauge length. As can be clearly seen from the figure, the specimens fabricated from the S355 structural steel baseline material exhibit the highest elongation. Conversely, the high-strength steels, Swebor 500 and Armox 500, demonstrate high yield strength and tensile strength values, accompanied by lower elongation compared to the S355 structural steel.

To facilitate tracking and evaluation of the obtained mechanical properties across all tested specimens, the complete set of results is summarized in Table 3.

Analysis of the obtained results revealed that the mechanical properties of the welded joints significantly depend on the base metal type. For the S355 structural steel, relatively uniform plastic deformation was observed, with fracture occurring primarily in the base metal or in the immediate vicinity of the heat-affected zone (HAZ). Conversely, due to their higher hardness and specific microstructure, the armour steels exhibited reduced plastic deformation prior to failure, alongside a more pronounced localization of stress and fracture within the weld zone.

The test results indicate that the proper selection of welding parameters and filler material plays a vital role in determining the quality and load-bearing capacity of the welded joint, particularly for high-strength steels. Furthermore, it was confirmed that the heat-affected zone (HAZ) represents a critical region of the welded structure, as it undergoes substantial microstructural alterations and degradation of mechanical properties.

The conclusions made by this analysis is mostly aligned with the conclusions of other authors which find that superior ballistic and mechanical properties of ARMOX steels to a fully tempered martensitic microstructure, which simultaneously imposes inherent limitations regarding ductility and strain hardening capacity [1]. Under tensile and dynamic loading, these materials are particularly prone to stress localization and premature failure driven by stress triaxiality and local plastic instability [3]. When joining such ultra-high-strength steels, thermal cycles during welding inevitably induce structural heterogeneity across the joint zones, leading to localized variations in mechanical resistance. To mitigate the risk of brittle failure within the weld metal—a critical drawback highlighted in high-hardness steel joining—austenitic or ductile filler metals are routinely implemented [6]. Consequently, the observed reduction in overall elongation and the stress concentration within specific joint regions for example HAZ/weld metal, align with literature findings, confirming that the soft austenitic weld matrix absorbs plastic strain while protecting the joint against catastrophic brittle fracture.

5. CONCLUSION

Based on the experimental investigations and the analysis of the results, several key conclusions can be drawn regarding the mechanical behaviour of dissimilar welded joints under tensile loading. The tests were performed on welded joints made of S355 structural steel and two types of armour steels (Armox 500 and Swebor 500), aiming to evaluate the influence of the base metal on the load-bearing capacity, plastic deformation capability, and fracture behaviour of the welded joint.

The experimental results demonstrated that the mechanical properties of the welded joints significantly depend on the mechanical and metallurgical characteristics of the base metal. For the S355 structural steel, a relatively uniform stress distribution was observed during tension, along with a pronounced plastic deformation capacity prior to fracture (Fig. 7). In the majority of tested cases, fracture occurred in the base metal or in the immediate vicinity of the heat-affected zone (HAZ), indicating that the weld metal quality was not the critical weakness of the structure.

The results for the armour steels revealed a specific mechanical behaviour resulting from their high hardness and strength. These materials exhibited reduced plastic deformation capacity alongside pronounced stress localization within the heat-affected zone (HAZ), specifically in the coarse-grained HAZ adjacent to the fusion line. Such behaviour can lead to earlier fracture initiation, particularly in regions subject to microstructural alterations induced by the welding heat input.

A critical aspect of the analysis concerns the heat-affected zone (HAZ), where significant microstructural and mechanical changes take place. The findings confirm that the HAZ represents one of the most critical regions in welded structures, particularly for steels with high mechanical properties.

Consequently, it can be concluded that welded joints fabricated from S355 steel display favourable mechanical behaviour and good ductility, making them suitable for structural components subjected to static loads. Conversely, armour steels—despite their high strength and resistance to mechanical damage—require stringent control of welding parameters due to their heightened sensitivity to microstructural changes.

Test specimens comprised both similar joints (same base metals) and dissimilar joints (combinations of the aforementioned steels). Particular attention was devoted

to the preparation of the weld zone to ensure the representativeness of the results and to minimize the influence of geometric imperfections.

Abstract: *The development of wearable electronic systems has led to an increased need for compact, lightweight and mechanically flexible energy sources that can be integrated into textile materials. This paper analyzes flexible electrochemical energy sources intended for wearable systems, with a special focus on technical solutions, materials and possibilities for their integration into smart textiles. The main categories of flexible energy devices are discussed, including flexible batteries, supercapacitors and fiber energy systems, as well as their advantages over traditional batteries. Special attention is given to the role of advanced nanomaterials, such as graphene and MXene, which allow improvement of the electrochemical and mechanical properties of these devices. Different methods of integrating energy components into textiles are also analyzed, including weaving conductive fibers, printing functional materials and coating fibers. The paper also discusses the potential of these systems in military wearable technologies, where it is necessary to provide reliable power supply for numerous electronic devices with minimal increase in the mass of the equipment. The analysis presented in this paper indicates that flexible electrochemical energy sources represent a promising solution for the development of a new generation of smart textiles and wearable systems.*

Keywords: *flexible batteries, supercapacitors, wearable electronics, MXenes, textile integration.*

1. INTRODUCTION

The modern development of wearable electronic systems has led to a significant increase in the demand for reliable, lightweight, and energy-efficient power sources. In military applications, wearable electronic systems include communication devices, navigation systems, biomedical sensors, and systems for real-time data acquisition and processing. Traditional batteries exhibit limitations in the context of wearable systems, primarily due to their rigid structure, limited mechanical flexibility, and relatively high mass. These drawbacks affect mobility, ergonomics, and operational efficiency in military conditions [1].

In this context, flexible electrochemical energy sources represent a promising solution that enables the combination of electrochemical performance and mechanical adaptability [2]. The development of these systems is based on the application of advanced materials, such as nanostructured composites and two-dimensional materials, as well as innovative structural approaches that enable integration into textile structures. The integration of energy systems into smart textiles is of particular importance, as it enables uniform mass distribution, improved comfort, and the application of self-powered devices [3].

The aim of this paper is to provide a comprehensive analysis of flexible electrochemical energy sources, primarily flexible batteries and supercapacitors, with an emphasis on their performance and design constraints. Special attention is given to their comparison with conventional rigid battery systems, particularly in terms of mechanical flexibility and operational stability under deformation.

Furthermore, the paper examines recent technical solutions enabling flexibility, including novel architectures and the use of advanced materials such as MXene and other conductive nanostructures. A dedicated focus is placed on strategies for integrating these energy

E-mail: boska93va@gmail.com
DOI: 10.5937/OTEH26107G

sources into textile platforms, including weaving conductive fibers, printing functional materials, and coating fibers with electrochemically active layers.

Finally, the study explores the applicability of these systems in wearable technologies, with particular emphasis on military applications.

2. FLEXIBLE ENERGY SOURCES

Flexible electrochemical energy storage devices may be defined as systems typically composed of electrodes, current collectors, electrolytes, separators, and supporting substrates, designed to storage chemical energy and preserve performance under bending, twisting, folding, and stretching [4]. The rapid development of portable and wearable electronics, including wireless sensors, flexible displays, electronic skins, and foldable devices, has created a growing demand for these systems.

To enable fully autonomous wearable devices, flexible energy storage technologies must provide high energy density, long lifespan, fast charging and discharging capability, and operational safety at an acceptable cost [5]. In addition, these systems must maintain stable performance under mechanical deformation, requiring both electrical reliability and mechanical durability. As shown in Figure 1, significant research efforts have been directed toward designing materials and architectures capable of withstanding bending, twisting, folding, and stretching without compromising functionality [1].

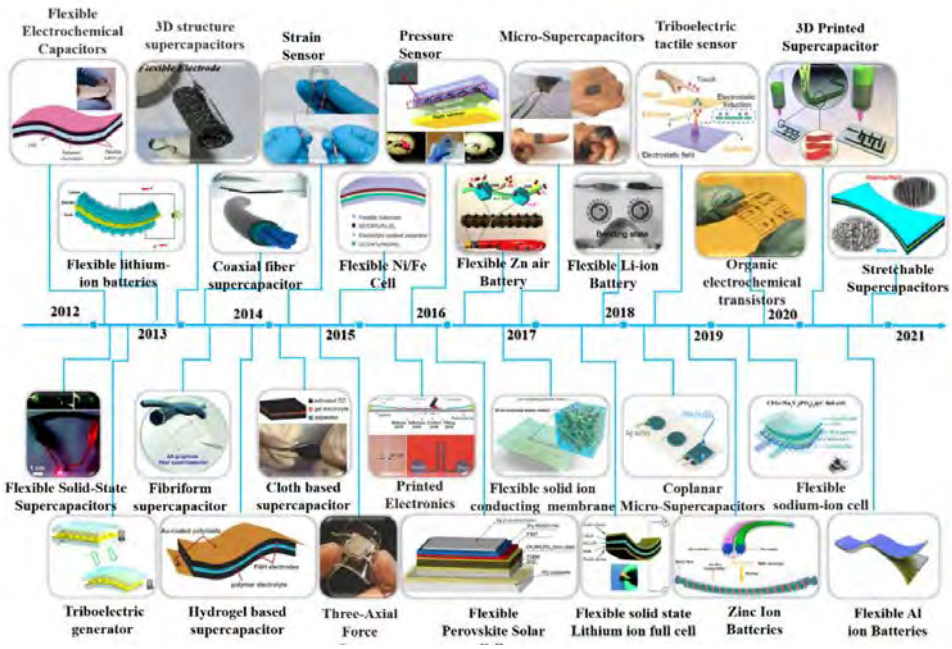

Figure 1. The evolution of flexible energy storage devices [1]

Flexible electrodes play a key role in meeting these requirements and are often designed without binders, conductive additives, or rigid current collectors. Namely, conventional electrode materials are typically rigid and mechanically brittle, limiting their use in flexible devices. Additionally, inactive binders may reduce capacity and introduce safety concerns, leading to the development of binder-free electrode designs [1].

Self-charging systems combining flexible energy storage with energy harvesting devices have also been developed, allowing wearable systems to achieve partial or continuous energy autonomy during operation [5]. The application of such storage + harvesting concept is illustrated in Figure 2 [2].

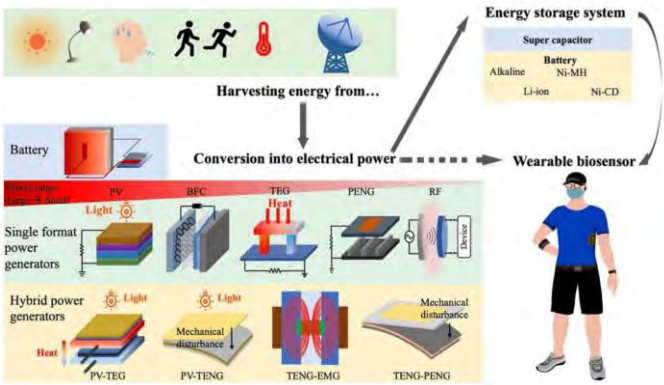

Figure 2. Schematic flow diagram of self-powered smart wearable sensors. Harvesting energy from various energy sources, converting into electric power, storing energy in storage section and powering wearable sensors. PV: photovoltaic; BFCs: biofuel cells; TEGs: thermoelectric generators; PENGs: piezoelectric nanogenerators; TENGs: triboelectric nanogenerators; RF: radio frequency; EMGs: electromagnetic generators [2]

Figure 2 illustrates the pathway from harvesting energy from various sources to its conversion into electrical energy, storage, and use for powering wearable sensors. The depicted energy sources include light, heat, radio waves, and vibrations. Photovoltaic (PV) systems are used for harvesting light energy, while biofuel cells (BFCs) represent an electrochemical energy source. Thermoelectric generators (TEGs) are used for harvesting thermal energy, whereas piezoelectric nanogenerators (PENGs) and triboelectric nanogenerators (TENGs) are technologies for harvesting mechanical energy. Radio-frequency (RF) systems utilize radio-frequency energy sources, while electromagnetic generators (EMGs) represent an additional technology for energy harvesting. The harvested energy is converted into electrical power, stored, and subsequently used to supply power to wearable sensors [2].

3. COMPARISON WITH TRADITIONAL BATTERIES

Traditional batteries, particularly lithium-ion batteries, remain the dominant energy storage technology due to their relatively high energy density and proven stability in portable electronic systems [1,4]. However, their rigid structure and limited mechanical flexibility represent a significant limitation for applications in wearable systems [1,2]. Flexible electrochemical energy sources have been developed to overcome these limitations.

While conventional batteries retain an advantage in energy density, flexible supercapacitors and hybrid systems exhibit higher power density and rapid charge/discharge capability, making them suitable for short-term but intensive energy demands in wearable devices [5,6]. This indicates that flexible energy sources are not a direct replacement for conventional batteries, but rather their complement in specific wearable applications.

Additionally, flexible systems enable new device architectures, such as fiber-based and textile-based configurations, which are not possible with traditional batteries. These approaches allow better integration into wearable systems, more uniform mass distribution, and improved ergonomics [7,8]. Furthermore, as highlighted in [9], distributed textile-based battery systems represent a paradigm shift compared to centralized conventional batteries. Instead of relying on a single rigid energy source, energy can be spatially distributed across clothing, significantly improving redundancy, fault tolerance, and ergonomic performance.

4. TECHNICAL SOLUTIONS FOR FLEXIBLE ELECTROCHEMICAL ENERGY SOURCES

The two most important flexible energy storage systems have been rechargeable batteries (flexible alkaline, zinc–carbon, polymer, etc.) and supercapacitors. Flexible rechargeable batteries offer high energy density but are limited by relatively low power density and slower charge/discharge rates. In contrast, supercapacitors provide high power density, rapid charge/discharge capability, and long cycle life, making them suitable for complementary applications.

4.1 Devices

4.1.1 Flexible Batteries

Flexible batteries represent one of the most important solutions for powering wearable electronic systems. The modern development of these systems is based on modifying conventional lithium-ion batteries using thin-film structures, polymer electrolytes, and flexible current collectors [4].

Two dominant structural configurations of flexible energy sources are ultrathin flexible structures (UFS) and one-dimensional fiber-based architectures (Figure 3). Depending on fiber density and structural orientation, fiber-based batteries can be classified as coaxial, multi-axial, or ultrathin flexible structures. Each configuration offers different advantages in terms of mechanical flexibility and electrochemical performance [4].

As shown in Figure 3, the following configurations can be observed: (a) coaxial one-dimensional structure, (b) multi-axial one-dimensional structures, (c) ultrathin flexible structure for AMAD, (d) spine-like structure, (e) interwoven structure, (f) node-type structure for AMAD, (g) serpentine interconnection, (h) origami and kirigami structures, and (i) coplanar electrode structure for IAMA [6].

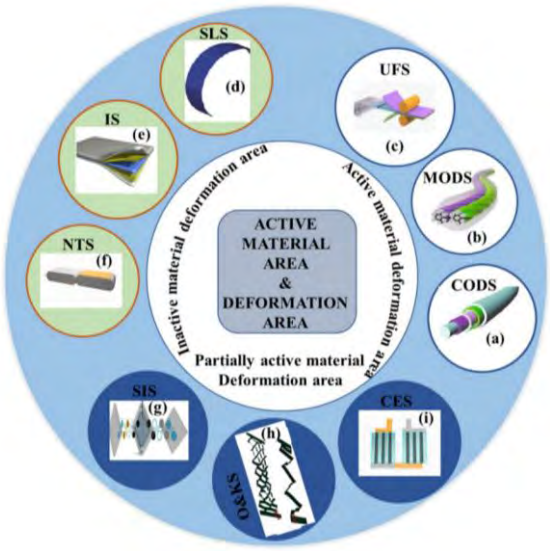

Figure 3. Structural designs for flexible and stretchable batteries, including active and inactive regions and deformation zones [4]

The integration of textile-based triboelectric nanogenerators (TENGs) with flexible batteries enables the development of self-charging hybrid systems. These systems can convert biomechanical energy generated during human motion into electrical energy, which is then stored in flexible batteries, extending operational time without external charging infrastructure [10].

Advanced design approaches include the development of fiber-based and textile-integrated batteries, as well as printed battery systems that can be applied in flexible wearable devices [9]. Additionally, techniques such as screen printing and inkjet printing allow deposition of functional materials onto textile substrates [7,8].

4.1.2 Supercapacitors

Flexible supercapacitors represent an alternative to batteries in applications requiring high power density and rapid charging, making them suitable for energy-demanding wearable systems [6]. Significant progress has been achieved in the development of fiber-shaped supercapacitors that can be directly integrated into textile structures. These systems are typically realized in coaxial, twisted, or layered configurations [11].

A schematic overview of supercapacitor operation, the number of publications in this field, and their integration into wearable electronics are shown in Figure 4 [6].

Fabric-based flexible supercapacitors show strong potential for integration into multifunctional wearable systems due to their high-power density and mechanical durability. Such systems can be directly embedded into military clothing, enabling energy delivery to components such as communication modules and sensor arrays [12].

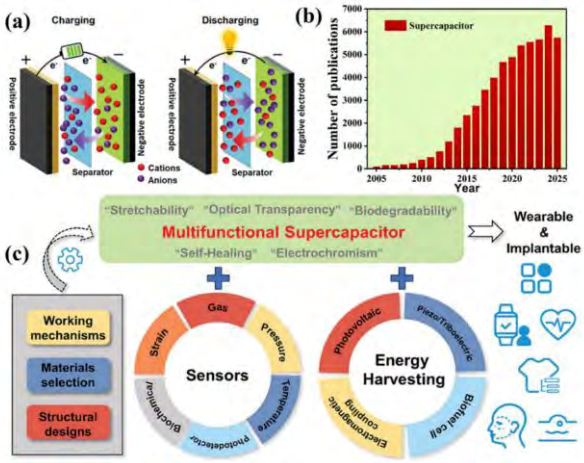

Figure 4. Overview of supercapacitor integration with sensors and electronic devices: (a) energy storage mechanisms, (b) publication trends, (c) schematic integration with wearable and implantable systems [6]

4.2 Advanced Materials

4.2.1 MXenes

Two-dimensional transition metal carbides, nitrides, and carbonitrides known as MXenes have emerged as a revolutionary class of materials for the development of multifunctional wearable electronic textiles [13]. Due to their unique structure and tunable surface functional groups, MXenes exhibit a range of exceptional properties, as shown in Figure 5 [13]. Their outstanding mechanical flexibility, hydrophilicity, tunable surface chemistry, and high electrical conductivity make them ideal for integration into textile systems [13].

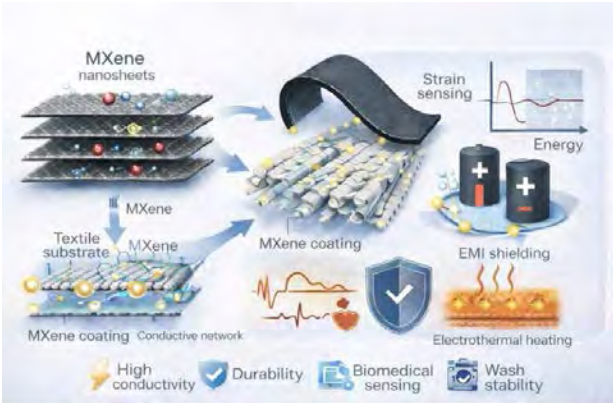

Figure 5. Structure and properties of MXenes [13].

Thanks to their large specific surface area and excellent electrical conductivity, MXenes enable improved energy and power density in flexible energy devices [14]. Particular attention has been given to their application in electrochemical energy storage, especially in supercapacitors. MXenes are highly suitable electrode materials due to their superior mechanical flexibility, energy density, and electrochemical performance [15].

Six main categories of MXene–polymer nanocomposites, classified based on dispersion state and macroscopic form, are shown in Figure 6 [16].

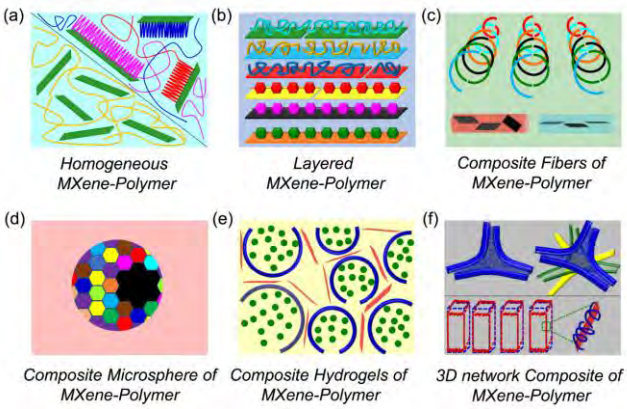

Figure 6. The Six Main Types of MXene–Polymer Nanocomposites [16]

4.2.2 Graphene

Graphene, a two-dimensional material composed of a single layer of sp^2-hybridized carbon atoms, has emerged as a key advanced material for flexible electrochemical energy storage systems. Owing to its exceptional electrical conductivity, high specific surface area, and outstanding mechanical strength, graphene exhibits a unique combination of properties that makes it highly suitable for wearable electronic applications. In addition, its intrinsic flexibility and low density enable seamless integration into textile-based platforms, supporting the development of lightweight and mechanically adaptable energy storage devices [7].

Due to its high specific surface area and excellent charge transport properties, graphene is widely used as electrode

material in flexible supercapacitors and batteries, enabling high power density through electric double-layer capacitance. It also maintains stable performance under mechanical deformation, which is essential for wearable systems. However, challenges such as sheet restacking and low intrinsic pseudocapacitance can limit its overall energy storage performance. To address these limitations, graphene is often combined with nanostructured materials and conductive polymers, forming composite systems with improved ion transport, enhanced capacitance, and better mechanical stability [17].

The schematic illustration (Figure 7) presents typical graphene-based composite electrode architectures, including polymer-functionalized and hybrid nanostructures. These designs enhance ion transport and prevent restacking, resulting in improved electrochemical performance and flexibility, which are essential for wearable and textile-integrated energy storage systems [17].

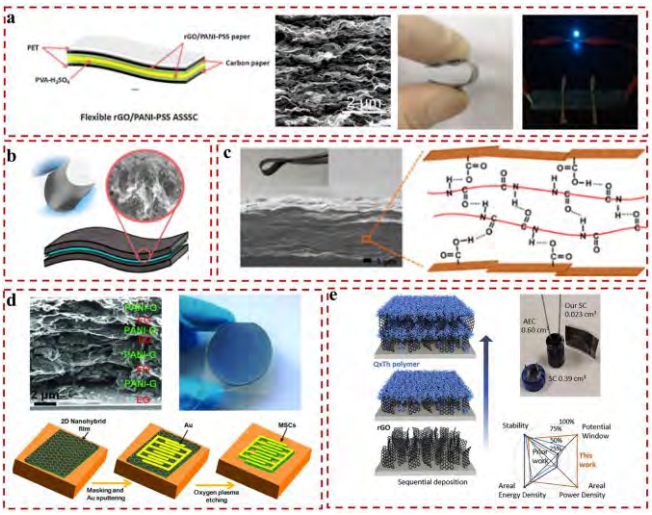

Figure 7. Flexible graphene-based supercapacitors [17]

5. INTEGRATION INTO TEXTILES

The integration of flexible electrochemical energy sources into textile structures represents a key step in the development of wearable systems, enabling direct incorporation of energy functions into clothing and equipment. This approach provides improved ergonomics, reduced weight, and uniform distribution of functional components, which is particularly important in military applications [8]. Modern integration strategies include weaving conductive fibers, printing functional materials, and coating textile substrates, often combining multiple methods to achieve optimal performance [7].

Printed distributed energy storage systems enable seamless integration into textile architectures without significantly altering mechanical properties, which is crucial for maintaining comfort and flexibility in long-term military use. [9]

5.1 Weaving Conductive Fibers

Weaving conductive fibers is one of the most direct approaches for integrating functional components into textiles.

Fiber-based supercapacitors and conductive fibers based on graphene, MXene, and conductive polymers can be incorporated during weaving or knitting processes, forming functional fabrics capable of storing and delivering energy [8].

5.2 Printing Functional Materials

Printing techniques provide a flexible and precise approach for integrating electrochemical components into textiles. Methods such as inkjet printing, screen printing, and direct ink writing (DIW) enable direct deposition of functional materials onto textile substrates, allowing fabrication of electrodes, interconnections, and energy devices with high geometric control [8,18]. Printing enables the development of thin-film, lightweight and flexible systems that can be adapted to complex textile structures.

Inkjet printing involves controlled deposition of microdroplets containing conductive or electrochemically active materials, enabling thin and uniform layers with high precision [18].

Screen printing allows thicker and more uniform layers, offering advantages in simplicity, cost-effectiveness, and scalability [18].

Direct ink writing (DIW) enables extrusion of viscous inks into continuous or 3D structures, allowing precise control over electrode architecture and mechanical stability [18].

5.3 Coating of Fibers with Functional Materials

Coating represents one of the simplest methods for integrating functional materials into textiles. Techniques such as dip-coating, spray-coating, and vacuum filtration enable deposition of thin conductive and electrochemically active layers while preserving textile flexibility [7,13].

Dip-coating involves immersion of the substrate in a solution, forming a uniform conductive layer after drying. Complex multilayer systems such as PU@PMA@EGaIn exhibit high conductivity (>10^5 S/m) and stretchability up to 500% [7].

Spray coating enables controlled deposition with efficient material usage, producing CNT–graphene/PU fibers with conductivity up to 8 S/m and stretchability up to 620% [7].

Vacuum filtration produces uniform nanocomposite films, such as aramid nanofiber/Ag nanowire papers with low surface resistance (0.12 Ω/sq) and high thermal stability (>500 °C), which represent model systems applicable also in flexible textile structures [7].

Figure 8. MXene/Ni coating process on PET fabrics [13]

By combining these methods, it is possible to achieve advanced functional structures, as illustrated in Figure 8. For example, the formation of a bilayer MXene/Ni coating on polyester fabric resulted in a significant improvement in electrical conductivity (up to 113.8 S/cm), hydrophobicity, and electromagnetic interference shielding effectiveness, while preserving the porosity of the material [13].

6. MILITARY APPLICATION

After discussing the integration of flexible energy devices into textile structures, it is important to consider their practical role in military applications. Modern wearable military systems require reliable, lightweight, and efficient energy sources to power communication devices, navigation systems, and biomedical sensors [2]. Flexible electrochemical energy sources provide a more uniform distribution of mass across uniforms and equipment, while supporting advanced wearable concepts such as smart uniforms with integrated systems for monitoring health status and tactical parameters [5].

In practical military applications, these technologies involve the direct integration of energy systems into uniforms, vests, and soldier equipment, allowing multiple devices to be powered without reliance on a centralized energy source [9].

These approaches are aligned with NATO soldier modernization programs, such as the “Future Soldier System” and related initiatives, which aim to digitalize and network the individual soldier as a combat platform. Within these systems, the soldier operates as a carrier of multiple electronic subsystems (communications, positioning, sensors), significantly increasing energy demands and necessitating distributed and flexible power solutions.

A specific application example includes powering wearable sensors for monitoring physiological parameters such as body temperature, heart rate, and fatigue level. These data enable real-time assessment of a soldier’s combat readiness, representing a key component of modern soldier system concepts [12].

Furthermore, NATO initiatives emphasize reducing logistical burden, where flexible and hybrid energy systems can significantly decrease the number of spare batteries a soldier must carry. The integration of multiple energy sources (storage + harvesting) enhances reliability, redundancy, and continuity of power supply under diverse operational conditions [12].

Overall, flexible electrochemical energy sources represent a key enabling technology for future soldier systems, as they support direct integration of energy functionalities into equipment, increase energy autonomy, and reduce logistical constraints.

7. CONCLUSION

Flexible electrochemical energy sources represent a key technological foundation for next-generation wearable electronic systems, particularly in smart textiles and military applications.

Their primary advantage lies in combining electrochemical performance with mechanical adaptability, enabling reliable operation under real-world conditions.

Comparative analysis shows that flexible systems complement rather than replace conventional batteries, forming hybrid energy architectures combining high energy density (batteries) and high power density (supercapacitors).

Advanced materials, particularly MXenes and their nanocomposites, significantly enhance conductivity, capacity, and mechanical stability.

Integration strategies such as fiber-based systems, printing, and coating enable distributed energy systems directly within textiles.

In military applications, these technologies support the “soldier-as-a-system” concept by reducing weight, improving ergonomics, and increasing energy autonomy.

Future research should focus on robust hybrid systems, interface optimization, and scalable manufacturing technologies.

Abstract: *Modern conflicts pose new challenges for personal ballistic protection equipment, particularly in the context of urban warfare and the use of unconventional tactical means. This study analyzes the performance of existing protective equipment, trends in the development of new materials and technologies, and the limitations of testing standards. Special attention is given to the use of unmanned aerial vehicles, which increase the risk of fragmentation and airborne threats, placing additional demands on the design, control, and application of protective equipment. Existing standards for ballistic protection testing are critically reviewed, highlighting limitations that may lead to insufficient assessment of effectiveness against current threats. The study also presents an overview of new composite and advanced materials that enable improved protection, lighter and more mobile equipment, as well as the potential application of modular and smart systems. The findings indicate the need for adaptation of standards and improvement of equipment design to ensure higher reliability and user safety under complex tactical and technologically advanced conditions. This study provides a systematic insight into the limitations and potential of modern personal ballistic protective equipment and contributes to a better understanding of its practical application.*

Keywords: *injury mechanisms, tactical requirements, advanced materials, testing standards.*

1. INTRODUCTION

The first quarter of the 21st century has brought radical changes to the nature of armed conflicts, shaped by the technological revolution and new geopolitical realities. Modern battlefields, such as the ongoing conflict in Ukraine, are characterized by asymmetric actions, non-linearity, and the massive use of high-tech systems, blurring the traditional boundaries between the front line and the rear. The dominance of artillery, coupled with the ubiquitous presence of unmanned aerial vehicles and loitering munitions, has presented personal ballistic protective equipment with challenges that exceed previous experiences from conflicts of earlier decades.

The primary issue facing modern protective systems is the discrepancy between advanced threats, materials, and existing testing standards. Injury analyses indicate that while modern vests effectively protect the torso, there is a shift in injury epidemiology toward unprotected body parts, such as the head, neck, and extremities, necessitating changes in equipment design and coverage.

The aim of this paper is a comprehensive performance analysis of existing protective equipment in light of modern threats, with a particular focus on the limitations of current standards. The study explores development trends in new materials, such as nanocomposites and non-Newtonian fluids, which promise enhanced protection with reduced mass and greater user mobility. Through a systematic review of injury mechanisms and technological innovations, the paper seeks to highlight the necessary directions for adapting protective systems to ensure reliability and safety in complex tactical conditions.

2. THREATS IN MODERN WARFARE

The end of the Cold War marked a profound turning point in the way armed forces are prepared, deployed, and equipped. Alongside shifts in military strategy, the defense industry itself underwent a radical transformation, embracing technologies of the Fourth Industrial Revolution to develop and produce advanced weaponry at unprecedented speed, even amid disruptions to global supply chains. Unlike in previous eras, innovations originating in the civilian sector—especially in information and communication technologies, electronics, and advanced materials—are now rapidly transferred to the military domain. This trend has allowed even smaller nations to field highly sophisticated, next-generation weapons systems, narrowing the technological gap on the battlefield.

The evolution of global military technology can be divided into four principal periods, each shaped by distinct security threats, forms of conflict, and dominant weapon systems [1]:

- Bipolar World – Late Cold War, 1970–1991
- Unipolar World – Post-Cold War, 1991–2007
- Omnipolar World – Multicentric, 2008–2022
- Polar Confrontation – "Collective West" vs. "Collective East," 2022–present

The current period is characterized by several notable trends [1]:

- Emergence of cyber threats and intensified non-kinetic operations
- Resurgence of strategic and tactical thermonuclear capabilities
- Emphasis on defensive systems and weapons with indirect effects, surpassing the focus on offensive and direct-effect arms
- Widespread use of unmanned aerial vehicles (UAVs) for both reconnaissance and combat roles
- Expansion of long-range missile systems across all military branches
- Revival of mass conventional ground forces, particularly infantry
- Increased investments in strategic reconnaissance, electronic intelligence, jamming systems, and command-information networks
- Growing focus on hypersonic missile technologies

The current battlefield has also seen the return of mass conventional ground forces, particularly infantry, alongside the growing importance of long-range missile systems, strategic reconnaissance, electronic intelligence, jamming capabilities, and command-information networks at all levels. Hypersonic missile technology has become a priority, reflecting the race to achieve strategic advantages in speed, range, and precision. Artillery has regained primacy on the battlefield, leveraging improved reconnaissance, rapid reaction times, and increasingly sophisticated precision munitions to prevent force concentrations and inflict maximum attrition. Traditional rapid offensive maneuvers have given way to combat resembling fortified or urban warfare, where proximity, complexity, and urban terrain pose heightened operational challenges.

Drones, particularly so-called "killer drones," have emerged as pivotal tools. Their impact stems from mass deployment rather than individual performance, enabling forces to penetrate enemy air defenses, shape battlefield engagements, and achieve operational objectives without risking personnel. Three categories of small drones stand out in terms of lethality: first-person view (FPV) drones, one-way attack (kamikaze) drones, and loitering munitions [2]. These systems effectively function as self-contained missiles. One-way attack drones deliver precise, self-detonating strikes, while loitering munitions hover over target zones, enabling attacks on beyond-line-of-sight objectives. Prominent examples include the U.S. Switchblade 300 and 600, as well as the Russian Lancet and KUB-BLA (Figure 1). Modern drone operations are increasingly treated as consumable assets, deployed not only for destruction but also to disrupt, exhaust, and manipulate enemy forces. Integrating drone intelligence and precision strikes reduces overall ammunition requirements, eases logistical burdens, and accelerates the tempo of artillery operations.

Figure 1. Switchblade 300 (left) and KUB-BLA (right)

The deployment of gliding bombs has also increased. These are traditional aerial bombs modified with deployable wings and guidance systems, allowing for extended range and improved accuracy. Mass production of these weapons reached 40,000 units in 2024 and 70,000 units in 2025 [3], proving decisive in recent conflicts, particularly on the Ukrainian battlefield.

2. DISTRIBUTION AND MECHANISMS OF COMBAT-RELATED INJURIES

In order to evaluate the performance of ballistic protective equipment, comparing injury mechanisms and their anatomical distribution provides critical insights into body armor efficacy. For this purpose, a comparative analysis was conducted between operations from 2001 to 2017 (primarily Iraq and Afghanistan) and the ongoing high-intensity conflict in Ukraine (2022–present).

The earlier period was characterized by asymmetric warfare with a high prevalence of improvised explosive devices (IEDs), standardized personal protective equipment, and near-immediate tactical medical evacuation. In contrast, the operational environment in Ukraine is defined by peer-to-peer conventional warfare, artillery dominance, widespread UAV deployment, variable armor coverage, and protracted casualty evacuation timelines.

While this comparison highlights shifts in dominant injury mechanisms and anatomical distributions driven by evolving threats and protective strategies, certain epidemiological and methodological limitations must be noted. Direct statistical comparison between these eras is confounded by variations in casualty documentation practices, differences in trauma system infrastructure, heterogeneity in worn armor capabilities, and distinct battlefield evacuation dynamics. Consequently, observed shifts reflect not only changes in ballistic armor performance, but also the broader systemic differences of these two operational environments.

2.1 Period from 2001. to 2017.

Analyses of combat injuries sustained during the conflicts in Iraq and Afghanistan indicate that, among 1,992,232 deployed US servicemembers, a total of 29,624 combat wounds were recorded in 7,877 casualties [4]. The anatomical distribution of these injuries consistently shows a predominance of extremity wounds, accounting for 51.9%, followed by injuries to the head and neck region (28.1%), while thoracic and abdominal injuries

each account for around 10%. These findings are corroborated across multiple studies, demonstrating a relatively stable distribution pattern despite variations in operational environments [5, 6].

A defining characteristic of these conflicts is the dominance of explosive mechanisms of injury (MOI), which account for roughly 74.4% of all combat casualties, significantly exceeding the proportion of gunshot wounds (19.9%) [5]. Explosive devices, including improvised explosive devices (IEDs), mortars, rocket-propelled grenades, and landmines, produce complex injury patterns characterized by multiple entry points, widespread tissue damage, and frequent involvement of multiple organ systems. In contrast to gunshot wounds, fragment-related injuries exhibit greater dispersion and are more likely to result in polytrauma.

Within explosive injury mechanisms, extremities remain the most frequently affected anatomical region (41.3%), followed by the head and neck (37.4%), while injuries to the torso are less common (8.8%) [5]. This distribution reflects the protective effect of modern ballistic equipment, which provides substantial coverage of the thorax and abdomen, while leaving the limbs, face, and neck comparatively exposed. Consequently, these unprotected or partially protected regions remain particularly vulnerable to injury, emphasizing persistent limitations in current protective system design. Supporting this observation, postmortem analyses from earlier conflicts indicate that over 20% of fatal penetrating injuries involved the facial region, particularly the midface [7].

Over the course of the Iraq and Afghanistan conflicts, a temporal shift in injury patterns has been observed, particularly concerning head injuries (Tables 1 and 2). The use of more effective protective equipment and body armour is a clear explanation for this shift in anatomical distribution of wounds. Surprisingly, the percentage of extremity injury did not change a lot, while with the protective measures, a decrease might have been expected. The proportion of casualties with head trauma increased significantly in both theaters, rising from approximately 20–30% in early phases of the conflicts to over 50% in later periods [8]. This trend coincides with the increased prevalence of explosive mechanisms and the widespread adoption of advanced body armor systems, which have reduced the incidence of fatal torso injuries but have not proportionally decreased injuries to exposed anatomical regions.

Table 1. Injured body region [8]

Body region	Afganistan			Iraq		
	2001 – 2006	2006 – 2009	2009 – 2017	2003	2004 – 2007	2008 - 2017
Head	30.3	58.8	59.0	20.9	34.8	53.0
Face	25.1	26.0	26.1	25.2	26.3	22.8
Chest	19.2	22.1	19.4	13.0	17.2	19.6
Abdomen	20.3	23.9	24.6	18.2	20.2	16.7
Extremity	51.1	47.4	50.0	47.0	50.9	45.0

Table 2. Mechanisms of injury [8]

Mechanism of injury	Afganistan			Iraq		
	2001 – 2006	2006 – 2009	2009 – 2017	2003	2004 – 2007	2008 - 2017
Explosive	61.4	80.5	77.4	70.1	78.7	79.8
Gunshot	29.1	17.9	21.2	18.4	18.1	16.6
Other	9.5	1.6	1.4	11.5	3.2	3.5

One hallmark of these conflicts has been the increase in explosive devices as primary MOIs. Explosive injuries significantly increase the likelihood of death, with a reported 34.1% increase in odds of killed in action (KIA) death in Afghanistan and a 114% increase in odds of KIA death and 72% increase in odds of DOW (died of wounds) death in Iraq [8]. These mechanisms frequently result in complex, multi-region trauma, further complicating treatment and reducing survival rates.

Traumatic brain injury (TBI) represents a major component of combat-related morbidity in these conflicts. Severe TBIs are most commonly caused by penetrating trauma, including injuries from fragments, shrapnel, and high-velocity projectiles. Approximately 3–6% suffer further infection, and 8–9.5% die due to their injuries [9].

2.2 Period from 2022. to the present

Among Ukrainian soldiers, the most prevalent injuries include extremity, facial, and neck wounds, as well as traumatic brain injury (TBI) [10]. These patterns reflect the high concussive forces associated with modern explosive weaponry, with injury zones predominantly affecting areas not effectively protected by current personal ballistic protective equipment. The conflict demonstrates both an intensification and magnification of the injury patterns previously documented among US personnel during operations in Iraq and Afghanistan, which can be attributed to the types of weapons deployed and the sustained exposure of combatants to high-intensity engagements over prolonged periods.

Modern explosives, including thermobaric devices, have resulted in a broader range and increased severity of traumatic injuries despite protective measures. These weapons are associated with burns, pulmonary trauma, and blast-related TBIs, often circumventing the protective effects of conventional body armour as well as fortifications such as trenches and bunkers. The Russian Federation's use of high-energy explosives has been linked to critical abdominal, vascular, and head injuries,

frequently involving penetrating fragments or secondary blast impacts [10].

A study analyzing 17,692 injured Russian soldiers between 2022 and 2024 on the Ukrainian battlefield evaluated both the tactical delivery platforms and the resulting injury mechanisms across different echelons of care [11]. As presented in Table 3 (derived from a cohort of n=5813 casualties admitted to tertiary military care), three-quarters (75.5 %) of casualties were targeted by UAV systems (including dropped munitions and FPV kamikaze drones), demonstrating the shift in modern firepower delivery. Importantly, UAVs function as tactical delivery platforms rather than distinct biophysical trauma vectors. The explosive payloads delivered by UAVs (such as small mortar shells, shaped charges, and antipersonnel grenades) predominantly inflict high-velocity fragment impacts and blast wave phenomena.

Table 3. Distribution of wounded casualties by primary threat delivery platform / weapon system [11]

Threat category		Percentage
Gunshot fire		4
Fragment and blast injuries from	artillery shells	20.5
	UAV	75.5

This distinction is further reflected in Table 4, which categorizes casualties strictly by terminal biophysical trauma mechanism. Unlike Table 3, the data for Tables 4, 5 and 6 originates from forward medical battalions (Level 2 care) evaluating 2014 casualties during the active operational phase and 1186 during the inactive phase. The prevalence of these injury mechanisms across different phases of hostilities is presented in Table 4, while their corresponding anatomical distribution is shown in Table 5. Across both phases, fragment impacts (66.5%–79.3%) and blast trauma (5.2%–15.1%) represented the primary biophysical mechanisms of wound creation.

Table 4. Prevalence of combat casualties categorized by terminal injury mechanism across operational phases. [11]

Mechanism of injury	Active phase	Inactive phase
Bullet wounds	5.6	2.2
Fragment injuries	79.3	66.5
Blast injuries	15.1	5.2
Other	/	26.1

Penetrating cavity and deep injuries, including neck wounds, were observed in 69% of cases during the active phase and 23.8% during the inactive phase of hostilities (Table 6). The proportion of lightly wounded patients increased markedly from 22.4% to 72.3%, reflecting the positional, low-intensity nature of current hostilities and the reduction of heavy enemy firepower. This trend also corresponds with the notable decrease in penetrating injuries, from 69% during the active phase to 23.8% during the inactive phase.

Table 5. Anatomical distribution of dominant injuries across operational phases [11]

Localisation	Active phase	Inactive phase
Head	4.5	11
Neck	2	0.7
Chest	6.9	8.9
Abdomen	5.2	5.9
Extremity	81.4	58.2

Table 6. Incidence of penetrating injuries [11]

Localisation	Active phase	Inactive phase
Head	58.2	25.9
Neck	56.1	25.9
Chest	75.2	18.1
Abdomen	75.2	27.7

Extremity injuries remain the most common among Russian casualties, with frequencies of 81.4% and 58.2% across different phases. In the inactive phase, 917 casualties (77.3%) presented with extremity injuries, though severe cases involving extensive soft tissue loss, amputations, or long bone fractures have decreased to 10.1%, compared to up to 60% during the active phase. Combined injuries without a dominant lesion rank second (14.5%), with 90.1% classified as mild. Head injuries constitute 11% of cases, of which only 21.4% involve TBI, primarily affecting the unprotected facial region, including the eyes. Thoracic injuries also deserve specific attention. The proportion of penetrating chest injuries has decreased to 18.1%, compared to 75.2% at the beginning of hostilities.

3. PERFORMANCE OF BODY ARMOUR

A comparative analysis of combat-related injuries in the conflicts in Iraq and Afghanistan (2001–2017) and the ongoing Russo-Ukrainian war (2022–2026) provides a functional framework for evaluating the operational performance and limitations of modern personal ballistic protection equipment. The observed injury patterns, together with their temporal and spatial shifts, directly reflect both the protective effectiveness of body armour and the evolving nature of battlefield threats.

Across both conflict periods, extremity injuries remain the most prevalent category, accounting for approximately 50–52% of casualties in Iraq and Afghanistan and reaching up to 81.4% among Russian forces, with similar trends reported among Ukrainian personnel. This persistent dominance highlights the inherent limitation of body armour systems, which primarily protect the central torso while leaving the limbs exposed (Figure 2).

Head, face, and neck injuries show an increasing relative prevalence over time. In Iraq and Afghanistan, head and neck trauma constituted approximately 28% of injuries, with an increasing trend during later stages of conflict. In the Russo-Ukrainian war, these injury types, including TBI, remain prominent and are further amplified by the increased use of UAV-delivered payloads and thermobaric weapons. This shift highlights the impact of modern weaponry and the limitations of protective equipment in shielding these regions.

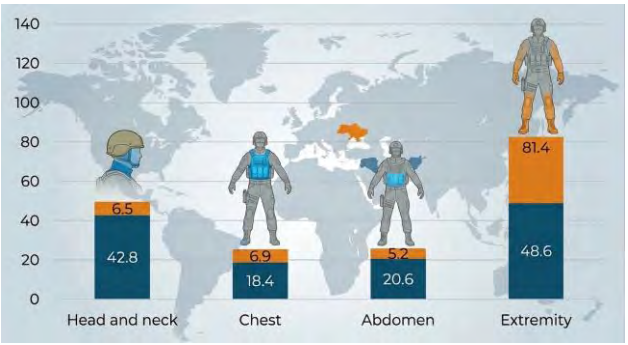

Figure 2. Change in anatomical distribution of injuries

Explosive mechanisms represent the dominant cause of injury in both conflict environments, with an increased impact in the recent war (Figure 3). In Iraq and Afghanistan, explosives accounted for approximately 74% of combat casualties, while in the Russo-Ukrainian conflict, they contribute to a majority of injuries across both sides. Fragments and blast induced injuries not only produce a higher proportion of multi-region and penetrating injuries but also result in more severe trauma, including burns, pulmonary injury, and TBI.

The distribution of thoracic and abdominal injuries demonstrates the effectiveness of modern ballistic protection. In Iraq and Afghanistan, these injuries accounted for approximately 10% of casualties, while in Ukraine, the proportion of penetrating thoracic injuries has decreased markedly from 75.2% during the active phase to 18.1% in later phases. This confirms that modern body armour systems, combining soft and hard ballistic elements, are highly effective in mitigating lethal injuries caused by rifle rounds and fragmentation. Ceramic plate systems significantly reduce mortality by preventing penetration of the thorax and upper abdomen, with remaining injuries often associated with coverage gaps or edge impacts. Historical data from explosive incidents, including IEDs and mines, further confirm that torso injuries are often mitigated in severity due to ballistic protection [12].

Figure 3. Change in the mechanism of injuries

Despite this effectiveness, current body armour systems exhibit critical limitations. Most importantly, they do not protect against blast overpressure, which has become a defining injury mechanism in modern warfare. Traumatic brain injury, particularly blast-induced TBI, is now considered a signature injury of modern warfare. While armour effectively protects against fragments, it does not mitigate the transmission of pressure waves, which can cause significant neurological damage even in the absence of external head penetration.

The protection offered by current systems is achieved at the cost of increased weight and reduced mobility. Body armour is heavy, thermally burdensome, and ergonomically restrictive, leading to decreased soldier mobility, increased fatigue, and impaired physical and cognitive performance. In hot operational environments, heat retention further increases the risk of thermal stress, thereby limiting sustained operational effectiveness.

Despite advances in protective design, significant portions of the body still remain unprotected. Regions such as the head, face, neck, groin, lateral torso, and extremities are particularly vulnerable, especially under high-energy ballistic and explosive conditions. While soft armour protects against lower-energy fragments and pistol rounds, it is insufficient against rifle projectiles. Hard armour systems, although effective, are limited to coverage of the central torso due to weight constraints, making full-body protection impractical without the use of emerging technologies such as exoskeletons, which remain in developmental stages with potential long-term applicability.

The protective effect of body armour has also influenced injury epidemiology. While body armor significantly reduces the incidence of fatal torso trauma, it does not lead to a proportional reduction in overall casualty rates. Instead, the introduction of advanced body armor alters the observed epidemiology of operational injuries: casualties who previously would have succumbed to lethal torso injuries now survive, thereby shifting the distribution of recorded non-fatal injuries toward unprotected anatomical regions (such as the head, neck, and extremities). Consequently, the apparent increase in non-torso injuries reported in combat databases [7] reflects a survivability bias, driven by improved survival from otherwise fatal torso trauma and exposure to modern threats such as explosive devices, urban combat, and targeted fires, rather than an inherent vulnerability induced by the armor itself.

4. NOVEL BALLISTIC PROTECTION MATERIALS

The development of materials for ballistic protection has evolved significantly in recent decades, driven by the need to simultaneously address multiple threats, including high-velocity projectile penetration, blast loading, and stab or spike resistance. Modern protective systems are no longer based on a single material solution but rely on hybrid, multifunctional architectures that combine different classes of materials to optimize energy absorption, dissipation, and structural integrity. Recent research trends emphasize lightweight, flexible, and adaptive materials, particularly those enabled by nanotechnology, advanced polymers, and shear thickening fluids and gels.

4.1 High-performance fibers and polymer composites

High-performance fibers remain the foundation of modern soft and hybrid armor systems. Materials such as aramid fibers and ultra-high molecular weight polyethylene (UHMWPE) exhibit exceptional specific strength and energy absorption capacity, making them indispensable for ballistic protection [13].

Recent advances have focused on improving interfacial properties and structural organization within composite systems. For instance, SiC nanoparticle-modified UHMWPE/polyurethane composites have demonstrated enhanced ballistic limits due to improved load transfer and reduced interlayer slippage [14]. Similarly, multilayer polymer fiber composites have been optimized to maximize energy absorption through controlled delamination and progressive failure [15].

Polymer matrix modifications, including epoxy toughening and thermoplastic reinforcement, contribute to improved impact resistance and structural stability [16].

In addition to projectile resistance, these materials also contribute to blast mitigation by distributing stress waves over larger areas and reducing backface deformation.

4.2 Shear thickening fluids and gels

One of the most promising developments in recent years is the integration of shear thickening fluids (STFs) and shear thickening gels (STGs) into textile and composite systems. STFs and STGs are non-Newtonian materials that exhibit a dramatic increase in viscosity under high shear rates, enabling dynamic stiffening during impact events. This property allows flexible materials to behave as rigid protective barriers upon loading.

Extensive research demonstrates that STF-impregnated fabrics significantly enhance both ballistic and stab resistance. The increased inter-yarn friction and restricted fiber mobility lead to improved energy absorption and reduced penetration depth [17, 18]. Furthermore, the incorporation of nanoparticles such as silica, graphene oxide, or clay into STFs further enhances their rheological performance and protective capabilities [19].

Recent innovations include hybrid systems combining STFs with ceramic particles such as boron carbide (B_4C), which provide additional hardness and penetration resistance [20]. These systems are particularly effective against sharp objects and low-velocity threats, where traditional fiber systems may fail.

Beyond ballistic protection, STFs also show significant potential in blast mitigation. Their ability to absorb and dissipate energy through reversible phase transitions contributes to reduced transmitted forces and improved wearer safety [21].

4.3 Nanocomposites

Nanotechnology has emerged as a transformative approach in the design of advanced ballistic materials. Polymer nanocomposites, reinforced with nanoparticles such as carbon nanotubes (CNTs), graphene, MXene, or ceramic nanofillers, exhibit significantly improved mechanical properties, including stiffness, toughness, and energy absorption capacity [22, 23].

The primary advantage of nanocomposites lies in their ability to modify material behavior at the molecular and interfacial level. For example, CNT-reinforced UHMWPE fabrics demonstrate enhanced impact resistance due to improved load distribution and crack bridging mechanisms [24]. Similarly, graphene-based nanocomposites offer exceptional strength-to-weight ratios and improved thermal and electrical properties, which can be beneficial for multifunctional protective systems.

The addition of hard nanoparticles increases surface hardness and reduces local deformation, thereby enhancing stab resistance [25]. Furthermore, nanostructured coatings and interlayers can significantly improve interfacial bonding and prevent delamination under dynamic loading.

Despite their advantages, challenges remain in terms of scalability, cost, and uniform dispersion of nanoparticles. Nevertheless, ongoing research continues to address these limitations, making nanocomposites a key area in ballistic protection.

4.4 Ceramic materials and hybrid armor systems

Ceramic materials such as alumina, silicon carbide (SiC), and boron carbide (B_4C) are widely used in hard armor systems due to their high hardness and compressive strength. Their primary function is to disrupt and erode incoming projectiles, thereby reducing their penetration capability. Recent studies highlight the superior performance of boron carbide in terms of hardness and low density, making it particularly attractive for lightweight armor applications [26].

Ceramics are inherently brittle, which limits their ability to absorb energy and makes them susceptible to cracking under repeated impacts. To overcome these limitations, modern armor systems employ hybrid configurations, combining ceramic front layers with fiber-reinforced composite backings. This approach allows efficient projectile fragmentation by the ceramic layer, followed by energy absorption and distribution by the composite layers [27].

Functionally graded materials (FGMs) represent an emerging concept in this domain. By gradually varying material properties across the thickness, FGMs can reduce stress concentrations and improve overall impact resistance [28]. Such materials are particularly promising for multi-threat protection, as they can be tailored to respond differently to various loading conditions.

4.5 Lightweight and multifunctional materials

The demand for lightweight and multifunctional protective systems has led to the exploration of novel materials such as aerogels, sandwich composites, and bio-inspired structures. Silica aerogels, for example, offer

extremely low density and high energy absorption capacity, making them suitable for impact mitigation and thermal protection [31].

Sandwich structures, combining different materials in layered configurations, enable optimization of mechanical performance by exploiting the synergistic effects of each component. These systems can be tailored to address specific threats, including ballistic impact, blast loading, and stab resistance.

Bio-inspired materials represent another promising direction [23]. Inspired by natural protective systems such as nacre or armor shells, these materials utilize hierarchical structures to achieve exceptional toughness and energy dissipation. Such designs have shown significant potential in improving impact resistance while maintaining low weight.

5. TEST STANDARDS LIMITATIONS

Standards for testing personal protective ballistic equipment, such as NIJ standards in the United States and GOST standards in Russia, have been developed for different operational conditions, which leads to differences in the definition of protection levels, threat types, and testing methods. One of the key limitations of the NIJ 0101 family of standards relates to Level IV protection, specifically the issue that certain ammunition (e.g., 7.62 mm with an M993 projectile) has greater penetration capability than the reference round used in the standard. It is important to emphasize that the NIJ standard was primarily developed for law enforcement use, where threats are statistically limited to handgun and standard rifle calibers, whereas military battlefields are characterized by the presence of a wide variety of ammunition calibers and projectile types.

In contrast, in the Russian Federation, the GOST 34286-2017 standard recognizes the need for higher protection levels corresponding to military conditions. The introduction of Level BR6 represents a response to the emergence of extremely high-penetration ammunition, where testing is conducted using 12.7×108 mm caliber ammunition from a distance of 50 meters. However, this standard only considers the presence or absence of penetration, without addressing the degree of trauma to the human body.

The most pronounced problems are observed in helmet testing. The NIJ 0106.01 standard has not been revised since 1980, making it insufficiently adapted to modern design solutions and threats. Over the past decades, there has been significant development in helmet design, particularly high-cut variants that provide better compatibility with communication and optical equipment but simultaneously reduce the protective surface area. Such helmets also feature a greater number of shell openings for mounting equipment. The standard does not account for these changes in geometry, which leads to problems in uniform testing. Due to the outdated nature of the NIJ 0106.01 standard, in practice, ammunition for Level IIIA from the NIJ 0101 standard family is often used for testing.

An additional limitation in ballistic helmet evaluation is the small number of standards designed to quantify non-penetrating neurotrauma. Modern combat helmets reliably arrest small-arms projectiles and fragments; however, energy transfer and shock wave propagation remain critical vectors for Traumatic Brain Injury (TBI). In combat environments, TBI represents a highly heterogeneous spectrum driven by distinct physical mechanisms:

- Penetrating TBI, resulting from direct projectile or fragment perforation;
- Blunt impact TBI, caused by Behind-Helmet Blunt Trauma (BHBT), where the severe dynamic backface deformation of a non-perforated helmet shell strikes the skull directly;
- Acceleration-induced TBI, driven by rapid linear and rotational accelerations imparted to the head, inducing shear stresses and diffuse axonal injury within brain tissue even in the absence of direct cranial impact; and
- Blast-associated TBI, induced by primary blast overpressure wave transmission through the helmet structure without mechanical shell compromise.

Existing ballistic standards (such as VPAM HVN 2009 and HPW-TP-0401.01B) attempt to evaluate head trauma via blunt impact metrics, but they are neither universally mandated nor capable of assessing rotational kinematics or blast wave dynamics. The absence of a standardized framework for quantifying non-penetrating TBI risk, specifically acceleration and blast overpressure mitigation, means helmets can fully satisfy conventional ballistic penetration criteria while failing to protect personnel from non-penetrating neurological trauma.

The greatest problem arises in blast-related injuries, as there is no standard for assessing protection. Blast waves represent a dominant injury mechanism in modern conflicts, yet their effects—including wave transmission through materials and indirect impacts on the central nervous system—are not considered in certification procedures for personal protective ballistic equipment.

All of these facts indicate a fundamental gap between laboratory standards and real combat conditions. While existing standards are successful in defining minimum ballistic protection criteria, they fail to encompass the complexity of modern injuries, particularly those caused by explosions and indirect biomechanical effects. This mismatch represents one of the key challenges in the further development of protective ballistic equipment and testing standards.

6. CONCLUSION

The analysis conducted in this paper unequivocally confirms that the development of personal ballistic protective equipment must keep pace with the dynamic changes on the modern battlefield. It has been established that dominant threats, such as drones and precision artillery, create complex injury patterns that exceed the protective capacities defined by outdated standards, particularly regarding head and facial protection.

The key contribution of this work lies in identifying the potential of advanced materials, such as carbon nanotube-reinforced composites and shear-thickening fluids, which enable the development of lightweight and flexible equipment resistant to multiple threats. It is concluded that an urgent revision of testing standards is essential for the future effectiveness of personal ballistic protective equipment, alongside the integration of modular and smart systems that balance maximum ballistic resistance with mobility.

Abstract: *Rapid industrialization and technological advancement have significantly increased the presence of hazardous chemicals in environmental matrices, posing risks not only to public health and ecosystems but also to environmental and water security. Among these contaminants, organophosphate compounds represent a critical class of toxic substances. While primarily used as agricultural pesticides, organophosphates share structural and toxicological features with certain nerve agents, making their environmental persistence and potential misuse a matter of concern within CBRN (Chemical, Biological, Radiological, and Nuclear) risk frameworks. Aquatic systems are particularly vulnerable, as wastewater discharges facilitate the transport of pesticides, synthetic dyes, and heavy metals into rivers, lakes, and groundwater reservoirs. The development of efficient, scalable, and low-cost remediation materials is therefore essential for both environmental protection and strategic water safety management. This study investigates the adsorption of chlorpyrifos onto bio-derived carbon materials synthesized via controlled carbonization of waste biomass. The objective was to assess their removal efficiency and evaluate their potential applicability in defensive water purification systems designed for contamination response and preventive risk mitigation. Material characterization was conducted using scanning electron microscopy (SEM), Fourier-transform infrared spectroscopy (FTIR), and Brunauer-Emmett-Teller (BET) surface area analysis to determine morphology, surface chemistry, and porosity. Adsorption experiments were monitored by ultra-performance liquid chromatography (UPLC) at three operational temperatures (22 °C, 30 °C, and 35 °C). Adsorption efficiency and equilibrium time were determined to assess operational feasibility under variable environmental conditions. The results provide mechanistic insight into interactions between organophosphate compounds and carbon-based materials and support the development of bio-derived adsorbents as cost-effective components in resilient water treatment systems relevant to environmental security and CBRN preparedness.*

Keywords: *chlorpyrifos, nerve agents, bio-derived carbon materials, adsorption.*

1. INTRODUCTION

Surface water pollution is a growing environmental problem that significantly affects ecosystems, human health, and biodiversity. Organophosphate pesticides, which are primarily used in agriculture to control pests and increase yields, stand out among the many pollutants degrading water quality. They do not decompose spontaneously in nature, adversely affect aquatic ecosystems, and are highly toxic to living organisms [1]. They reach the waters through runoff from agricultural lands, where they can remain for a long time, and through interactions with other substances in the water, more toxic compounds can form. Exposure to organophosphate pesticides is associated with many health diseases, both in humans and animals [2].

The aim of this work was to investigate the adsorption of chlorpyrifos (CHP) on carbon materials obtained from biowaste. The adsorption of these substances was investigated at different concentrations, three temperatures, and various contact times, with a constant amount of material. A carbon material derived from biowaste, obtained by carbonizing used rabbit litter, was used as an adsorbent. Morphological characterization of the material was performed using a scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX). Functional surface groups were identified using Fourier transform infrared spectroscopy (FTIR), and the material's specific surface area was also examined using BET (Brunauer-Emmett-Teller) analysis.

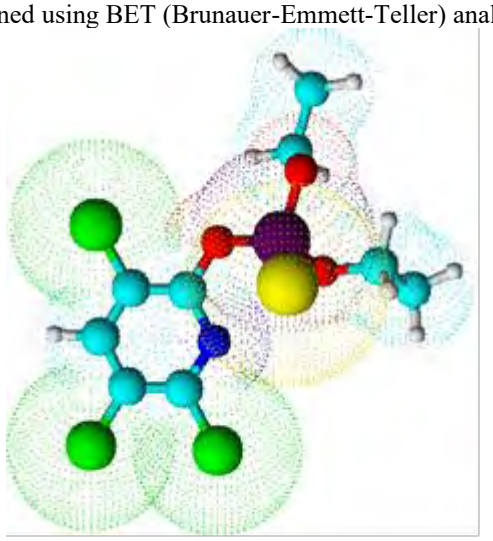

Figure 1. Chemical structure of CHP

CHP (Figure 2) adsorption on carbon materials was monitored experimentally using ultra-high-performance liquid chromatography (UPLC). Contaminant and carbon material suspensions were incubated for a specified period of time at three different temperatures, after which the time required for equilibrium to be established will be determined, after which no further CHP adsorption on the adsorbent will occur. Adsorption efficiency will be tested at a constant carbon material concentration.

The results will be processed using the Dubinin-Radushkevich and Dubinin-Astakhov isotherm models to determine characteristic adsorption parameters and describe the adsorbent surfaces.

2. EXPERIMENTAL

2.1. Chemicals

Daily prepared working solutions of CHP in ethanol were used in the work, at concentrations ranging from 5×10^{-4} to 5×10^{-6} mol dm^{-3}, obtained by diluting the 1×10^{-1} mol dm^{-3} solution. Ethanol (C_2H_5OH) and acetonitrile (CH_3CN), HPLC grade, were obtained from J.T.Baker.

2.2. Methods

UPLC – Chromatographic analyses were performed on an ultra-high-performance liquid chromatography Waters ACQUITY system with a binary pump (Binary Solvent Manager), an automatic sampler (Sample Manager), and a detector (Photo Diode Array - PDA) in the wavelength range from 190 to 500 nm. Analyses were performed at a constant eluent composition (isocratic conditions). An ACQUITY UPLC TM BEH C18 chromatographic column was used as the stationary phase, and the mobile phase was 20% water, 80% acetonitrile.

Other laboratory equipment – included a Sartorius 2632 analytical balance and a Mettler technical balance. Eppendorf Research automatic pipettes were used to measure liquid samples. Samples were mixed on a Vortex V1 plus BOECO mixer and an Orbital shaker-Incubator Grant-bio ES-20 mixer at a constant, set temperature. Separation of the solid and liquid phases was performed using a Mini Spin PLUS centrifuge (Eppendorf) at 14,500 rpm. The samples were filtered using a KX Syringe Filter with a 13 mm diameter and a 0.22 µm pore size.

3. RESULTS AND DISCUSSION

3.1. Synthesis of carbon materials derived from biowaste

The carbon materials (CM) used as adsorbents were obtained from biowaste, by carbonizing the used rabbit litter. The first adsorbent includes all components of the spent litter (CM I), while the second contains unused sawdust (CM II). The first step in the synthesis process is to dry the biowaste in an oven at 90 °C for 24 h, after which they were carbonized in a furnace atmosphere at 650 °C for 1 h. At the end, carbon material suspensions were prepared in ethanol at a concentration of 2 mg cm^{-3} (suspension stock).

3.2. Characterization of carbon materials

SEM and EDX spectroscopy – The morphology of the carbon materials was analyzed using a SEM (JEOL, Ltd., Akishima, Tokyo, Japan). The homogenized sample powder was placed on a carbon support strip using tweezers, then introduced into the SEM chamber. The chemical composition of the investigated carbon materials was determined using EDX.

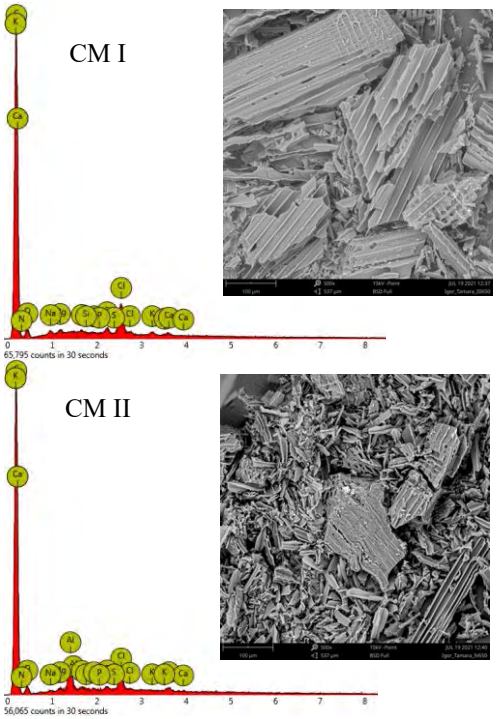

Figure 3. SEM micrograph and EDX spectrum of CM

From the micrographs shown in Figure 2, it can be seen that the primary structure of both materials is retained, and that they are rough and porous. Based on the spectra, the most abundant element is carbon, at 92.94% in CM I and 93.02% in CM II. In addition, the composition of CM I includes 5.26% oxygen and 1% chlorine. CM II also consists of oxygen with 4.59% and aluminum with 1.16%. Other elements, such as calcium, magnesium, silicon, and others, are present in trace amounts, that is, at levels below 1%.

BET analysis – In order to determine the specific surface area of the carbon material, an automatic volumetric sorption analyzer (Sorptomatic 1990 Finnigan) was used. The analysis was performed using isothermal adsorption of nitrogen at 77.13 K. Before adsorption, the samples were degassed in a vacuum for 4 h at 90 °C and 16 h at 200 °C.

The value of the specific surface for CM I is S_{BET} = 10 m^2g^{-1} while for CM II, S_{BET} = 487 m^2g^{-1}. It is observed that the second material has almost 50 times greater specific surface area compared to the first.

FTIR – In order to determine the characteristic functional groups present in the adsorbents, a Nicolet iS20 FT-IR spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA) was used. The wavelength range was from 4000 to 500 cm^{-1}, with 64 scan/a every 4 cm^{-1}.

The band assignments were made in accordance with the literature [3].

Each functional group has a characteristic position on the FTIR spectrum (Table 1). Each band present corresponds to a specific vibration of the particular chemical bond of the given material.

Table 2. Characteristic functional groups of CM I and CM II

Band position (cm^{-1})	Functional group	Type of vibration
617	O-H free	deformation
655	-COOH	deformation
702	-COOH	deformation
863	C-H aromatic out-of-plane	bending
887	C-H aromatic out-of-plane	bending
1033	C-H aromatic compounds	deformation
1110	C-O	deformation
1380	C-N	stretching
1458	C-H skeletal vibration aromatic ring	deformation
1589	C=C skeletal vibration of aromatic ring	stretching

CM I and CM II have common peaks originating from the C-H bending vibration, the -COOH deformation vibration and the O-H free, deformation vibration. However, in the FTIR spectrum of CM II, a bathochromic shift of the C-H and -COOH bands can be observed. The cause of this phenomenon may lie in the different chemical compositions of these two materials. Despite the shift of the two mentioned characteristic bands, the O-H vibration occurs in both materials at the same position. In addition, CM I contains a band characteristic of the C=C stretching vibration, which is not present in the spectrum of CM II. CM II is also characterized by various deformation vibrations, including C-H and C-O, and by one C-N stretching vibration.

3.3. Adsorption of pesticides on carbon materials at different temperatures

The adsorption of CHP was investigated at 22 °C, 30 °C, and 35 °C, with a constant amount of adsorbents, over a pesticide concentration range of 5×10^{-4} to 1×10^{-6} mol dm^{-3}. The experimental data were fitted using the nonlinear forms of the Dubinin-Radushkevich and Dubinin-Astakhov isotherm models, as shown in Figure 4. The corresponding adsorption parameters, which provide insight into the surface characteristics and adsorption behavior of the adsorbents, are summarized in Table 3.

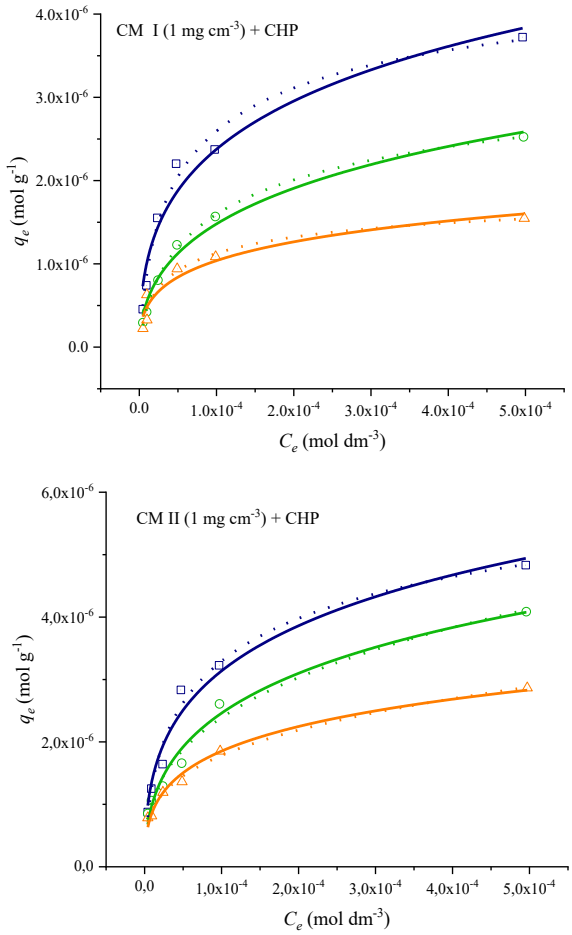

Figure 5. Nonlinear forms of isotherms applied to the adsorption process of CHP on CM:

□ 22 °C ○ 30 °C △ 35 °C

Dubinin-Radushkevich · · · Dubinin-Astakhov

The obtained results for the adsorption of CHP on both carbon materials indicate that the process can be well described by the Dubinin-Radushkevich and Dubinin-Astakhov isotherm models at all temperatures (Figure 6). It can be observed that CM II exhibits a higher adsorption capacity for CHP compared to CM I.

Table 4. Parameters of adsorption isotherm models for adsorption, obtained by fitting experimental data

T/°C	*22*	*30*	*35*
Dubinin – Radushkevich *CM I*			
q_{DR}/mol g^{-1} ×10^6	11 ± 2	8,5 ± 0,9	4,0 ± 0,8
K_{DR}/mol^2 kJ^{-2}	260 ± 30	300 ± 20	230 ± 40
E_a/J mol^{-1}	44 ± 3	41 ± 2	46 ± 4
χ^2×10^{14}	7,23928	1,21053	2,10462
R^2	0,95958	0,98599	0,9324
Dubinin – Radushkevich *CM II*			
q_{DR}/mol g^{-1} ×10^6	13 ± 2	12 ± 2	7,0 ± 0,6
K_{DR}/mol^2 kJ^{-2}	240 ± 20	270 ± 20	230 ± 10
E_a/J mol^{-1}	45 ± 2	43 ± 2	46 ± 2
χ^2×10^{14}	6,55679	3,69693	1,05219
R^2	0,97612	0,98031	0,98633
Dubinin – Astakhov *CM I*			
q_{DA}/mol g^{-1} ×10^6	4,6 ± 0,7	3,8 ± 0,3	1,9 ± 0,6
n	5 ± 2	4 ± 0,4	5 ± 2
E_a/J mol^{-1}	26 ± 1	23,8 ± 0,6	26 ± 2
χ^2×10^{14}	3,27003	16,6068	1,87611
R^2	0,98631	0,99856	0,9548
Dubinin – Astakhov *CM II*			
q_{DA}/mol g^{-1} ×10^6	7 ± 2	32 ± 9	40 ± 10
n	3 ± 1	1 ± 1	0,9 ± 0,8
E_a/J mol^{-1}	24 ± 2	10 ± 2	6 ± 5
χ^2×10^{14}	5,68135	4,29678	8,0718
R^2	0,98448	0,98283	0,99213

Based on the q_{max} values derived from the isotherm parameters, the maximum amount of adsorbed CHP decreases with increasing temperature (Table 5). The Dubinin-Radushkevich model indicates that the adsorption is predominantly physical (E < 8 kJ mol^{-1}), while the Dubinin-Astakhov model provides a better fit to the experimental data, likely due to surface heterogeneity of the adsorbents (n ≠ 2) [4].

4. CONCLUSION

In this study, the adsorption of CHP onto carbon materials derived from biowaste was investigated at 22 °C, 30 °C, and 35 °C. SEM analysis confirmed a rough, porous morphology for both materials, while BET results showed a considerably higher specific surface area for CM II than for CM I. Accordingly, CM II generally exhibited better adsorption performance.

The Dubinin-Radushkevich and Dubinin-Astakhov isotherm models successfully described the adsorption process. The calculated adsorption energies indicate that CHP adsorption is predominantly physical, while the applicability of the Dubinin-Astakhov model suggests the importance of surface heterogeneity.

The adsorption capacity decreased with increasing temperature, indicating that CHP adsorption was more favorable at 22 °C. Although the obtained adsorption capacities were moderate, the results show that low-cost carbon materials derived from biowaste have potential for mitigating organophosphate contaminants in aquatic systems. Further optimization of precursor selection, carbonization conditions, porosity, and surface chemistry is needed to improve their adsorption efficiency and

practical applicability.

Abstract: *Titanium is classified as a critical element and its application is very important in many industrial sectors. The synthesis of titanium compounds in this paper includes the synthesis of titanium oxide, ruthenium oxide-titanium oxide, core (titanium oxide)/shell(gold) particles and TiAlV-alloy. The synthesis is carried out using ultrasonic pyrolysis and aluminothermic reduction. As starting material, titanium oxy sulphate and tetra-n butylorthotitanat were used. Ultrasonic spray pyrolysis(USP) is simple technique for synthesizing nanoparticles and thin films,via ultrasonic atomization to create fine aerosol droplets that undergo thermal decomposition. Aluminothermic reduction represents an exothermic reeaction using aluminium as the reducing agent. Although the preparation of pure titanium is difficult because of its reactivity and high tendency to form oxides, some innovative solutions will be considered such as molten salt electrolysis. The great affinity of titanium towards oxygen is the biggest problem of how to obtain titanium metal powder and prevent oxidation.*

Keywords: *titanium, ultrasonic spray pyrolysis, synthesis*

1. INTRODUCTION

Titanium (Ti) is a transitional metal with an atomic number of 22 and is an especially interesting element due to its properties and the properties of the alloys it makes. Titanium is a low-density metal (4,5 g/cm^3) and possess high strength and corrosion and creep resistance, which makes it an attractive metal either in pure form or an alloy for various advance applications such as aero space engineering (light weight, high strength), energy production (as catalysts for solid oxide cells and various photo reactive coating) biomedical devices (high strength, corrosion resistance) and various other industry sectors [1].

The synthesis of metal and metal compounds particles plays a crucial role in applications such as protective coating, catalysis, electronic materials, energy production and storage. Among various producing techniques, Ultrasonic Spray Pyrolysis (USP) has gained attention due to its ability to produce homogeneous particles with controlled size, composition, continuous and low-cost production [2].

Thw main aim is to present synthesis of titanium oxide, titanium oxide-ruthenium oxide and gold titanium oxide powders using ultrasonic spray pyrolysis method. The second way is alumiothermic reduction for production of Titanium aluminium vanadium (TiAlV) alloys using reduction of titanium oxide and vanadium oxide.

2. EXPERIMENTAL

2.1. Synthesis of titanium oxide

Titanium oxysulfate ($TiOSO_4$); Venator, Duisburg, Germany solution was tested for the synthesis of nanosized titanium oxide using an ultrasonic generator (PRIZNANO, Kragujevac, Serbia) to produce aerosols, highlighting the scalability and versatility of the USP method for oxide nanopowder synthesis. Most important part of this experimental setup are: pump for an injection of precursor solution, ultrasonic atomizer, furnace with 4 heating zones, reaction tube, and an electrostatic precipitator, as shown at Figure 1.

DOI: 10.5937/OTEH26110S

Figure 1. Experimental setup for USP-synthesis with an electrostatic precipitator

The experimental preparation of titanium oxide powders from aqueous solutions of titanium oxysulfate, Venator, Duisburg was carried at a temperature of 1000°C in a compressed air atmosphere, with a solution flow rate of 5 l/min. The obtained particles are shown at Figure 2.

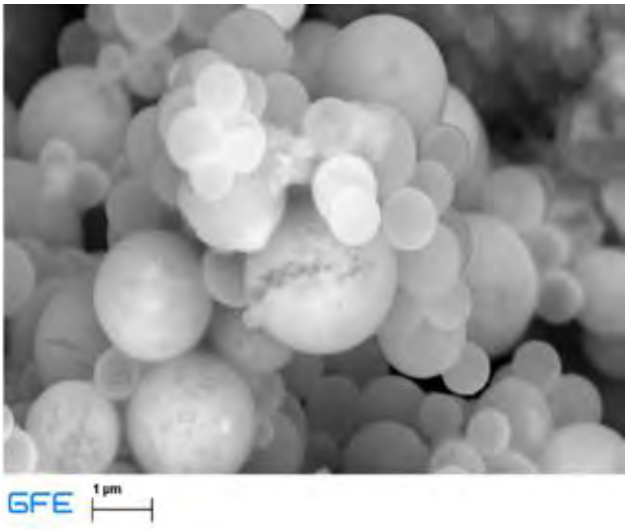

Figure 2. SEM Analysis of TiO_2-powders obtained from titanium oxysulphate by USP

The SEM image shows spherical particles formed through the ultrasonic spray pyrolysis process. The particles appear uniform in shape, with a size range in the micrometer scale, approximately 0.5–1 µm for ones, indicating possible agglomeration during or after formation [2]

2.2. Synthesis of Titanium oxide /ruthenium oxide powders

A new precursor was investigated in order to perpare titanium oxide. Ruthenium (III) chloride hydrate, hydrochloric acid, tetra-n-bytil orthotitanate and water were used as precursor for the synthesis of RuO_2/TiO_2 nanoparticles by USP using the equipment as shown in our previous publications [3]. The most important parts of the set up are the ultrasonic atomizer, the reactor and wet scrubber as the particle collector. The temperature and pressure control was adjusted using a thermostat and a vacuum pump. Atomization of the obtained solution after dissolution of precursor took place in an ultrasonic atomizer (Gapusol 9001, RBI/ France) in order to create the aerosol, as shown at Figure 3.

Figure 3. Experimental setup for USP-synthesis with wet scrubber

Regarding to our previous results the resonant frequency was selected between 0.8 MHz and 2.5 MHz. Under spray pyrolysis conditions a carrier gas flows continuously through the quartz tube at a certain flow rate. Atomized precursor droplets generated by the ultrasonic generator are further transported by carrier gas to the furnace. After thermal decomposition in the furnace, the Ru-Ti based nanoparticles were collected. The synthesis was performed in a nitrogen or oxygen atmosphere with different molar ratios of Ru and Ti: 1.0; 0.33; 0.22, and 0.17 in the precursor solution. The proposed mechanism of formation of catalyst carrier (or core material TiO_2) was shown on Fig. 4:

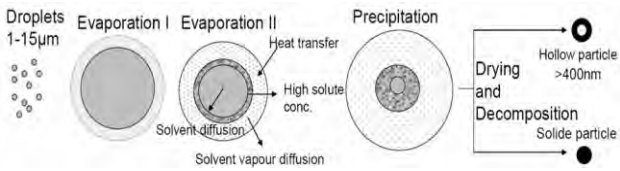

Figure 4: Formation mechanism for the synthesis of nanosized TiO_2 in single step

The chemism of TiO_2 formation is presented with Eq. 1:

$$0.5\ C_{16}H_{36}O_4Ti + HCl + H_2O = 0.5\ TiO_2 + 2\ C_4H_9OH + 0.5\ Cl_2 \quad (1)$$

During evaporation of one aerosol droplet, following precipitation from solution, oxidation and sintering the different form and size can be formed depending on the used reaction parameters. Model of one droplet to one nanoparticle was accepted in thid synthesis. The RuO_2/TiO_2 nanoparticle synthesis was performed at different operating parameters. The chemical composition of of RuO_2/TiO_2 powders with structural analysis is shown in Table 1.

Table 1: Rietveld XRD analysis of obtained powder

Molar ratio of Ru and Ti in the solution	Anatase TiO_2 (%)	Rutile TiO_2 (%)	RuO_2
0.33	5.1	63.8	31.1
0.22	-	83.7	16.3
0.17	-	87.8	12,2

Fig. 5 displays SEM images from a FIB section of RuO_2/TiO_2 nanospheres obtained at 800°C. The dark areas indicate the TiO_2 core, which consists of several sub-particles, each of which is decorated by ruthenium-rich particles of the size of 1-5 nm.

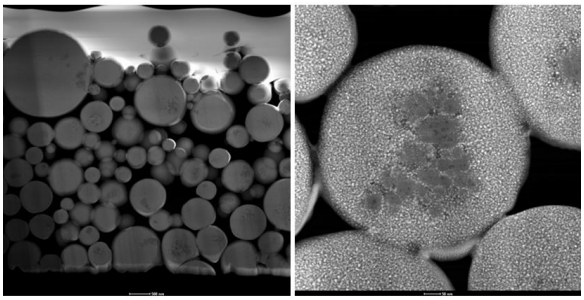

Figure 5: FIB and SEM analysis of obtained powder (T=800°C, ratio 0.333; f=2.5 MHz)

STEM/EDS analysis of the dark areas confirmed a high titanium concentration, but also the presence of Ru. Separated areas containing pure titanium oxide or ruthenium oxide were not detected. It confirms that is very difficult to obtain ideally core (TiO_2)/shell (RuO_2) structure using ultrasonic spray pyrolysis method.

2.3. Synthesis of gold/titanium oxide using ultrasonic spray pyrolysis

Synthesis of gold/titanium oxide particles was performed using hydrogen tetrachloroaurate ($HAuCl_4$) with Tetra-n butylorthotitanat. Very fine particles were prepared in hydrogen and nitrogen atmosphere using same equipment shown at Figure 3, The obtained core/shell particles ere shown at Figure 6 with their particle size distribution on Figure 7.

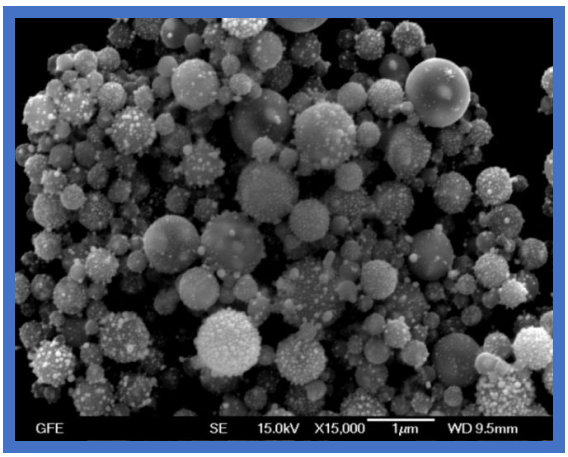

Figure 6: Au/TiO_2 particles obtained by USP

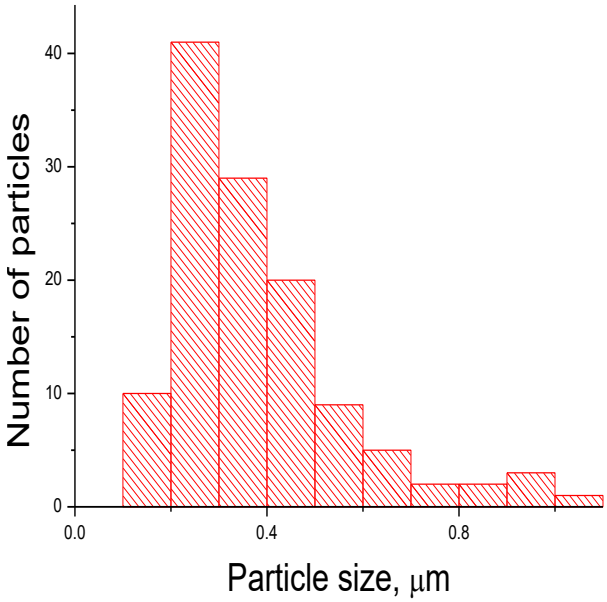

Figure 7. Particle size distribution of Au/TiO_2 particles

The obtained particles contain core (TiO_2) and shell (Au).. Average diameter of core (TiO_2) amounts about 350 nm, and smaller than 100 nm for shell (Au). G. Alkan et al [4] explains the mechanism of the metal/oxide core-shell Ag/TiO_2 and Au/TiO_2 nanoparticle formation via one-step ultrasonic spray pyrolysis (USP) by establishing a new model. The general knowledge on the standard "droplet-to-particle" (DTP) mechanism, nucleation, and growth processes of noble metals, as well as physical and chemical properties of core and shell materials and experimental knowledge, were utilized with the purpose of the construction of this new model.

2.4. Synthesis of TiAlV alloys from TiO_2 and V_2O_5 using aluminothermic reduction

Aluminothermic reduction is based on self-propagating high temperature reaction through reduction reaction of titanium oxide and vanadium oxide using aluminum powder. The reduction of titanium oxide with aluminum does not provide enough heat for self-propagation. The heat released from the reaction mixture must therefore be regulated by adding boosters such as $KClO_4$. Stoichiometrical values of Al to TiO_2 and V_2O_5 varied in order to prepare Ti60Al24V16 alloys. In order to improve the reaction behaviour and the separation of slag and metal, calcium oxide was added to the reaction vessel to adjust the melting point of the resulting slag system. The experimental setup is shown in Figure 8:

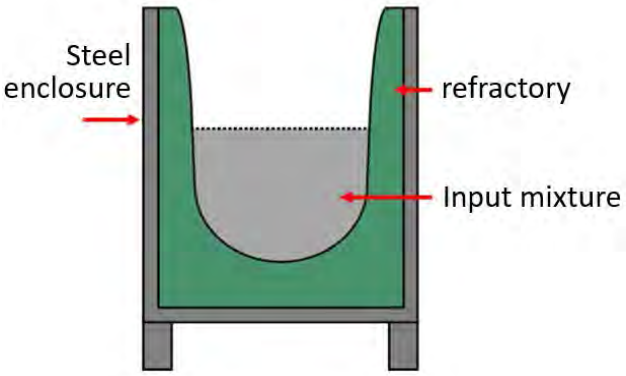

Figure 8: Experimental setup for aluminothermic reduction.

In contrast to ideal spherical particles of TiO_2 obtained by ultrasonic spray pyrolysis. the particles of TiAlV-powder have irregular form as shown at Figure 9.

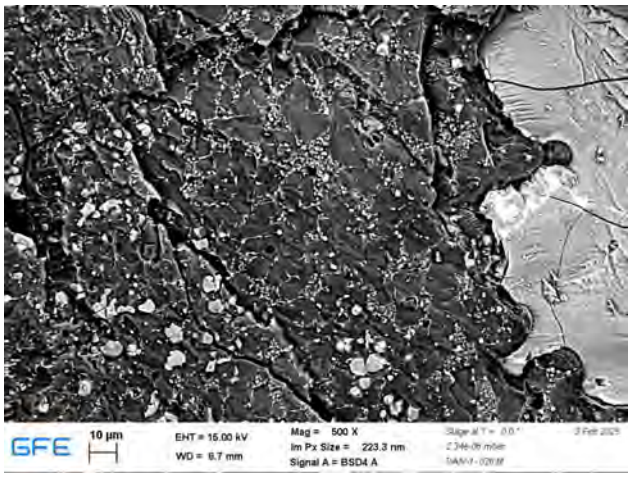

Figure 9: SEM Analysis of TiAlV-alloy obtained using aluminothermic reduction

Cheng et al. [5] mentioned the relevant equations in accordance with stoichiometry for synthesizing Ti-6Al-4V alloy are as follows (the molar ratio of CaO/Al_2O_3 is 0.4), and the calculated adiabatic temperature amounts 1750 K. Mechanism of process is presented with equations (2)-(5).

$$3\ TiO_2 + 4\ Al \rightarrow 3\ Ti + 2\ Al_2O_3 \quad (2)$$

$$3\ V_2O_5 + 10\ Al \rightarrow 6\ V + 5\ Al_2O_3 \quad (3)$$

$$TiO_2 + 0.021\ V_2O_5 + 1.52\ Al \rightarrow 3\ Ti\text{-}6Al\text{-}4V + 0.70\ Al_2O_3 \quad (4)$$

$$TiO_2 + 0.021\ V_2O_5 + 1.52\ Al + 0.28CaO \rightarrow 3Ti\text{-}6Al\text{-}4V + 0.25\ CaO{\cdot}2Al_2O_3 + 0.035CaO{\cdot}6Al_2O_3 \quad (5)$$

3. CONCLUSION

The synthesis of titanium oxide, ruthenium oxide/titanium oxide and gold/titanium oxide powders was successfully performed using the ultrasonic pyrolysis process from different precursors. Precursors such as titanium oxysulfate and tetra-n-bytil orthotitanate have been successfully chosen for the formation of titanium-based compounds by USP. Due to the great affinity of titanium towards oxygen, the reduction of titanium oxide and vanadium oxide was carried out using aluminum powder, producing an alloy of aluminum, titanium and vanadium.

Abstract: *Radionuclides in the environment are a significant concern, especially due to the increasing release of radioactive cobalt (^{60}Co) into water streams in emergencies. This trend presents considerable environmental risks that require urgent attention. There is growing interest in the development of low-cost inorganic ion-exchange materials for the treatment of various types of radioactive liquid waste. This study investigates an efficient method for the direct immobilization of cobalt (Co^{2+}) ions onto porous ceramic foam based on zeolite and bentonite. The aim of the present research was to establish a simplified approach for water purification and remediation in emergencies. The material was synthesized using an eco-friendly foam method and subsequently sintered at 800°C, a temperature significantly higher than that typically employed in conventional calcination methods for zeolites. The characteristics of the prepared porous material were analyzed using scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX). The adsorption behavior of Co^{2+} ions onto the porous ceramic material was found to vary significantly in the presence of surfactants. To assess the leachability of the adsorbed Co^{2+} ions, a simulated acid rain test procedure was employed. Consequently, the porous ceramic foam, based on natural zeolite, provides a viable means for processing radioactive waste in an environmentally friendly manner.*

Keywords: *zeolite, bentonite, adsorption, remediation, surfactant.*

1. INTRODUCTION

To reduce global warming emissions, many countries are shifting from fossil fuels toward nuclear and renewable energy. Nuclear power offers high energy output with minimal greenhouse gas emissions. However, its major disadvantage is the potential generation of hazardous radioactive materials in emergencies during accidents, malfunctions, or decommissioning, posing risks to human health and the environment [1].

Radioisotopes realised in accidents can easily be dissolved in water [2,3], which can lead to rapid environmental contamination.

In addition, radioactive wastewater is often produced during the decontamination of contaminated surfaces. Such radioactive contaminated water typically contains cesium, strontium, and cobalt, as well as suspended organic matter originating from surfactants used in the decontamination process [4].

Cobalt is of particular concern, as it is a highly toxic radionuclide, and the removal of Co^{2+} from radioactive water has received increasing attention in recent years [5].

Regarding to the remediation of aqueous systems contaminated with radionuclides, radioactive water must be properly treated and converted into a stable solid form prior to disposal.

Remediation of radionuclide contaminated water increasingly prioritizes approaches that are technically effective, sustainable, and low-maintenance. According to IAEA guidance (IAEA-475) [6], remediation strategies should be selected based on thorough site characterization and, where feasible, the use of passive treatment methods.

In recent years, extensive research has focused on inorganic ion-exchange materials capable of adsorbing radionuclides from wastewater. Conventional organic resins exhibit several limitations, including poor heat resistance, insufficient radiation stability, and difficulties associated with the treatment of secondary solid waste [5,7].

In contrast, inorganic ion-exchange materials offer several advantages: lower cost, strong resistance to radiation damage, higher ion-exchange and adsorption capacities, and the ability to directly solidify secondary waste through grouting [2]. Although organic compounds such as surfactants can influence the adsorption behavior [7,8].

Porous ceramic materials, which rank among the most commonly used inorganic materials today, have shown great potential as adsorbents for various metal ions [9]. In general, porous ceramics are defined as materials with porosity levels exceeding 30% [10]. Within this category, two primary ceramic structural types are distinguished: 2D honeycomb and 3D foam structures. A variety of fabrication techniques have been developed for producing ceramic foams, including the replica template method, sacrificial template method, and direct foaming [11].

This study investigates the effects of suspended organics and Co^{2+} ions on the adsorption performance of ceramic foam, with the aim of improving their application in radioactive water remediation.

2. EXPERIMENTAL

2.1. Materials and chemicals

The materials used for the synthesis of porous ceramics were natural zeolite from the Slanci deposit (Serbia), natural bentonite with a particle size of 63 µm provided by Bentoprodukt d.o.o., Šipovo (Bosnia and Herzegovina), sodium dodecyl sulfate (SDS) as the foaming agent (Merck, Germany), a hydrogen peroxide solution (H_2O_2, 30%, Centrohem, Serbia) as the blowing agent. Analytical grade salts cobalt(II) nitrate hexahydrate ($Co(NO_3)_2 \cdot 6H_2O$, ≥99.0%) was purchased from Merck (Germany). Sulfuric acid (H_2SO_4, 95.0-97.0%), nitric acid (HNO_3, 65.0%), and sodium chloride (NaCl) were obtained from Centrohem (Serbia). Three types of surfactants were used: SAFOL 23E6.5 (SAFOL) consisted of C_{12}–C_{13} oxo alcohol + 6.5 mol ethylene oxide/mol (Sasol Chemical Industries, South Africa) as non-ionic surfactants, cetyltrimethylammonium chloride (HDTMA, Acros Organics, USA) as cationic surfactants, and sodium dodecyl sulfate (SDS, Merck, Germany) as anionic surfactants.

2.2. Sample preparation

The porous ceramics samples were prepared according to the procedure described in our previous study [12]. The samples were prepared using the foam method. The resulting samples of porous ceramics made from natural zeolite and bentonite clay after sintering with an average porosity of 63%, are referred to as CF.

2.1. Batch adsorption and desorption experiments

The effects of surfactants on the adsorption of Co^{2+} was investigated. In all experiments, 1 g CF was added into 100 mL simulated radioactive solution containing Co^{2+} ions and different surfactants. The initial concentrations of Co^{2+} ions were applied at 100 mg L^{-1}.

Surfactants SAFOL 23 E6.5, HDTMA, and SDS were introduced to Co^{2+} ions solution at their respective critical micelle concentrations 0.037 mmol L^{-1}, 1 mmol L^{-1}, and 8.2 mmol L^{-1}, respectively. After mixing 1 g of CF with the respective solutions for 24 h, the solutions were filtered through a 0.45 µm PTFE syringe filter. The filtrates were subsequently diluted with deionized water prior to AAS analysis. Adsorption capacity and removal efficiency were calculated using Eq. (1) and Eq. (2):

$$Q_e = \frac{(C_0 - C_e)V}{m} \quad (1)$$

$$(\%) = \frac{C_0 - C_e}{C_0} x100 \quad (2)$$

where Q_e (mg g^{-1}) is the adsorption capacity; C_e (mg L^{-1}) is the concentration in the equilibrium solution; C_0 (mg L^{-1}) is the initial concentration of the solution, V (L) is the volume of the added solution, and m (g) is the mass of adsorbent.

Further, CF saturated with Co^{2+} and surfactant was shaken in a 100 mg L^{-1} simulated acid rain (SAR) solution for 24 h for desorption testing. The SAR solution was prepared using a mixture of H_2SO_4 and HNO_3 adjusted to pH 5.6 [13]. Desorption experiments were conducted at 105 rpm and 25 °C for 24 h. The concentration of metal ions in the supernatant was measured by AAS, and the desorption rate was calculated using Eq. (3).

$$W = \frac{m_d}{m_a} x100\% \quad (3)$$

where W (%) is the desorption rate; m_d (g) is the amount of metal ions in the desorption solution; m_a (g) is the amount of adsorbed metal ions by the sintered samples.

2.4. Analytical method

The morphology of the sintered samples was examined by scanning electron microscopy (SEM) with Energy-Dispersive X-ray (EDX) Spectroscopy (JEOL 6610LV, Japan). The concentration of metal ions in aqueous solutions during adsorption and desorption experiments was measured by an atomic absorption spectrometer (AAS, SpectrAA 55B, Varian, USA). A Vanta Max series portable handheld X-ray fluorescence (XRF) spectrometer (Olympus, USA) evaluated the metal ions adsorbed onto sintered samples.

3. RESULTS AND DISCUSSION

The morphology of the sintered sample CF is shown in Fig. 1. The micrographs reveal a heterogeneous surface characterized by pores of varying sizes distributed throughout the structure. The overall morphology appears relatively rough, indicating an irregular sintering profile. The EDX spectrum exhibits pronounced peaks corresponding to Si, Al, and Fe, confirming the presence of silicon-, aluminum-, and iron-bearing oxides within the sample. Notably, no elevated carbon signal is detected, supporting the conclusion that organic constituents were fully decomposed during the sintering process. The EDX analysis of is shown in Table 1 to indicate the atomic and oxide percentage.

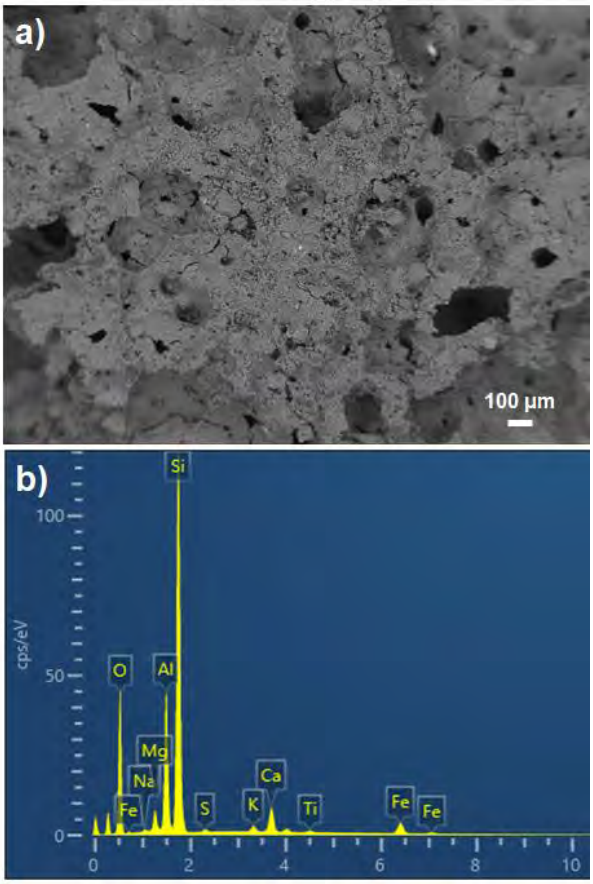

Figure 1. SEM and EDX images of the CF.

Table 1. EDX analysis of the CF.

Element	Atomic (%)	Oxide	Oxide (%)
O	63.52		
Si	22.8	SiO_2	65.37
Al	8.1	Al_2O_3	19.71
Ca	1.75	CaO	4.68
Fe	1.49	FeO	5.12
Mg	1.46	MgO	2.8
K	0.36	K_2O	0.81
Na	0.22	Na_2O	0.33
S	0.17	SO_3	0.65
Total	100	Total	100

In this study, stable Co^{2+} ions replaced radioactive ^{60}Co to investigate cobalt adsorption behavior in aqueous systems. The use of stable Co^{2+} provides the same relevant chemical properties and adsorption characteristics as the ionic form of cobalt found in radioactive wastewater, while avoiding the radiological hazards and additional safety requirements associated with handling ^{60}Co. Therefore, stable Co^{2+} ions were selected as a safe and practical substitute for studying cobalt adsorption under controlled laboratory conditions. However, it should be noted that the experiments conducted do not account for the radiological characteristics of ^{60}Co, such as activity and radioactive decay.

Previous studies have demonstrated that ceramic materials are effective adsorbents for the treatment of radioactive wastewater [8]. However, the influence of surfactants commonly present in such wastewater on the adsorption behavior of metal ions onto ceramic foam has not been comprehensively examined. In incident crisis, detergents used to decontaminate workers' bodies and protective clothing contain various surfactants that may interact with both radionuclide ions and the ceramic surface. This study therefore examines how various surfactant types influence Co^{2+} ions adsorption onto CF (Fig. 2).

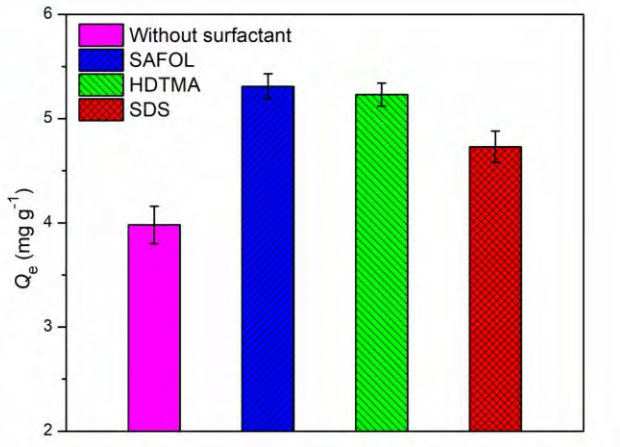

Figure 2. The effect of surfactants on the adsorption capacity values of Co^{2+}.

The presence of surfactants highly affected the adsorption of Co^{2+} ions onto CF. When surfactants were present in the metal solutions, the adsorption of Co^{2+} sharply increased. For non-ionic surfactants, SAFOL had the most significant effect on the adsorption of Co^{2+} onto ceramic foam, compared to other surfactants. The equilibrium adsorption capacities of SAFOL, HDTMA and SDS after 24 h of contact were 5.31 mg g^{-1}, 5.23 mg g^{-1} and 4.73 mg g^{-1}, respectively. The higher adsorption observed with SAFOL may be attributed to its non-ionic character, which can modify the CF surface and facilitate the interaction of Co^{2+} ions with available adsorption sites. The formation of a surfactant layer may also provide additional favorable sites for Co^{2+} uptake.

Parka et al. [8] investigated the efficiency of ammonium molybdophosphate–polyacrylonitrile composites for the adsorption of cobalt, strontium, and cesium ions from radioactive laundry wastewater. Their findings demonstrated that the introduction of nonionic, cationic, and anionic surfactants–specifically Triton-X, HDTMA, and SOBS–at concentrations corresponding to their CMC

values significantly enhanced the adsorption of Co^{2+} ions. This improvement was attributed to surfactant-induced modifications of the adsorbent surface and altered interactions between the adsorbent matrix and metal ions, highlighting the potential of surfactant-assisted adsorption as an effective strategy for radionuclide removal. The present results are consistent with these findings, while the slightly higher adsorption observed for SAFOL suggests that its non-ionic nature may provide more favorable conditions for Co^{2+} adsorption onto CF.

The XRF spectra of the sintered samples before and after adsorption are shown in Fig. 3.

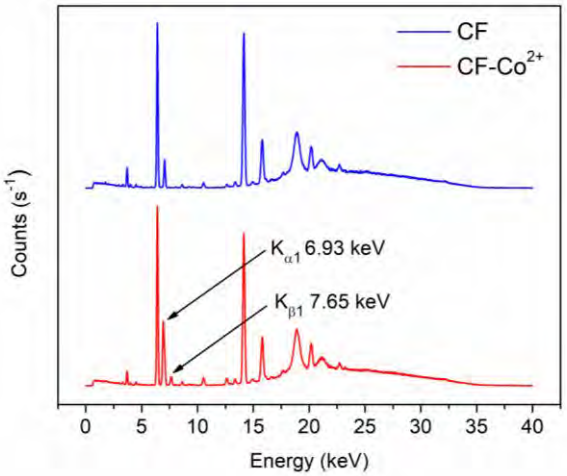

Figure 3. The XRF spectra of the sintered samples before and after adsorption of Co ions.

The XRF spectra of the sintered samples before and after adsorption. The XRF spectra shows that the peaks are moved when spectra's of untreated ceramic foam and sample after the adsorption of Co^{2+} ions, without interference of surfactants, are compared. Characteristic peaks of cobalt can be observed in sintered sample which is according by available literature [14]. The detection of cobalt directly on the CF surface by XRF provides additional evidence that Co^{2+} ions were effectively retained by the ceramic foam during the adsorption process.

The amount of cobalt in CF was evaluated using XRF to confirm and verify the existence of the maximum experimentally observed Qe. The XRF results presented in Fig. 4 showed a good correlation with the AAS results, confirming the change in metal ion concentrations in the aqueous solutions after adsorption from the solution of 100 mg L^{-1} concentration at 25 °C after 24 h.

This consistency between the XRF and AAS results supports the reliability of the experimentally determined adsorption capacity and confirms the occurrence of Co^{2+} uptake by CF.

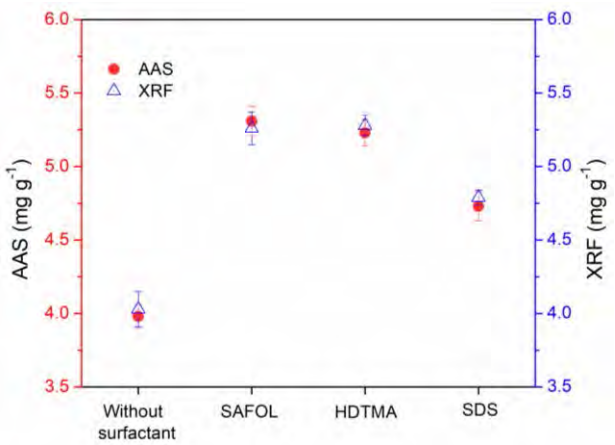

Figure 4. Comparison between concentration measured by AAS and fluorescence intensity measured by XRF for heavy metal ions adsorbed onto sintered samples.

In the SAR solution, no desorption of Co^{2+} ions from the ceramic foam was observed, indicating strong binding between the ions and the ceramic surface. The Co^{2+} concentration in the SAR solution was below the detection limit of the AAS method (0.05 mg L^{-1}). These findings suggest that the adsorbed samples can be considered suitable materials for the immobilization of Co^{2+} ions and may offer an environmentally safe option for their long-term containment.

5. CONCLUSION

A ceramic foam derived from natural zeolite and bentonite was synthesized and evaluated for its efficiency in the removal of cobalt (Co^{2+}) ions from aqueous solutions, simulating radionuclide-contaminated water.

The study confirmed the applicability of ceramic foam for removing Co^{2+} from simulated radioactive water. In all cases, the presence of surfactants enhanced Co^{2+} adsorption onto the ceramic foam, with similar overall adsorption trends observed across the three surfactant types.

The most pronounced improvement occurred with the non-ionic surfactant, which yielded the highest adsorption capacity of 5.31 mg g^{-1}.

In conclusion, the adsorption characteristics of the zeolite–bentonite ceramic foam demonstrate qualities that correspond to immobilization of Co^{2+} ions and sorption-based remediation strategies.

Abstract: *Adhesively bonded joints represent a reliable method of joining materials in modern structures, and the development of new adhesives has enabled their application under demanding service conditions, including defense systems and military equipment. This study examines the effects of manual sanding, laser cleaning, and laser surface texturing on the lap shear strength of single-lap adhesively bonded joints fabricated from EN AW 5754 aluminum alloy and X5CrNi18-10 stainless steel using three structural adhesives. The results showed that laser cleaning provided the highest lap shear strength, while conventional sanding proved optimal for all adhesives investigated. Joints made of stainless steel exhibited 16% to 40% higher strength compared to joints made of aluminum alloy under identical surface preparation conditions using the same adhesive. The results contribute to a better understanding of the relationship between laser surface treatment and the mechanical performance of adhesively bonded joints and provide guidance for their application in defense-related structures, where high requirements are imposed on reliability, durability, and resistance to dynamic loading.*

Keywords: *adhesive bonded joints, surface preparation, lap shear strength, aluminum alloys, stainless steel.*

1. INTRODUCTION

The requirements of the modern defense industry for lightweight, reliable, and high-performance structural joints have driven intensive development in the field of adhesive metal bonding. Defense platforms, ranging from armored vehicles and aircraft to naval vessels and ballistic protection systems, increasingly employ multi-material structures in which bonded joints offer advantages that traditional mechanical fasteners or welding cannot provide: a more uniform stress distribution, reduced structural mass, excellent fatigue resistance, and the elimination of stress concentrations in the joint zone [1, 2, 3].

Surface preparation prior to bonding is a key factor determining the quality and durability of adhesive joints. In addition to conventional mechanical methods, such as sanding and sandblasting, and chemical etching, laser surface treatment has emerged as an environmentally friendly, repeatable, and highly controllable alternative [4]. Depending on the selected processing parameters, laser cleaning and laser texturing can increase surface roughness, enhance surface wettability by inducing superhydrophilic behavior, and modify the chemical composition of the surface layer, thereby contributing to improved joint strength [5, 6].

The materials most commonly used in defense structures, namely 5000-series aluminum alloys and austenitic stainless steels, present particular challenges for adhesive bonding. Aluminum alloys are characterized by the

presence of a stable oxide layer that adversely affects adhesive wetting, while stainless steels are difficult to bond without appropriate mechanical or chemical surface preparation [7]. The aim of this study was to investigate the influence of different mechanical and laser surface preparation methods on the lap shear strength, wettability, and fracture mechanisms of adhesively bonded joints made from these materials, as well as to discuss their potential application in defense systems.

2. MATERIALS AND METHODS

2.1. Base materials and adhesives

The investigation was carried out on EN AW 5754 aluminum alloy (H22 temper) and X5CrNi18-10 stainless steel (EN 1.4301) plates, both 2 mm thick. Both materials were water-jet cut into specimens measuring 100 mm × 25 mm in accordance with EN 1465 [8]. Three structural adhesives were used for bonding: two two-component adhesives, SikaPower®-880 (2K, high fatigue resistance) and SikaFast®-580 (2K, acrylic-epoxy hybrid), and one one-component adhesive, SikaPower®-492 G (1K, high strength). The main characteristics of the investigated adhesives are summarized in Table 1. Single-lap joints with an overlap length of 12.5 mm were fabricated, and the adhesive layer thickness was maintained at 0.3 mm using spacers [9].

Table 1 Main characteristics of the investigated structural adhesives

Adhesive	Type	Chemical basis	Main characteristic
SikaPower®-880	2K	Epoxy adhesive	High fatigue resistance and structural bonding.
SikaFast®-580	2K	Acrylic-epoxy	Fast curing, high strength and impact resistance.
SikaPower®-492 G	1K	Heat-curing epoxy hybrid	High static strength for structural applications.

2.2 Surface preparation methods

Four surface preparation methods were applied: (1) manual abrasion using a Scotch-Brite™ abrasive pad (SB), (2) manual sanding with P180 abrasive paper (P180), (3) laser cleaning (LC) (Jetlaser M100, 45 W laser power, pulse energy of 1.25 mJ), and (4) laser texturing (LT) using a nanosecond pulsed fiber laser (FL-mark-C equipped with a JPT MOPA source, λ = 1064 nm, 30 W). Circular and linear surface patterns with depths of 40 µm and 80 µm were produced during the texturing process. Before the mechanical and laser texturing treatments, the specimens were degreased with SIKA® Remover-208, a solvent-based cleaning agent for heavily soiled, non-porous surfaces, intended for cleaning and degreasing surfaces prior to bonding.

2.3 Testing methods

The testing program included:

– surface roughness measurements using a Mitutoyo SJ-301 contact profilometer (Ra and Rz parameters);

– contact angle measurements using an Osilla goniometer with double-distilled water; and

– static lap shear strength testing of single-lap joints using an Instron 8802 universal testing machine (250 kN capacity) at a crosshead speed of 1 mm/min, in accordance with ISO 4587 [10].

Fracture surface analysis was performed using a high-resolution digital camera and the images were processed using ImageJ image processing software.

3. RESULTS AND DISCUSSION

3.1 Surface roughness and wettability

Surface roughness measurements were performed in three separate measurement regions for each specimen, in two mutually perpendicular directions: longitudinally and tangentially. Sanding with P180 abrasive paper resulted in higher surface roughness than Scotch-Brite™ preparation for both materials investigated. The average roughness values obtained after P180 sanding were Ra = 1.75 µm and Rz = 10.8 µm for the EN AW 5754 aluminum alloy, and Ra = 0.45 µm and Rz = 3.75 µm for X5CrNi18-10 stainless steel.

Laser texturing produced a superhydrophilic surface immediately after treatment, as evidenced by a contact angle of approximately 0°. However, the contact angle gradually increased during exposure to ambient air, which has been attributed to the adsorption of organosilicon compounds from the environment [11, 12].

3.2 Lap shear strength of adhesively bonded joints

The lap shear strength results for adhesively bonded joints prepared using different surface treatment methods are presented separately for the EN AW 5754 aluminum alloy (Figure 1) and X5CrNi18-10 stainless steel (Figure 2).

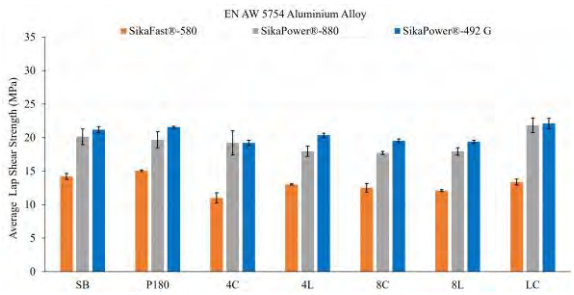

Figure 1. Average lap shear strength of single-lap adhesive joints prepared using different surface preparation methods for EN AW 5754 aluminum alloy (SB – Scotch-Brite; P180 – abrasive paper; 4C and 8C – circular patterns at 40 and 80 µm depth; 4L and 8L – linear patterns at 40 and 80 µm depth; LC – laser cleaning)

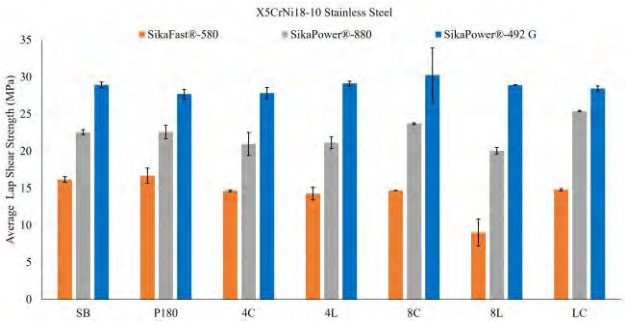

Figure 2. Average lap shear strength of single-lap adhesive joints prepared using different surface preparation methods for X5CrNi18-10 stainless steel

Laser cleaning provided the highest lap shear strength for the SikaPower®-880 adhesive, particularly for joints made of X5CrNi18-10 stainless steel, while the corresponding values for EN AW 5754 aluminum alloy were also among the highest obtained. For the SikaFast®-580 adhesive, sanding with P180 abrasive paper resulted in the highest shear strength. In the case of SikaPower®-492 G, P180 preparation provided high joint strength, although comparable or higher values were achieved after laser surface texturing, particularly for stainless steel.

For all three adhesives, joints made of X5CrNi18-10 stainless steel generally exhibited approximately 16–40% higher lap shear strength than those made of EN AW 5754 aluminum alloy under identical surface preparation conditions. This behavior may be attributed to differences in the surface characteristics of the two materials and their interaction with the adhesive [9].

3.3 Fracture mechanisms

Cohesive failure, which is generally considered an indicator of a high-quality adhesive joint, was the dominant failure mode for the SikaPower®-880 adhesive after laser cleaning and P180 sanding for both materials. In contrast, predominantly adhesive (interfacial) failure was observed for laser textured specimens, indicating insufficient adhesion. This behavior was associated with surface oxidation and the redeposition of molten particles generated during laser processing, as confirmed by the surface analyses performed in this study [9, 13, 14].

From the perspective of defense applications, the predominance of cohesive failure is particularly important for the reliability of adhesively bonded joints subjected to vibration and impact loading, such as ballistic impact and blast loading. In addition, laser surface preparation offers practical advantages for defense manufacturing due to its high repeatability, ease of automation and elimination of hazardous chemical cleaning agents.

4. CONCLUSION

Based on the experimental investigations, the following conclusions can be drawn:

– Laser cleaning provided the highest lap shear strength for the SikaPower®-880 adhesive and promoted predominantly cohesive failure, indicating the formation of high-quality adhesive joints. Owing to its repeatability, ease of automation, and elimination of hazardous chemical cleaning agents, laser cleaning represents a promising surface preparation method for defense manufacturing.

– Among the conventional mechanical treatments, sanding with P180 abrasive paper consistently provided high lap shear strength for all adhesives investigated and represents a practical alternative when laser equipment is unavailable, particularly for field applications.

– Under identical bonding and surface preparation conditions, X5CrNi18-10 stainless steel exhibited 16–40% higher lap shear strength than EN AW 5754 aluminum alloy. This behavior is attributed to the more favorable surface characteristics of stainless steel, making it a suitable material for load-bearing bonded joints in metal structures.

– Future research should focus on the behavior of adhesively bonded joints under cyclic and dynamic loading, as well as on long-term durability under environmental conditions relevant to defense applications, including high humidity, temperature variations, and UV exposure.

Acknowledgments

Abstract: *Machine elements, both simple and complex, are frequently affected by geometric stress concentrations, which significantly influence their load capacity. This is particularly important for components made of structural steels, which are widely used in highly loaded applications. Under overload conditions, unplanned increases in operating load, local stresses at stress concentration areas may reach critical values, including the yield strength and ultimate tensile strength. Available data provides limited information on the influence of geometric stress concentration on the static mechanical properties of materials. In this study, theoretical and experimental investigations are conducted in order to establish a correlation between geometric stress concentration in the form of the notch and static material properties, namely yield strength and ultimate tensile strength. Different notch geometries were analyzed, and corresponding stress–strain (σ–ε) diagrams were obtained through tensile testing of flat samples in laboratory conditions. The results indicate that samples with notches, made of S355 structural steel, have higher values of yield strength and ultimate tensile strength compared to unnotched samples of equivalent cross-sectional area in the notch root. The obtained experimental results can be used for a more precise analysis of the load capacity of machine parts made of S355 with geometric stress concentration.*

Keywords: *geometric stress concentration, strain concentration, yield strength, ultimate tensile strength, S355 structural steel.*

1. INTRODUCTION

Stress concentration is an important factor in the design of machine components, since geometrical discontinuities such as notches, holes, or sharp changes in cross-section cause a non-uniform stress distribution. These local stress increases can strongly influence the mechanical behavior of a component and may lead to premature failure.

Many engineering failures have been linked to stress concentration. A well-known example is the failure of Liberty ships during World War II, where structural fractures originated at welded joints and geometrical discontinuities [1]. However, similar effects occur much more frequently in engineering practice, where they may not lead to catastrophic failure but can still significantly affect the performance and reliability of components. Consequently, a considerable number of studies and experimental investigations have been devoted to the analysis of stress concentration and notch effects on mechanical properties. Various sample geometries have been employed, including cylindrical and flat samples, as well as specially designed geometries aimed at controlling the stress state, such as butterfly-type samples [2]. In addition, different notch configurations have been

Corresponding author: J. Antić;

DOI: 10.5937/OTEH26113A

investigated, such as V-shaped, U-shaped, semicircular and key-hole notches [3,4]. Furthermore, various materials have been considered in order to evaluate their influence on stress concentration and notch effects.

In the present study, the influence of geometry on the stress state and mechanical behavior of S355 structural steel was analyzed. Structural steel S355 is widely used in engineering applications, particularly for load-bearing and safety-critical components. Due to its frequent use in structures exposed to significant loads, it is essential to understand how stress concentration influences its mechanical properties. Special attention is given to notch yield strength (σ_T) and notch ultimate tensile strength (σ_m), as these represent critical points in the material response.

Four different flat sample geometries were considered, including one smooth sample and three samples with different notch geometries. The aim of this work is to investigate the effect of notch geometry on yield strength and ultimate tensile strength and to better understand the role of stress concentration in structural steel components.

2. MATERIALS AND METHODS

2.1. Material

The samples used in this study were made of structural steel S355. According to [5], the minimum value of yield strength (R_e) for this material is 355 MPa, while ultimate tensile strength (R_m) is specified between 470 and 630 MPa. As defined in [7], R_e represents the maximum value of stress prior to the first decrease in force in uniaxial conditions, while R_m is the stress corresponding to the maximum force.

The samples were initially cut using a water jet process into plates of dimensions 22 × 210 × 8 mm. The final sample geometry, including the notch profile, was obtained by CNC milling. The end surfaces were subsequently ground to achieve a uniform thickness of 6 mm with high accuracy.

2.2. Sample Geometry

Tensile tests were performed on flat samples. The general sample geometry is shown in Figure 1, where the notch radius (R) and the distance between notch centers (D) are defined as the varying parameters.

Four different geometries were considered by varying R. The minimum cross-sectional area at the notch root was kept constant and equal to that of the smooth sample. As a result, D varied accordingly.

For each geometry, the stress concentration factor (α_k) was determined analytically using expressions provided in literature [6]. The factor α_k is defined as the ratio between the maximum stress at the notch root (σ_{max}) and the nominal stress (σ_{nom}):

$$\alpha_k = \frac{\sigma_{max}}{\sigma_{nom}} \tag{1}$$

where σ_{nom} is calculated from the applied force and the minimum cross-sectional area at the notch root. Due to the presence of the notch, the stress at the notch root is locally increased (Figure 2), and the corresponding σ_{max} can be determined using Equation 1.

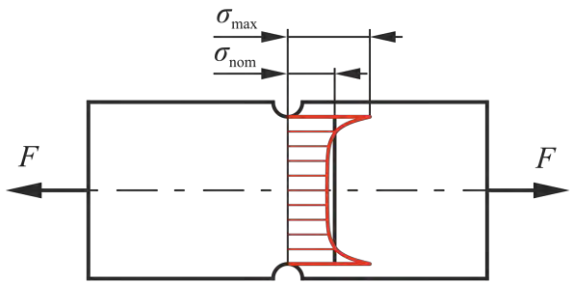

Figure 2 Stress distribution in the notch region under tensile loading

The values of R, D and α_k are summarized in Table 1. The first sample was smooth (without a notch), whereas the remaining samples contained notches with progressively decreasing radii.

Table 1. Values of R, D, and α_k for different sample geometries

	R [mm]	D [mm]	α_k [-]
E1	0 (smooth sample)	-	1
E2	3.75	20	1.69
E3	1.25	15	2.38
E4	0.625	13.75	3.07

2.3. Experimental Procedure

Tensile tests were performed using an Shimadzu testing machine with a 250 kN capacity at the Faculty of Technology and Metallurgy, University of Belgrade (Figure 4). Testing was carried out under displacement control, with a constant crosshead separation rate of 5 mm/min. The experimental procedure was conducted in accordance with [7].

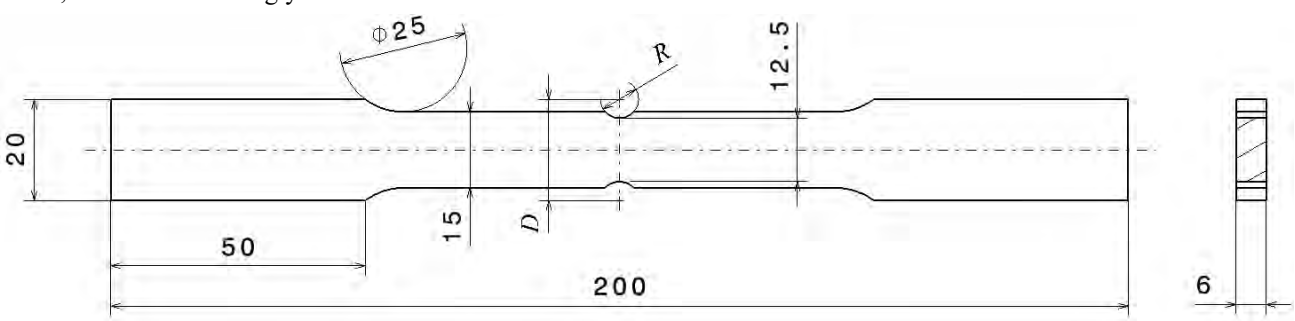

Figure 1 Geometry and dimensions of the tested specimen

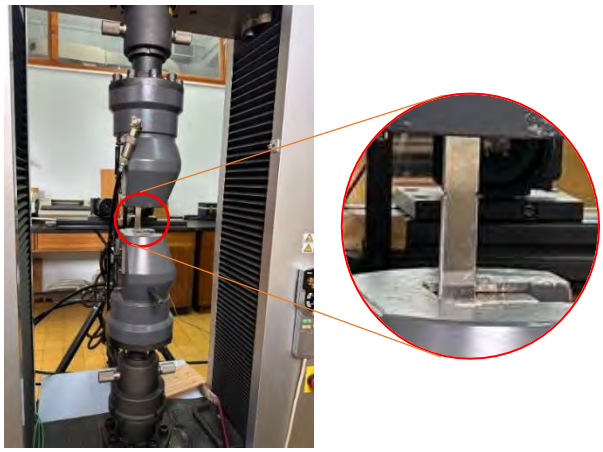

Figure 4. Tensile testing machine with mounted sample

All tests were performed at room temperature. Force and crosshead displacement were recorded during testing. Strain was determined from the crosshead displacement, while the engineering stress $\sigma(t)$ was calculated as:

$$\sigma(t) = \frac{F(t)}{A_0} \tag{2}$$

where $F(t)$ is the applied force at time and A_0 is the initial area at the narrowest section of the sample (12.5 × 6 mm, as shown in Figure 1). The calculated stress values were then paired with the corresponding strain to construct the engineering stress–strain curves.

3. RESULTS

The fractured samples for all tested geometries are shown in Figure 5. The samples were aligned from one side in order to enable a direct comparison of their elongation after fracture. A noticeable difference in elongation can be observed between the smooth and notched samples. The smooth sample exhibits the highest elongation, while only minor differences in elongation are observed among the notched samples.

Figure 5. Fractured samples after tensile testing

The fracture surfaces of the tested samples are shown in Figure 6. The morphology indicates ductile fracture, characterized by pronounced material tearing. However, the extent of plastic deformation is reduced in the notched samples compared to the smooth sample.

Figure 6. Fracture surfaces of tested samples

Engineering stress–strain (σ–ε) curves obtained from tensile tests for all four sample geometries are presented in Figure 7.

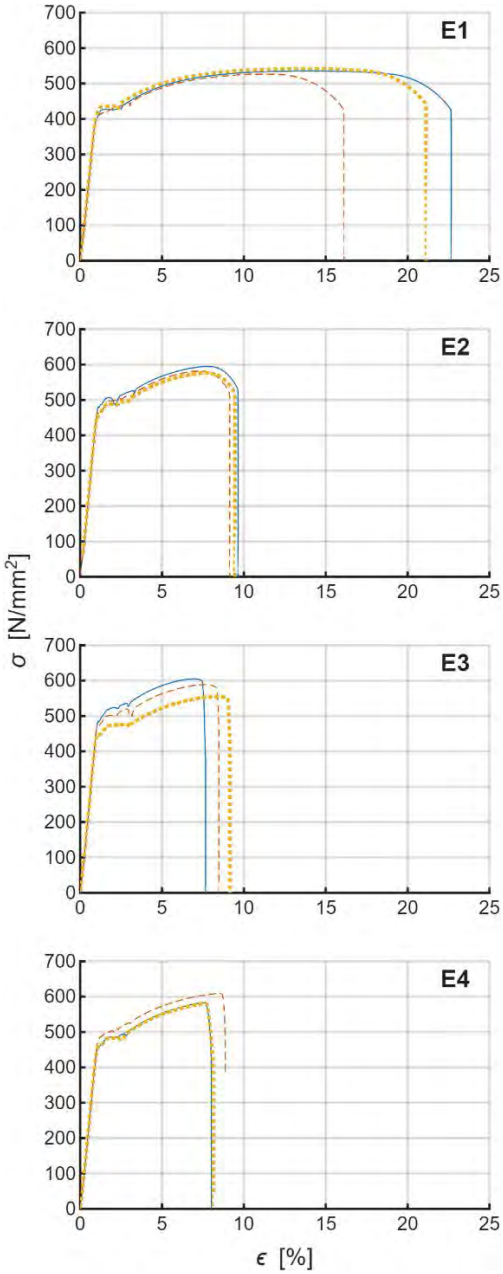

Figure 7. Stress–strain diagrams for four sample geometries (E1–E4), with three samples per geometry

The curves exhibit similar overall behavior, with a clear elastic region followed by yielding and plastic deformation up to fracture. For most geometries, a good agreement between the curves can be observed. Although one of the smooth samples exhibited noticeably lower elongation

compared to the others, the overall repeatability of the results was satisfactory. The value reported in the paper was obtained from the testing-machine data and is based on the crosshead displacement, rather than on the elongation measured directly on the specimen. It was used only for a relative comparison among the tested specimens. It does not represent the percentage elongation after fracture A, as defined by the tensile-testing standard, and a direct comparison of this value with the standard requirement for A would therefore not be appropriate.

4. DISCUSSION

The average values obtained from the three smooth samples are:

$$R_e = 422.8\frac{\mathrm{N}}{\mathrm{mm}^2};\ R_m = 534.5\frac{\mathrm{N}}{\mathrm{mm}^2};\ \varepsilon_{\max,1} = 19.98\%. \quad (3)$$

Table 2 summarizes the average values obtained from three samples for each notched geometry.

Table 2. Average values of σ_T, σ_m, and ε_{max} for notched samples and their corresponding ratios to the smooth-sample values

	σ_T	$\frac{\sigma_T}{R_e}$	σ_m	$\frac{\sigma_m}{R_m}$	ε_{max}	$\frac{\varepsilon_{max}}{\varepsilon_{max,1}}$
E2	467.0	1.105	584.5	1.094	9.414	0.47
E3	467.7	1.106	582.8	1.090	8.434	0.422
E4	468.7	1.109	591.0	1.106	8.341	0.417

The measured value of R_e exceeds the minimum value specified by the standard by approximately 19%, while the corresponding value of R_m falls within the prescribed range.

The obtained results show that, for all notched samples, both σ_T and σ_m exceed the corresponding values of R_e and R_m, respectively. The values of σ_T are from 10.5% to 10.9% higher than R_e, while σ_m exceeds by 9.4% to 10.6%. The differences between individual notch geometries are very small, remaining below 1% for σ_T, whereas the variation in σ_m slightly exceeds 1%. This indicates a limited influence of notch geometry on strength within the investigated range for tested material.

In addition to the increase in strength, a significant reduction in elongation is observed for notched samples compared to the smooth sample. The elongation of the notched samples is reduced to 42–47% of the smooth sample elongation.

The literature shows that the effect of stress concentration on mechanical properties is not unambiguous. In some cases, the triaxial stress state in the notch region results in lower values of σ_T and σ_m compered to the R_e and R_m due to early crack initiation at stress concentration sites, corresponding to notch weakening [8]. However, cases of increased strength have also been reported. In such cases, the material in the notch region is constrained in its deformation, as its elongation is restricted by the surrounding material. This constraint leads to the development of tangential and radial stresses, resulting in a triaxial stress state, which requires higher axial stress levels for yielding and plastic deformation [9]. As a result, an apparent increase in strength, known as notch strengthening, is observed, which is consistent with the results obtained in the present study.

Similar behavior has been reported in [10], where tensile tests were performed on cylindrical samples made of 316L(N) stainless steel with symmetric double U-notches. Five different U-shaped notches with varying radii were considered, and the results showed a clear increase in both σ_T and σ_m as the notch radius decreased.

Similar findings were reported in [11], where tensile tests on cylindrical cast iron samples with V-shaped notches showed that the maximum strength of the notched samples exceeded that of smooth samples. This behaviour was attributed to the increased stress triaxiality in the notch region, with the notch strengthening effect becoming more pronounced as the level of stress triaxiality increased.

Most experimental studies reported in the literature are conducted on cylindrical samples, whereas the present study focuses on flat samples. Although the phenomenon of notch strengthening has been widely investigated, its quantitative characterization for flat samples remains limited. In this context, the present results contribute to a better understanding and quantification of notch strengthening in flat sample geometries.

For the investigated sample geometry and considered levels of stress concentration, the increase in σ_T and σ_m for all notched samples (E2–E4) relative to the R_e and R_m was clearly quantified. Conventional expressions for elastoplastic materials indicate that notch yield strength and notch ultimate tensile strength are close to those of the smooth sample [12]:

$$R_e \approx \sigma_T,\quad R_m \approx \sigma_m. \quad (4)$$

The results of this study confirm that these expressions are on the side of safety and can be applied as such in engineering practice. For more accurate calculations, the results presented in this study can be used.

5. CONCLUSION

The results of this study show that all notched samples exhibit higher values of σ_T and σ_m compared to the R_e and R_m, which can be attributed to the phenomenon known as notch strengthening. The increase in strength is approximately 10%, while the differences between individual notch geometries remain below 1% for the tested geometries.

A significant reduction in elongation is observed in the notched samples, with values reaching only 42–47% of those measured for the smooth sample.

The results further indicate that, within the investigated range, the variation in notch geometry has a limited influence on strength, while its effect on ductility is more pronounced for the tested material.

ACKNOWLEGEMENTS

Abstract: *The temporal variability of the ambient dose equivalent rate, $\dot{H}^*(10)$, in Vranje, Serbia, and its relationship with meteorological parameters during 2024 were investigated. Hourly $\dot{H}^*(10)$ data reported by an automatic radiation monitoring post within the early warning network and calculated daily $\dot{H}^*(10)$ were analyzed against daily values of selected meteorological variables using descriptive statistics, nonparametric tests, simple correlation and multiple linear regression analyses. A statistically significant seasonal effect was confirmed, while diel differences were consistent but environmentally small. Within the hourly $\dot{H}^*(10)$ dataset, multi-hour spikes were identified and were associated with rainfall events. Correlation analysis indicated that temperature-related variables and atmospheric moisture were positively associated with $\dot{H}^*(10)$, while pressure, cloud cover, and precipitation showed inverse relationships. The multiple regression model explained a moderate proportion (27.9 %) of the daily variability of $\dot{H}^*(10)$, suggesting that meteorological factors contribute substantially, but not entirely, to the observed fluctuations. Improved understanding of background radiation dynamics at local scale under varying weather conditions enables robust interpretation of environmental monitoring data and strengthens the reliability of the early warning network.*

Keywords: *dose rate, seasonal variation, monitoring, radionuclide, weather.*

1. INTRODUCTION

Natural background radiation is an omnipresent part of the environment. The ambient gamma radiation mainly originates from terrestrial radionuclides (decay series of ^{238}U and ^{232}Th including short-lived radon progeny, and ^{40}K), cosmic radiation and cosmogenic radionuclides. Anthropogenic contributions to the background radiation are much smaller and mainly reflect fallout from atmospheric nuclear weapons testing and contamination from nuclear accidents [1].

Because a meaningful fraction of the near-surface gamma signal is linked to radon progeny and atmospheric mixing, the background level is not constant. Rain can cause short-term increases in dose rate by washing out aerosol-bound radionuclides, particularly radon progeny, from the atmosphere and depositing them on the ground, followed by decay toward baseline [2]. Temperature, humidity, pressure, wind, cloudiness, and boundary-layer stability modulate radon exhalation, dispersion, and deposition. Conversely, snow cover attenuates terrestrial radiation [3]. Recent studies report diurnal and seasonal structures in dose-rate time series and statistically detectable associations with meteorological variables [2, 6].

This variability is operationally important for early warning networks. Automatic stations continuously monitor the ambient dose equivalent rate, $\dot{H}^*(10)$ (an operational quantity used for area monitoring) to provide rapid indication of a nuclear or radiological emergency. In Serbia, the national early warning system is operated by the Serbian Radiation and Nuclear Safety and Security Directorate (SRBATOM). The legacy network was established in 2007 with nine stations, while the 2023 modernization expanded coverage to 33 automatic radiation monitoring posts (ARMP), including Vranje, which was not part of the earlier system.

Vranje was selected due to local and societal motivations. Southern Serbia was among the areas investigated for potential environmental consequences of depleted uranium (DU) used during the 1999 NATO campaign, and DU-related monitoring and remediation have been reported for sites in the wider region [7]. Vranje is often

DOI: 10.5937/OTEH26114T

mentioned in public discourse in connection with perceived increases in cancer burden, which makes transparent, data-driven radiation monitoring relevant for risk communication and public trust [8].

The aims of this study were: (i) to quantify variability of the ambient dose equivalent rate in Vranje, with emphasis on seasonal and diurnal contrasts; and (ii) to evaluate the influence of meteorological parameters on dose-rate variability, including multivariable regression.

This work is relevant for nuclear security: improved characterization of "normal" variability can reduce unnecessary mobilization and analyst fatigue, while preserving sensitivity and credibility when a genuine radiological threat or release occurs, especially when small anomalies may be partially masked by weather-driven background shifts. These results can support interpretation within the national early warning system by helping distinguish meteorologically induced fluctuations from event-like anomalies that might trigger alarms [9].

2. MATERIALS AND METHODS

Study area

Vranje is a town in southern Serbia (42°33' N, 21°55' E, 430 m a.s.l), near the borders with North Macedonia and Bulgaria. The area of Vranje Basin is characterized by an assembly of crystalline schists, gneisses, and granitoids of Paleozoic age, overlain locally by Neogene-Quaternary sediments. Alluvial deposits are developed along the South Morava and its tributaries. Surrounding elevations are composed predominantly of metamorphic and igneous formations. The dominant soil types are alluvial soils (Fluvisols) and colluvial deposits in valley bottoms. Cambisols and Leptosols are prevalent on surrounding slopes and hilly terrain. According 2022 Census, the City of Vranje has approximately 74000 inhabitants.

Vranje has a moderate continental climate, with hot summers and fairly cold winters. Based on climate data from Republic Hydrometeorological Service of Serbia (RHSS) (1981 to 2010) a mean annual air temperature is 11.1 °C, with cold winters (average of –0.1 °C in January) and warm summers (21.6 °C in July and August). Total annual precipitation is 578.3 mm, with wetter spring and drier late summer. Prevailing winds are northeasterly, with low to moderate speeds (2.2–4.2 m s^{-1}). Total sunshine hours are 2123.9 h.

Based on the available data, no nuclear or radiological emergencies were reported in 2024 within the area surrounding the ARMP. The closest nuclear facilities are the Vinča Nuclear Institute in Belgrade (app. 270 km, straight-line) and the Kozloduy Nuclear Power Plant in Bulgaria (app. 200 km). Therefore, it can be reasonably concluded that the Vranje ARMP was not influenced by potential nuclear effluents during the reporting period.

Data Collection

Datasets were collected from publicly available sources. Hourly averaged values of $\dot{H}^*(10)$ were retrieved from the European Radiological Data Exchange Platform (EURDEP) from January 1 to December 31, 2024 (station RS31149) [10]. Meteorological parameters identified as a key relevant drivers influencing ambient background radiation [11], namely daily mean of atmospheric pressure (p), air temperature (T), minimum air temperature at 5 cm above the ground (T_{5cm}), relative humidity (RH), vapor pressure (e), sunshine hours (S), cloud cover (N), wind speed (U), and precipitation (R), were taken from the Meteorological Annual for 2024 [12].

The Main Meteorological Station (MMS) Vranje is located at 42º33' N latitude and 21º55' E longitude, at 433 m a.s.l. The ARMP is permanently installed within the boundaries of the MMS Vranje, and is equipped with the MIRA dose monitoring system from Scienta Envinet. MIRA measures $\dot{H}^*(10)$ with two temperature and background compensated Geiger–Muller tubes: in the low-dose (LD) range from 10 nSv h^{-1} to 1 mSv h^{-1} with a sensitivity of 823 count · h · min^{-1} · μSv, and in high-dose (HD) range from 0.01 mSv h^{-1} to 10 Sv h^{-1}.

Measurement uncertainty of the $\dot{H}^*(10)$ in the LD range was evaluated following Guide to the expression of uncertainty in measurement principles (JCGM GUM-1:2023). The manufacturer-specified accuracy of ± 15 % was taken as a Type B uncertainty component with rectangular distribution, which corresponds to a relative standard uncertainty of 8.66 %. The statistical component was estimated from counting statistics assuming Poisson behavior of the detector for hourly averaged data. Within the observed dose rate range in this work, the relative standard uncertainty (Type A) due to counting statistics fell in the range 0.8–1.2 %. The combined relative standard uncertainty was ~8.7 %. The expanded relative uncertainty at 95 % confidence level ($k = 2$) of the reported values was about 17.5 %.

Statistical analysis

The Kolmogorov-Smirnov (K-S) and Shapiro-Wilk (S-W) tests assessed normality of the $\dot{H}^*(10)$ and meteorological data at a significance level of 0.05. Outliers in $\dot{H}^*(10)$ was performed using mean absolute deviation (MAD) approach, and all observations with absolute value of z-score higher than 3.5 were treated as outliers.

Statistical analyses were conducted using IBM SPSS 29.0. Correlation and linear regression analyses assessed relationships among $\dot{H}^*(10)$ and the meteorological records. OriginPro 8.5 was utilized for plotting.

The Kruskal-Wallis (K-W) test, followed by the Mann-Whitney (M-W) U test, was applied to the original variables to assess whether the season (winter, spring, summer, autumn) or diel period (day, night) influenced the variability of the $\dot{H}^*(10)$. For the K-W test, a significant difference was recognized at $p < 0.05$, while for the M-W test, p value was set after the Bonferroni correction based on the number of pairwise comparisons (six tests, adjusted threshold $p < 0.001$).

Seasons for the georeferences of the ARMP Vranje were

determined using the 2024 astronomical equinox and solstice dates. Sunrise and sunset times were calculated based on zenith angle 90.833°, accounting for atmospheric refraction and daylight-saving time adjustments.

3. RESULTS AND DISSCUSION

Ambient dose equivalent rate

The number (n) of 8784 hourly averaged $\dot{H}^*(10)$/nSv h^{-1} values was reported by the MIRA station RS31149 in 2024. The descriptive statistics of $\dot{H}^*(10)$ for the total number of observations are presented in the Table 1. The $\dot{H}^*(10)$ values ranged from 82.74 to 260.50 nSv h^{-1} with a mean of 101.32 nSv h^{-1}. The coefficient of variation (CV) which is in a good indicator in environmental studies of the presence of external impacts, was rather small (7.75 %), which highlights the absence of any major external influence on the natural background radiation.

The K-S test of normality (0.086, $p < 0.001$), along with the evaluation of the Q-Q plot, confirmed a pronounced non-normal distribution of $\dot{H}^*(10)$, with a heavy upper tail. A skewness of 3.65 and kurtosis of 37.73 indicated a highly right-skewed and leptokurtic distribution.

The MAD method for outlier detection, which is a preferred robust method for heavy-tailed, non-normally distributed datasets, identified 109 outliers in total (6 in winter, 16 in spring, 51 in summer, and 36 in autumn). A closer inspection of the detected outliers showed that these values were not isolated but formed multi-hour clusters, and it was confirmed that all of them, without exception, were recorded on rainy days.

Table 1. Descriptive statistics of the ambient equivalent dose rate, $\dot{H}^*(10)$/nSv h^{-1} by season and diel cycle

Season	Period	n	Mean	SD	CV/%	Median	Min	Max	Kurtosis	Skewness

Meteorological data

The mean air pressure recorded at MMS Vranje in 2024 was 966.5 mb, the relative humidity 73 %, the air temperature 13.6 °C, the minimum air temperature at 5 cm above the ground 5.6 °C, the vapor pressure 11.5 mb, the wind speed 1.5 m s^{-1} and the cloud cover 4.7 tenths. There were a total of 2393 h of sunshine hours, 121 calm days, 715 mm of precipitation, 115 rainy days, 12 snowy days and 6 days with snow cover.

Temporal variation

As shown in Table 1, the highest values of $\dot{H}^*(10)$ were recorded in summer, followed by autumn, with mean values of 106.89 and 101.47 nSv h^{-1}, respectively. The lowest $\dot{H}^*(10)$ was measured in winter (mean 96.90 nSv h^{-1}), followed by a slight increase in spring, when the average value was 99.85 nSv h^{-1}. The same seasonal order was reported by other similarly designed studies in South Korea, Poland and Romania [2, 5, 13]. Based on the SD and CV values, the variability of the dose rate was in the same order: summer > autumn > spring > winter. Dose rates were slightly, but consistently higher during the night than during daylight.

Diurnal variation in gamma radiation is commonly linked to diurnal fluctuations in atmospheric radon concentrations and the formation of nighttime temperature inversions, which lead to a decrease in gamma radiation after sunrise and a progressive rise after sunset [2]. This interpretation is supported by a study reporting that the diurnal pattern was observed only in gamma energies originating from terrestrial background radioactivity, majority from the ^{214}Bi [6]. A similar pattern was observed in our study. Figure 1 presents mean values of $\dot{H}^*(10)$ in each hour for different seasons. It is evident that across all seasons, $\dot{H}^*(10)$ showed a clear diurnal pattern. In that regard, winter was the most stable, with mean hourly $\dot{H}^*(10)$ varying slightly from 96 to 99 nSv h^{-1}, with a weak decline at midday. $\dot{H}^*(10)$ increased in spring from 98 to 102 nSv h^{-1} and showed a daytime minimum followed by evening recovery. Summer had the highest $\dot{H}^*(10)$ values, from 104 to 111 nSv h^{-1}, and the strongest cycle, peaking in early morning (02:00 to 06:00 h), dropping toward midday when the lowest values were reported (11:00 to 15:00 h), then rising again at evening and night. Autumn is intermediate, with morning

maximum (07:00 h, 105 nSv h^{-1}) and midday minimum (15:00, 98 nSv h^{-1}). The calculated *SD* indicated larger variability in summer and autumn than in winter and spring.

Monthly averages showed in Figure 2 confirmed the existence of seasonal variability. Values were lowest from January to March. An increase occurred during spring and early summer, with a peak in August. The period September–October was characterized by a steady decline. A smaller secondary rise was observed in November, followed by a decline in December. Amestoy at al. [14] attributed such seasonal variability to changes in surface soil moisture affecting gamma rays primarily originating from Th and K. They reported that increases in soil moisture of 25 % at the end of summer and 43 % at the beginning of spring corresponded to decreases in gamma radiation from these two radionuclides by the same percentages.

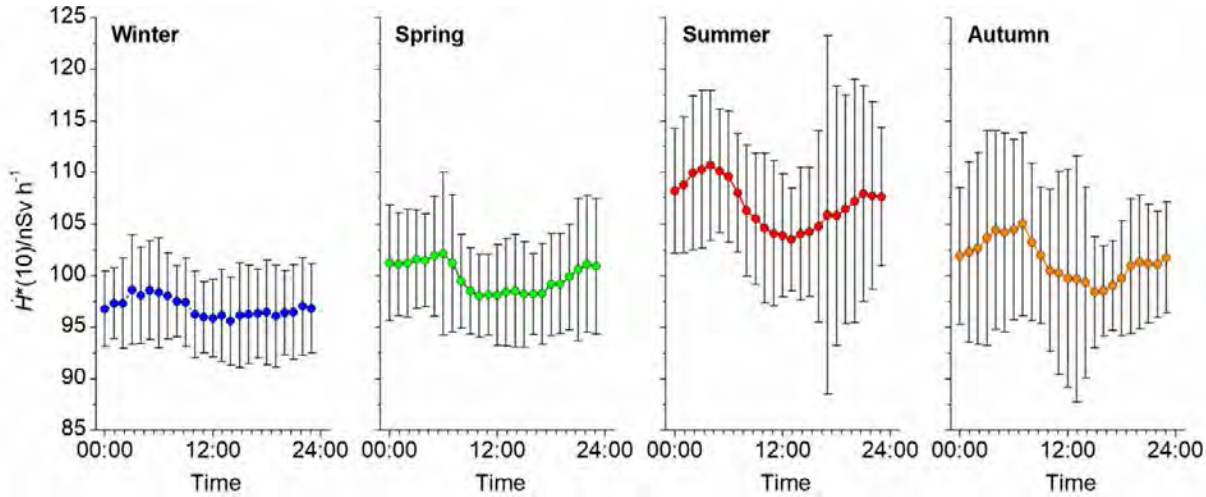

Figure 1. Diurnal variation of the ambient equivalent dose rate by seasons (error bars indicate ±*SD*)

Based on Table 1 and Figure 2, nighttime $\dot{H}^*(10)$ mean values were consistently higher than during daylight (by approximately 1 %). The difference was most pronounced during the summer months and was the highest in June (3.5 %). The exception was noted in November, when the mean dose rate during the day exceeded the nighttime value by 2 %. Such nocturnal enhancement of the ambient dose occurs as radon builds up in the stable boundary layer [15].

The K-W test confirmed a statistically significant seasonal effect ($\chi^2 = 2644.707$, $df = 3$, $p < 0.001$) on $\dot{H}^*(10)$. The mean ranks increased from winter (2606.29) to spring (3960.93) and autumn (4454.47), while the highest values were obtained in summer (6471.33).

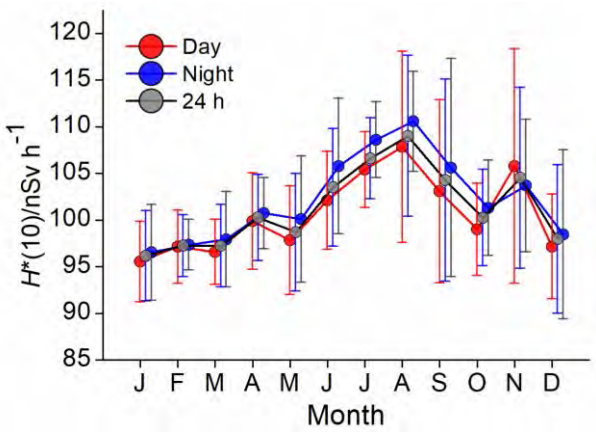

Figure 2. Monthly variation of the ambient equivalent dose rate by diel period (error bars indicate ±*SD*)

Pairwise M-W tests (Table 2) confirmed statistically significant differences for all seasonal pairs ($p < 0.001$). However, the strength of the contrasts was not uniform. The largest separation quantified by the effect size (*ES*) calculated as the quotient of the *Z* value and the square root of the number of observations in the comparison, was observed between winter and summer ($ES = 0.69$), and between spring and summer ($ES = 0.53$). Comparisons involving autumn were mainly moderate (with summer $ES = 0.42$; with winter $ES = 0.38$), while difference between spring and autumn was small ($ES = 0.11$).

For the diel cycle (Table 2), a day–night difference was detected ($Z = -5.676$, $p < 0.001$), but the *ES* was negligible. Therefore, although diel modulation is statistically detectable, it is likely not environmentally important compared with the seasonal effect.

Correlation and linear regression analysis

Since meteorological data at 1 h-resolution were not available and only daily averages of selected meteorological parameters were accessible, mean daily $\dot{H}^*(10)$ values were calculated as the averages of 24 hourly values (from 00:00 to 23:00 h) and further used for the purposes of correlation and linear regression analysis.

Since the S-W test showed that all variables included in the analysis did not conform to a normal distribution, Spearman's correlation coefficient was chosen to quantify interrelations between them. The results are presented in Table 3. All correlations were statistically significant (confidence level 99 %) except for wind speed. According to the classification proposed by Joo et al. [5] the daily

mean air temperature, air temperature at 5 cm above the ground, vapor pressure and sunshine hours were moderately and positively related to the mean daily $\dot{H}^*(10)$, whereas atmospheric pressure, relative humidity, cloud coverage, and precipitation showed weak inverse associations.

Autumn	2156	1651.69	3561036.00					

The results of the correlation analysis show that temperature-related variables were the main meteorological factors influencing the environmental dose rate. This can be explained by the fact that higher temperatures reduce soil moisture and empty soil pores, which in turn increase the dose rate in the air [2]. On the other hand, temperatures below 0 °C lead to soil freezing, which at the very least hinders gas exchange with the atmosphere and consequently limits the migration of radon into the air [3]. The positive correlation with sunshine hours together and the negative correlation with cloud cover result from the coincidence of sunny weather with high-pressure, low-wind, and stable atmospheric mixing conditions, which are characteristic of a moderate continental climate and promote near-surface radon accumulation [11].

Table 3. Spearman's correlation coefficient between mean daily $\dot{H}^*(10)$ and meteorological parameters (significant at the 0.01 level; *nonsignificant correlation)

Para.	Coeff.	Para.	Coeff.	Para.	Coeff.
p	–0.26	*RH*	–0.34	*N*	–0.21
T	0.57	*e*	0.53	*U*	–0.09*
T_{5cm}	0.51	*S*	0.33	*R*	–0.24

An inverse association with atmospheric pressure is probably a consequence of inhibited emission of radioactive gases from the soil under conditions of high atmospheric pressure [2]. In addition, photon intensity is inversely proportional to atmospheric pressure, which also influences the gamma dose rate [9]. Also, the reason for the negative association with atmospheric pressure may lie in the barometric modulation of secondary cosmic radiation, as greater atmospheric mass increases shielding and reduces the cosmic-ray contribution at ground level as well as reduction of cosmogenic radionuclides generation (e.g. ^{7}Be, ^{14}C) [11, 14]. Since it is well established that wet deposition of radon progeny present in the atmosphere, particularly ^{214}Pb and ^{214}Bi, leads to an increase in ambient gamma dose rate [2], a positive correlation between gamma dose rate and precipitation would be expected. The negative value of Spearman's correlation coefficient for precipitation initially appears to contradict the observed hourly spikes during rain. However, this is explained by the dual nature of precipitation's impact: while "washout" causes immediate, short-lived increases in $\dot{H}^*(10)$, the resulting increase in soil moisture over a 24-hour period reduces radon emanation and attenuates terrestrial gamma radiation, leading to a net decrease in the daily mean [2]. Although the correlation with wind speed was not statistically significant, the negative coefficient suggests that under conditions of weak wind flow, atmospheric mixing is reduced and air masses may become relatively stagnant. This limited dispersion can promote the accumulation of radionuclides near their release or resuspension sources, thereby contributing to elevated ambient dose rates in the surrounding area [11].

Multiple linear regression analysis quantified the meteorological influence on the $\dot{H}^*(10)$ daily mean using the dataset of daily averaged meteorological parameters ($n = 366$). Meteorological parameters are interconnected as a change in one variable can affect others [11]. To avoid multicollinearity among thermodynamic variables (p, T, T_{5cm}, e), vapour pressure was selected as a representative measure of atmospheric moisture, while sunshine duration was used as a radiative descriptor rather than N. The explanatory model given by regression Eq. (1) explained 27.9 % of the variance in $\dot{H}^*(10)$ daily averages which is below the explanatory power reported in some studies [11]. All predictors kept in the analysis contributed significantly to the model ($p < 0.05$), and based on the variance inflation factor ($VIF < 3.5$), multicollinearity was acceptable. Although precipitation showed a statistically significant monotonic association with $\dot{H}^*(10)$ based on the Spearman's correlation coefficient, it did not exhibit a significant linear effect in the multiple regression and did not improve model

performance. This confirms that precipitation effects are likely nonlinear and episodic at the daily scale.

$$\dot{H}^*(10) = 107.233 + 0.610e - 0.129RH - 0.301S - 0.911U \quad (1)$$

Given the standardized regression coefficients, β, vapour pressure (e) showed the strongest positive association (0.479), indicating that higher absolute humidity is associated with increased $\dot{H}^*(10)$ which is directly linked to the air temperature, and precipitation. Relative humidity (RH) displayed a moderate negative effect (–0.331) when vapour pressure was included in the model, indicating a conditional moisture-related influence. Sunshine hours, S, (–0.227) and wind speed, U, (–0.126) were negatively associated with $\dot{H}^*(10)$, which is consistent with enhanced atmospheric mixing and dilution under increased solar radiation and wind [2]. The Durbin–Watson statistic (0.89) indicated positive serial correlation, reflecting the time-series nature of daily observations. Therefore, results of the regression should be interpreted as associations rather than independent effects.

4. CONCLUSION

This study, based on a one-year time series, demonstrates that variations in the $\dot{H}^*(10)$ in Vranje exhibit distinct seasonal and diurnal patterns. These variations are primarily attributed to the meteorological modulation of the natural gamma background, as the radionuclide composition of the soil remained constant at the monitoring location throughout the study period. The $\dot{H}^*(10)$ peaked during the summer, while nighttime values were consistently higher than daytime across all seasons. This phenomenon is largely attributed to the nocturnal accumulation of radon decay products within a more stable atmospheric boundary layer. Correlation and regression analyses indicate that temperature and atmospheric humidity indicators are the most stable covariates on a daily scale. Conversely, precipitation events trigger short-term increases in the dose rate lasting several hours. Distinguishing these meteorologically induced fluctuations from potential artificial contamination is essential for robust environmental monitoring. Furthermore, the annual mean $\dot{H}^*(10)$ of 101.32 nSv h^{-1} is consistent with the expected natural background radiation for the regional geological landscape, providing a data-driven confirmation that observed levels remain within normal environmental limits and supporting transparent risk communication regarding historical radiological concerns. Overall, these findings establish local reference values for Vranje and facilitate more accurate data interpretation within the early warning network, which could ultimately reduce the frequency of false alarms during adverse weather events.

Abstract: *The widespread production and application of fuel cells are primarily hindered by the high cost of their components, particularly catalysts. The presence of fuel impurities leads to the degradation and poisoning of catalysts in Proton Exchange Membrane (PEM) fuel cells, significantly reducing their efficiency and lifetime. Consequently, considerable research efforts have been directed toward the development of cost-effective and durable catalysts, as well as suitable support materials. In this study, non-stoichiometric tungsten oxides were synthesized and used as supports for PtRu-based catalysts intended for PEM fuel cells. The electrochemical performance of the obtained PtRu/WO_x+C catalysts was evaluated using cyclic voltammetry and linear sweep voltammetry. The results indicate that the limiting diffusion currents for the hydrogen oxidation reaction are rapidly achieved and remain stable over a wide potential range relevant to anodic operation in PEM fuel cells. The synthesized catalysts exhibit higher catalytic activity and improved resistance to CO poisoning compared to commercial catalysts. Among the investigated samples, the 30% PtRu/WO_x+C catalyst demonstrated the highest catalytic activity and CO tolerance, highlighting its potential as a promising candidate for practical and commercial applications.*

Keywords: *Anode catalyst, CO tolerance, PEM fuel cell.*

1. INTRODUCTION

The development of renewable energy technologies is essential for reducing carbon dioxide and other harmful emissions while improving energy sustainability and security of supply. Among various energy conversion systems, fuel cells have attracted significant attention due to their ability to convert chemical energy directly into electricity and heat. Fuel cell stacks, consisting of multiple individual fuel cells, can be installed near the point of energy consumption, enabling efficient and decentralized energy generation [1,2].

Proton Exchange Membrane (PEM) fuel cells are considered among the most promising technologies due to their high efficiency, low operating temperature, and environmentally friendly operation, producing electricity, heat, and water. However, their large-scale

Corresponding author: S. Brković;
E-mail: snezana.miulovic@vin.bg.ac.rs
DOI: 10.5937/OTEH26115B

commercialization is still limited by high cost and insufficient durability. These challenges are mainly related to catalyst degradation, support oxidation, and sensitivity to fuel impurities [3].

Platinum-group metals, particularly platinum, are widely used as electrocatalysts for hydrogen oxidation and oxygen reduction reactions due to their high activity. However, their high cost and susceptibility to carbon monoxide (CO) poisoning negatively affect the performance and lifetime of PEM fuel cells [4]. Therefore, the development of more durable and cost-effective catalysts and catalyst supports remains a major research focus. The aim of this study is to develop non-stoichiometric tungsten oxide materials as catalyst supports for PtRu anode catalysts in PEM fuel cells. Tungsten oxide is investigated due to its potential to improve CO tolerance and catalyst stability. The influence of different PtRu loadings on electrochemical performance is evaluated using thin-film electrodes combined with rotating disk electrode (RDE) voltammetry.

2. MATERIALS AND METHODS

2.1. Catalyst preparation

In this study, tungsten oxide was synthesized by dispersing 1 g of tungsten powder (Sigma-Aldrich) in 25 cm^3 of deionized water. Subsequently, 25 cm^3 of 30 wt.% hydrogen peroxide (Sigma-Aldrich) was added, followed by the addition of an additional 20 cm^3 of 30 wt.% H_2O_2 after 15 minutes. The suspension was then allowed to evaporate, dried at 110 °C, and a lemon-yellow powder was obtained, designated as WO_x (non-stoichiometric tungsten oxide).

Anode catalysts were prepared by introducing appropriate amounts of commercial hexachloroplatinic acid (H_2PtCl_6, Merck) and ruthenium chloride ($RuCl_3$, Merck) into 35 ml of 0.005 mol dm^{-3} perchloric acid ($HClO_4$, Sigma-Aldrich) containing the synthesized WO_x support. The mixture was subjected to ultrasonic treatment and magnetic stirring for 30 minutes each. Subsequently, 5 ml of 0.1 mol dm^{-3} sodium borohydride solution was added dropwise under continuous stirring, and the suspension was further stirred for 30 minutes. Vulcan XC72R carbon black was then added, followed by an additional 30 minutes of stirring. The resulting suspension was allowed to settle, filtered, washed with deionized water, and dried at 50 °C for 24 hours. The obtained PtRu/WO_x+C catalyst samples contained 10%, 20%, and 30% PtRu loadings.

2.2. Cyclic voltammetry and kinetics

The electrochemical properties of the prepared catalysts were investigated after confirming their composition, using catalyst thin films deposited onto a gold rotating disk electrode (RDE) with a fixed platinum loading of 40 µg cm^{-2}.The synthesized catalysts were evaluated for potential application in PEM fuel cells and compared with a commercial 30% PtRu/C reference catalyst.
Electrochemical measurements were initiated by cyclic voltammetry after purging the 0.5 mol dm^{-3} $HClO_4$ electrolyte with nitrogen for 30 minutes at room temperature. The potential was cycled between 0.03 and 1.2 V vs. RHE at a scan rate of 100 mV s^{-1}. Hydrogen oxidation reaction (HOR) kinetics were investigated using linear sweep voltammetry (LSV) at different rotation rates (1000, 1500, 2000, and 2500 rpm) in the potential range of 0 – 0.3 V vs. RHE. Kinetic and mass activities were calculated using the Koutecky–Levich equation ($1/i = 1/i_k + 1/i_l$) and the specific activity relationship ($i_m = i_k/L$) [5].

The CO tolerance of the catalysts was evaluated by CO adsorption at 50 mV vs. RHE for 2000 s, followed by potential scanning up to 0.9 V and subsequent potential cycling between 0 and 1.2 V vs. RHE to promote CO oxidation.

3. RESULTS AND DISCUSSION

The crystalline structure of the prepared WO_x catalyst support was characterized by X-ray powder diffraction (XRPD) using a Philips PW-1710 diffractometer. The XRPD pattern revealed the coexistence of WO_2 and WO_3 phases, indicating the presence of tungsten in different oxidation states and confirming the non-stoichiometric nature of the WO_x support. The elemental composition of the prepared Pt–Ru catalysts and catalyst support (WO_x) was determined by energy-dispersive X-ray spectroscopy (EDS) using a JEOL JSM-6610LV microscope. The obtained results confirmed the successful preparation of the Pt–Ru catalysts, with a Pt: Ru weight ratio of 2:1 and Pt and Ru mass percentages close to the nominal values, showing only minor deviations.

Figure 1 presents the cyclic voltammograms of the commercial PtRu/C catalyst and the 30% PtRu/WO_x+C catalyst.

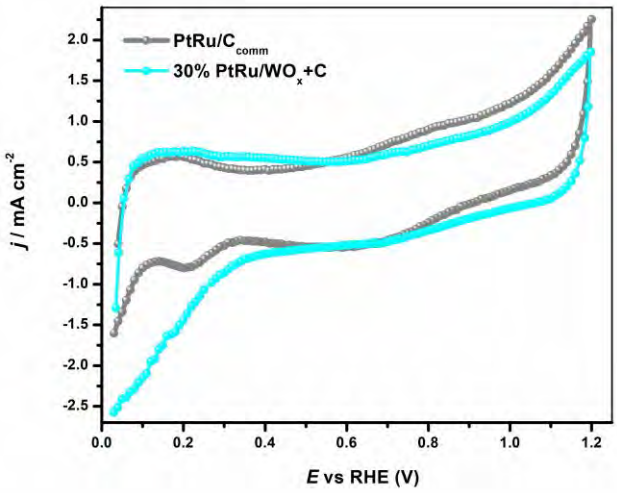

Figure 1. Comparison of the cyclic voltammograms of the commercial and 30% PtRu/WO_x+C catalysts

In the characteristic hydrogen adsorption/desorption region (0.03 V < E < 0.35 V vs. RHE), the PtRu/C catalyst exhibits well-defined and relatively symmetrical anodic and cathodic peaks, which are associated with hydrogen adsorption and desorption processes on the Pt-based active sites.

The H_2 oxidation polarization curves (insets of Figure 2) recorded at different rotation rates for the commercial

30% PtRu/C catalyst (left) and the 30% PtRu/WO_x+C catalyst (right) are presented as insets in Figure 2. For both catalysts, the limiting diffusion current density is reached rapidly, at an overpotential of approximately 60mV, indicating fast hydrogen oxidation kinetics. Furthermore, both catalysts exhibit well-defined and stable polarization behavior over a broad potential range corresponding to the anode operating region of an active PEM fuel cell.

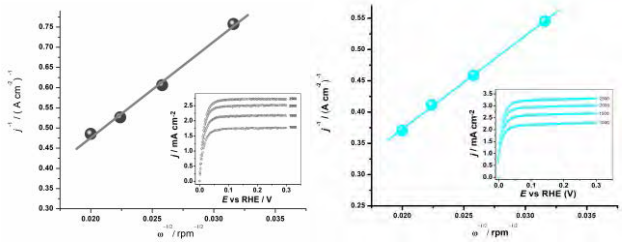

Figure 2. LSV curves of H_2 oxidation at different rotation speeds with the fitted Koutecky-Levich line at 0.02 V vs. RHE for 30% PtRu/C (left) and 30% PtRu/WO_x+C (right)

The current densities at different rotation speeds were extracted from the HOR polarization curves, and the corresponding Koutecky–Levich plots were constructed (Figure 2), for 30% PtRu/C (left) and 30% PtRu/WO_x+C (right). The kinetic current density at an overpotential of 20 mV (j_k) was determined, and the corresponding mass activity (j_m) was calculated for all catalysts (Table 1).

Table 1. Kinetic current densities and mass activities

Catalysts	j_k / *mA cm*$^{-2}$	j_m / *A* mg_{Pt}^{-1}
30% PtRu/C	7,86	0,197
10% PtRu/WO_x-C	10,51	0,263
20% PtRu/WO_x-C	11,40	0,285
30% PtRu/WO_x-C	12,97	0,324

As shown in Table 1, all synthesized catalysts exhibit higher hydrogen oxidation activity than the commercial 30% PtRu/C catalyst. Among the investigated samples, the 30% PtRu/WO_x+C catalyst demonstrated the highest activity, with a kinetic current density of 12.97 mA cm^{-2} and a mass activity of 0.324 A mg_{Pt}^{-1}.

Since the prepared catalysts are intended for application in PEM fuel cells, high tolerance to carbon monoxide poisoning is of crucial importance. Therefore, all synthesized catalysts were evaluated in a gas mixture containing 98% H_2 and 2% CO, simulating the reformate fuel typically used in practical PEM fuel cell systems. The catalysts' tolerance to CO poisoning was evaluated by comparing the HOR polarization curves recorded in pure H_2 and in a gas mixture.

The first cycle of the cyclic voltammogram (CO stripping) corresponds to the electrooxidation of adsorbed CO (CO_{ads}), characterized by a pronounced CO oxidation peak. The second cycle, referred to as the baseline cyclic voltammogram, should coincide with the voltammogram recorded in a pure hydrogen atmosphere, indicating complete removal of the adsorbed CO layer.

The inset of Figure 3 presents the CO_{ads} stripping voltammogram of the commercial 30% PtRu/C catalyst. The first cycle of the cyclic voltammogram, denoted as the CO stripping curve, exhibits a broad and well-defined oxidation peak corresponding to the electrooxidation of CO adsorbed on the catalyst surface. The second cycle, representing the baseline cyclic voltammogram after the removal of adsorbed CO, coincides with the voltammogram recorded in a nitrogen atmosphere. The electrochemically active surface area for CO oxidation (ESA_{CO}) was calculated from the charge associated with the CO oxidation peak (Q, mC) using the equation ESA=Q/q, yielding a value of 0.605 cm².

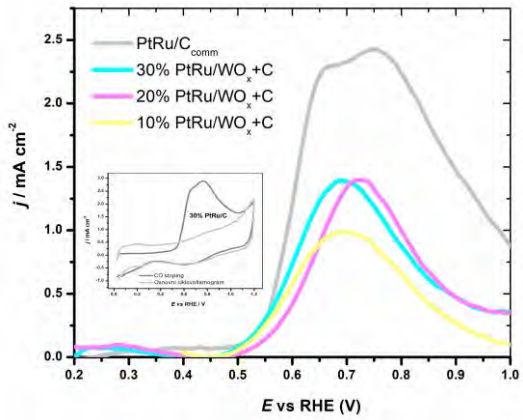

Figure 3. Cyclovoltammogram of CO_{ads} desorption - comparison of CO_{ads} oxidation peaks of commercial, 10%, 20% and 30% PtRu/WO_x+C catalyst,

Figure 3 shows the high-potential region of the cyclic voltammograms, corresponding to the CO_{ads} oxidation peaks of all prepared catalysts. Comparison of the CO stripping voltammograms recorded for the PtRu/WO_x+C catalyst series with that of the commercial PtRu/C catalyst reveals differences over the entire investigated potential range. In the low-potential region (E < 0.5 V vs. RHE), these deviations are attributed to the presence of OH species at the interfacial region between the WOx support and PtRu nanoparticles (PtRu|WO_x [6].

In the high-potential region (E > 0.5 V vs. RHE), all catalysts undergo rapid COads oxidation and removal from the surface. For the commercial PtRu/C catalyst, a broad double oxidation peak is observed, with the main peak located at 0.760 V vs. RHE, whereas the PtRu/WO_x+C catalysts exhibit only a single CO_{ads} oxidation peak. Furthermore, these peaks are shifted by 40–70 mV toward lower potentials compared with the CO_{ads} oxidation peak of the commercial catalyst. In this potential region, CO_{ads} oxidation proceeds mainly through reaction with OH species formed on oxidized metal sites, Pt–OH_{ads} and Ru–OH_{ads}, on both the synthesized catalysts and the commercial PtRu/C catalyst. Since differences in the amount of oxidized CO species are observed between the PtRu/WO_x+C catalysts and the commercial catalyst, an additional effect must contribute to the enhanced CO removal. The improved CO tolerance of the PtRu/WO_x+C catalysts is attributed to the electronic interaction between the WO_x support and PtRu nanoparticles, which modifies the chemisorption properties of the PtRu active site [6]. This electronic effect may also explain the less complex CO oxidation peak profiles observed for the PtRu/WO_x+C catalysts compared with the commercial PtRu/C catalyst.

Table 2. Electrochemical active surface area for CO oxidation and CO oxidation mass activity

Catalysts	ESA_{CO} /cm^2	$j_{m,CO}$ / A mg_{Pt}^{-1}
30% PtRu/C	0.605	0,028
10% PtRu/WO_x-C	0.204	0,050
20% PtRu/WO_x-C	0.270	0,060
30% PtRu/WO_x-C	0.290	0,121

The ESA_{CO} values were calculated from the integrated areas of the CO_{ads} oxidation peaks for the PtRu/WO_x+C catalysts. The obtained values (Table 2) are significantly lower than that of the commercial PtRu/C catalyst.

Figure 4 presents the HOR polarization curves recorded in pure hydrogen and in a 98% H_2 + 2% CO gas mixture at an electrode rotation rate of 2000 rpm and a scan rate of 5 mV s^{-1}. As expected, the anodic current density recorded in the H_2/CO mixture is lower than that obtained in pure hydrogen due to partial blockage of the active Pt sites by adsorbed CO. During the reverse potential scan from 0.9 V to 0 V vs. RHE, the catalyst surface is progressively freed from CO_{ads}, resulting in higher current densities than those observed during the forward scan.

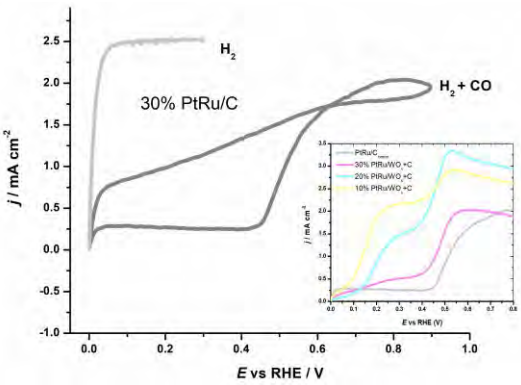

Figure 4. HOR curves for commercial 30% PtRu/C catalyst recorded in pure H_2 and mixture (H_2 +2%CO) gases, at 2000 rpm; inset: HOR curves in H_2 + 2%CO mixture at 2000 rpm - Comparison of anode branches of commercial and PtRu/WO_x+C catalyst

The current density at an overpotential of 20 mV was extracted from the reverse scan, and the corresponding mass activity in the presence of CO ($j_{m,CO}$) was calculated (Table 2). Mass activity $j_{m,CO}$ (A mg_{Pt}^{-1}) in a mixture (98% H_2 + 2% CO) of gases of all analyzed catalysts (inset of Figure 4) was also determined and the obtained values are shown in Table 2.

According to the results summarized in Table 2, all synthesized catalysts outperformed the commercial 30% PtRu/C catalyst in terms of resistance to CO poisoning. Of the investigated samples, the 30% PtRu/WOx+C catalyst achieved the highest mass activity in the presence of CO, demonstrating the best overall electrochemical performance under poisoning conditions.

4. CONCLUSION

WO_x was synthesized and subsequently used as a support for the preparation of Pt- and Ru-containing catalysts. Their electrochemical performance was evaluated by cyclic voltammetry and rotating disk electrode (RDE) voltammetry. Particular emphasis was placed on investigating carbon monoxide poisoning to assess the CO tolerance of the synthesized catalysts.

The results revealed that the mass activities for the hydrogen oxidation reaction (HOR) measured in a gas mixture containing 98% H_2 and 2% CO were considerably lower than those obtained in pure hydrogen. Among the investigated samples, the commercial 30% PtRu/C catalyst exhibited the lowest mass activity, whereas the synthesized PtRu-based catalysts demonstrated significantly improved performance.

The enhanced catalytic activity can be attributed to the formation of the PtRu|support interfacial region, as well as to the generation of Ru–CO_{ads} species, which promote the release of Pt active sites and facilitate the HOR. In addition, most of the synthesized catalysts displayed a shift of the CO_{ads} oxidation/desorption peak toward lower potentials, indicating a higher resistance to CO poisoning compared with the commercial catalyst.

Overall, these findings demonstrate the promising catalytic performance of the synthesized 30% PtRu/WO_x catalyst, particularly in terms of its improved catalytic activity and enhanced CO tolerance, and provide a basis for further evaluation under full-cell conditions.

Abstract: *The development of environmentally friendly corrosion inhibitors has attracted increasing attention due to the need for sustainable alternatives to conventional synthetic compounds. In this study, the corrosion inhibition performance of β-pinene, a naturally occurring bicyclic monoterpene commonly found in plant essential oils, was investigated for carbon steel in 1 M hydrochloric acid solution. The inhibitory effect of β-pinene was evaluated using electrochemical impedance spectroscopy (EIS), potentiodynamic polarization measurements, scanning electron microscopy (SEM), and contact angle analysis. The EIS results demonstrated a significant increase in polarization resistance with increasing β-pinene concentration, reaching 292.2 Ω cm² at 60 ppm compared with 23.4 Ω cm² for the uninhibited solution. The inhibition efficiency increased progressively with inhibitor concentration, from 80.0% at 15 ppm to 92.0% at 60 ppm. Potentiodynamic polarization measurements confirmed the concentration-dependent protective effect of β-pinene, with the corrosion current density decreasing from 173.0 μA cm⁻² for the blank solution to 19.2 μA cm⁻² at 60 ppm, corresponding to an inhibition efficiency of 88.9%. The polarization results indicated that β-pinene acts as a mixed-type corrosion inhibitor with a predominant cathodic effect, mainly through adsorption on the carbon steel surface. SEM analysis revealed a considerably smoother and less damaged surface in the presence of β-pinene, confirming the formation of a protective adsorbed layer. Furthermore, contact angle measurements demonstrated an increase in surface hydrophobicity after inhibitor adsorption, supporting the formation of an organic protective film. The obtained results show that β-pinene effectively suppresses carbon steel corrosion in acidic media and highlight its potential as a green corrosion inhibitor and as an active phytochemical contributing to the protective properties of β-pinene-containing essential oils.*

Keywords: *β-pinene; green corrosion inhibitor; carbon steel; electrochemical measurements; SEM.*

1. INTRODUCTION

Metal corrosion in acidic environments remains a major challenge in many industrial processes, including acid pickling, descaling, and cleaning. Hydrochloric acid (HCl) is widely used because of its high efficiency in removing oxide layers and surface contaminants; however, its aggressive nature accelerates metal dissolution. Consequently, corrosion inhibitors are commonly employed to minimize corrosion in acidic media [1,2].

Although conventional corrosion inhibitors are generally effective, many exhibit toxicity and poor biodegradability, which has encouraged the search for environmentally friendly alternatives [3,4]. Among the most promising green corrosion inhibitors are plant-derived essential oils and their phytochemical constituents because of their renewability, biodegradability, and low environmental impact [5,6].

β-Pinene is a naturally occurring bicyclic monoterpene widely distributed in the essential oils of numerous aromatic and medicinal plants. It is frequently found in essential oils that have demonstrated promising corrosion inhibition performance in acidic media [7,8]. However, since essential oils are complex mixtures, their inhibition efficiency cannot be attributed to a single constituent. Therefore, investigating β-pinene as an individual phytochemical is important for understanding its actual contribution to the corrosion protection provided by β-pinene-containing essential oils.

Despite the increasing interest in plant-derived corrosion inhibitors, studies focused on the inhibition behavior of individual phytochemicals remain limited. In particular, the corrosion inhibition performance of β-pinene under well-defined experimental conditions has not been sufficiently investigated.

Therefore, the present study evaluates the corrosion inhibition performance of β-pinene toward carbon steel in 1 M HCl solution. Electrochemical impedance spectroscopy (EIS), potentiodynamic polarization measurements, scanning electron microscopy (SEM), and contact angle measurements were employed to assess its

E-mail: andjela.simovic@ihtm.bg.ac.rs

DOI: 10.5937/OTEH26116S

inhibition efficiency and the characteristics of the protective film formed on the steel surface. The obtained results provide further insight into the potential application of β-pinene as an environmentally friendly corrosion inhibitor.

2. EXPERIMENTAL PART

2.1. Materials

β-Pinene (Sigma-Aldrich) was used as the corrosion inhibitor in this study. A stock solution was prepared in 30% (v/v) ethanol, and the ethanol content was maintained at the same level in both the inhibited and blank solutions to eliminate its influence on the corrosion behavior. Test solutions were prepared by dissolving β-pinene in 1 M HCl to obtain concentrations of 15, 30, and 60 ppm.

The corrosion experiments were performed using carbon steel with the following chemical composition (wt.%): Mn 0.276, Cu 0.025, Cr 0.030, Ni 0.012, C 0.080, and Fe as the balance. Before each experiment, the steel specimens were sequentially ground using silicon carbide abrasive papers with grit sizes ranging from 200 to 1500. The polished samples were then rinsed with deionized water, cleaned with absolute ethanol, and dried in air before use.

2.2. Methods

2.2.1. Electrochemical Measurements

The corrosion inhibition performance of β-pinene was evaluated using a GAMRY Reference 600 Potentiostat/Galvanostat/ZRA in a conventional three-electrode electrochemical cell. Carbon steel served as the working electrode, a saturated calomel electrode (SCE) as the reference electrode, and a platinum wire as the counter electrode.

Prior to electrochemical measurements, the working electrode was immersed in the test solution for 1 h to allow stabilization of the open-circuit potential (OCP). Electrochemical impedance spectroscopy (EIS) measurements were carried out at OCP over the frequency range from 100 kHz to 0.01 Hz using a sinusoidal perturbation amplitude of 10 mV and 10 points per decade. Potentiodynamic polarization measurements were subsequently performed within the potential range of ±250 mV versus the corrosion potential at a scan rate of 1 mV s^{-1}. The experimental data were analyzed using Gamry Echem Analyst.

2.2.2. Surface Characterization

The surface morphology of carbon steel specimens after exposure to 1 M HCl in the absence and presence of β-pinene was examined using a JEOL 840A scanning electron microscope. Before immersion, all carbon steel specimens used for SEM observation and contact angle measurements were mechanically polished to a 1000-grit finish to ensure a uniform initial surface.

The wettability of the steel surface was evaluated by contact angle measurements after immersion in the β-pinene-containing solution. Following exposure, the specimens were rinsed with distilled water and dried at room temperature. A droplet of Milli-Q water was placed on the specimen surface, and the contact angle was determined using an optical microscope (Smart 5MP Pro, Delta Optical Instruments, Inc., North Little Rock, AR, USA). The recorded images were analyzed using Image-Pro Plus 4.0 software (Media Cybernetics Inc., Rockville, MD, USA).

3. RESULTS

3.1. Electrochemical Impedance Spectroscopy

The Nyquist plots obtained for carbon steel in 1 M HCl solution in the absence and presence of β-pinene at concentrations of 15, 30, and 60 ppm are presented in Figure 1. In all cases, the impedance spectra consist of a single depressed capacitive semicircle, indicating the presence of one dominant time constant associated with the charge-transfer process at the metal/electrolyte interface. The depressed shape of the semicircle is characteristic of non-ideal capacitive behavior arising from surface heterogeneity, roughness, and the adsorption of inhibitor molecules on the steel surface.

Compared with the uninhibited solution, the diameter of the capacitive semicircle increases markedly in the presence of β-pinene, indicating an increase in polarization resistance and improved corrosion protection. Moreover, the semicircle diameter becomes progressively larger with increasing inhibitor concentration, demonstrating the concentration-dependent inhibition performance of β-pinene. The largest semicircle is observed for the solution containing 60 ppm β-pinene, suggesting the formation of a more compact and protective adsorbed layer on the carbon steel surface [9].

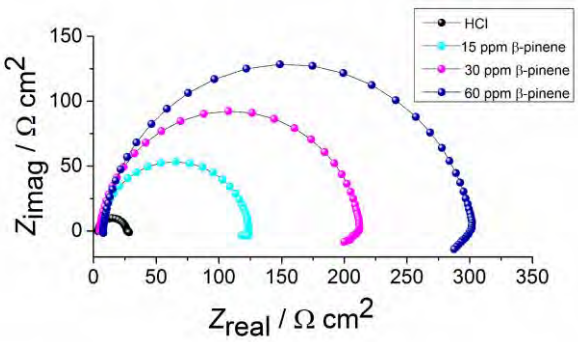

Figure 1. Nyquist plots of carbon steel in 1 M HCl solution in the absence and presence of β-pinene at different concentrations (15, 30, and 60 ppm)

The corresponding Bode plots are presented in Figure 2. The impedance spectra retain the same general shape in both the blank and inhibited solutions, indicating that the addition of β-pinene does not change the corrosion mechanism but rather suppresses the corrosion rate

through adsorption on the metal surface. The phase-angle diagrams exhibit a single maximum in the intermediate-frequency region, confirming the existence of only one time constant and supporting the use of a single-time-constant equivalent electrical circuit for fitting the experimental data.

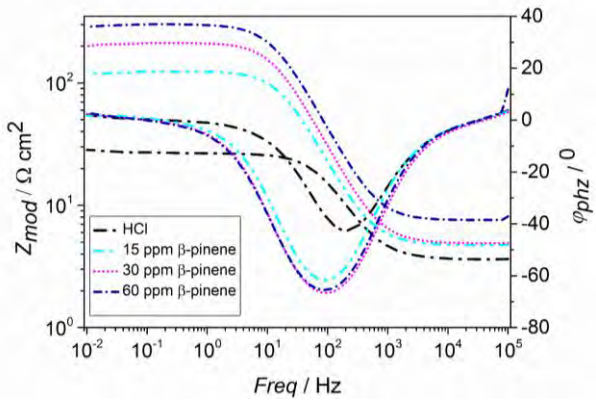

Figure 2. Bode plots of carbon steel in 1 M HCl solution in the absence and presence of β-pinene at different concentrations (15, 30, and 60 ppm)

The equivalent electrical circuit shown in Figure 3 was used to fit the impedance spectra, and the obtained electrochemical parameters are summarized in Table 1. The selected circuit consists of the solution resistance (*Rs*), in parallel with the polarization resistance (*Rp*) and a constant phase element (CPE), which accounts for the non-ideal capacitive behavior of the steel/electrolyte interface caused by surface heterogeneity. The constant phase element (CPE) is characterized by two parameters, Y_o and n, where Y_o represents the CPE magnitude and n is the exponent describing the deviation from ideal capacitive behavior.

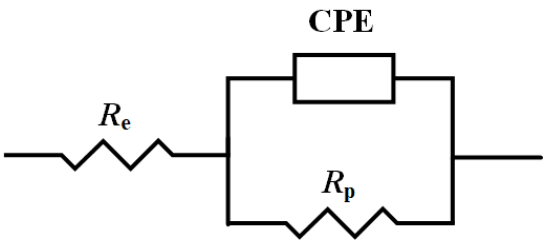

Figure 3. Equivalent electrical circuit used for fitting the EIS data

The inhibition efficiency (η%) was calculated from the polarization resistance values according to the following equation [7]:

$$\eta(\%) = \frac{R_p - R_p^0}{R_p} \times 100 \quad (1)$$

where R_p and R_p^0 are the polarization resistance values obtained in the inhibited and uninhibited solutions, respectively.

As the β-pinene concentration increases, the polarization resistance (*Rp*) increases from 23.4 Ω cm² for the blank solution to 118.6, 205.7, and 292.2 Ω cm² for 15, 30, and 60 ppm, respectively. At the same time, the CPE magnitude (Y_o) decreases from 194.7 × 10^{-6} Ω^{-1} s^n cm^{-2} to 63.4 × 10^{-6} Ω^{-1} s^n cm^{-2}, indicating a reduction in the effective double-layer capacitance due to the adsorption of β-pinene molecules on the steel surface [8]. The inhibition efficiency increases with inhibitor concentration, reaching 80.0%, 88.6%, and 92.0% for 15, 30, and 60 ppm, respectively. These results confirm that β-pinene effectively inhibits carbon steel corrosion in 1 M HCl by forming an adsorbed protective film, with the highest protection achieved at the highest investigated concentration.

Table 1. Electrochemical impedance spectroscopy (EIS) parameters and inhibition efficiency of carbon steel in 1 M HCl solution containing different concentrations of β-pinene.

Solution	R_s / Ω cm²	R_p / Ω cm²	Y_o / 10^{-6}/ Ω^{-1} s^n cm^{-2}	*n*	*η* / %
1 M HCl	3.6	23.4	194.7	0.910	/
15 ppm β-pinene	4.7	118.6	118.2	0,891	80.0
30 ppm β-pinene	4.9	205.7	86.3	0.926	88.6
60 ppm β-pinene	7.4	292.2	63.4	0.923	92.0

3.2. Potentiodynamic Polarization Measurements

The potentiodynamic polarization curves for carbon steel in 1 M HCl solution in the absence and presence of β-pinene at different concentrations are presented in Figure 4. The addition of β-pinene results in a significant decrease in the corrosion current density (jcorr), indicating effective inhibition of the corrosion process. As the inhibitor concentration increases, the corrosion current density decreases progressively from 173.0 μA cm⁻² for the uninhibited solution to 36.8, 27.5, and 19.2 μA cm⁻² in the presence of 15, 30, and 60 ppm β-pinene, respectively.

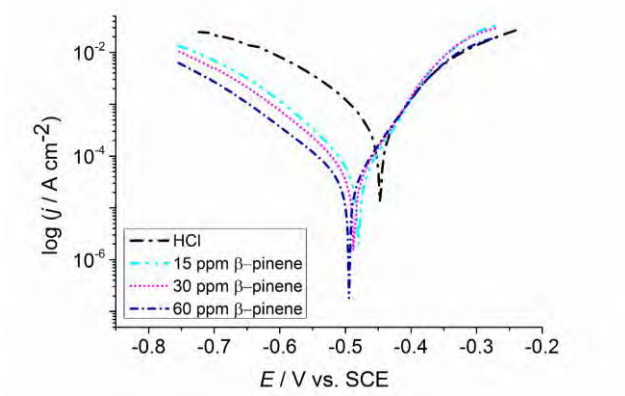

Figure 4. Potentiodynamic polarization curves of carbon steel in 1 M HCl solution in the absence and presence of β-pinene at different concentrations (15, 30, and 60 ppm)

A noticeable reduction in the cathodic branch is observed for all inhibited solutions, whereas the anodic branch remains almost unchanged compared with the blank solution. This behavior indicates that β-pinene predominantly suppresses the cathodic reaction, most likely by blocking the active sites involved in hydrogen evolution through adsorption on the steel surface. The corrosion potential shifts slightly toward more negative values with increasing inhibitor concentration, from −448 mV for the blank solution to −495 mV at 60 ppm β-pinene. Since the displacement of the corrosion potential does not exceed 85 mV, β-pinene may be classified as a mixed-type corrosion inhibitor with a predominant cathodic effect.

The electrochemical parameters obtained by Tafel extrapolation are summarized in Table 2. The inhibition efficiency (η%) was calculated from the corrosion current density values using the following equation [10]:

$$\eta(\%) = \frac{i^0_{corr} - i_{corr}}{i^0_{corr}} \times 100 \quad (2)$$

where i^0_{corr} and i_{corr} represent the corrosion current densities obtained in the absence and presence of β-pinene, respectively.

Increasing the β-pinene concentration leads to a continuous reduction in the corrosion current density, accompanied by an increase in inhibition efficiency from 78.7% at 15 ppm to 88.9% at 60 ppm. These results are consistent with the EIS measurements, confirming that the adsorption of β-pinene on the carbon steel surface effectively suppresses the corrosion process, with the highest protection achieved at the highest investigated concentration.

Table 2. Electrochemical parameters obtained from potentiodynamic polarization measurements for carbon steel in 1 M HCl solution in the absence and presence of β-pinene at different concentrations.

Solution	j_{corr} / μA cm^{-2}	E_{corr} / mV vs. SCE	η / %
1 M HCl	173.0	-448	/
15 ppm β-pinene	36.8	-480	78.7
30 ppm β-pinene	27.5	-488	84.1
60 ppm β-pinene	19.2	-495	88.9

3.3. SEM Analysis

The surface morphology of carbon steel after immersion in 1 M HCl solution in the absence and presence of 60 ppm β-pinene was examined by scanning electron microscopy (SEM), and the corresponding micrographs are presented in Figure 5. The steel specimen exposed to the uninhibited acidic solution (Figure 5a) exhibits extensive surface deterioration characterized by a rough and irregular morphology, confirming the severe corrosive action of hydrochloric acid. The observed damage indicates significant dissolution of the steel surface during exposure to the aggressive medium.

In contrast, the steel sample immersed in the solution containing 60 ppm β-pinene (Figure 5b) displays a considerably smoother and more homogeneous surface with substantially fewer signs of corrosion attack. In several regions, the polishing marks produced during the mechanical preparation of the specimen remain visible, indicating that the steel surface was effectively protected from extensive corrosion. These observations suggest that β-pinene adsorbs onto the carbon steel surface, forming a protective film that acts as a barrier against the aggressive acidic environment. The SEM results are in good agreement with the electrochemical measurements, confirming the effective corrosion inhibition provided by β-pinene.

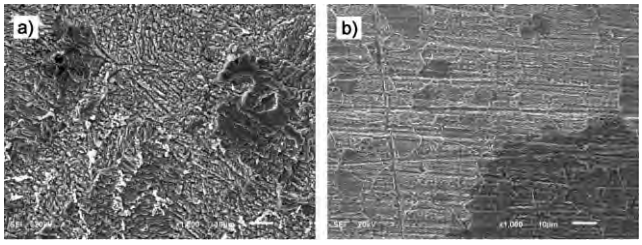

Figure 5. SEM micrographs of carbon steel after immersion in 1 M HCl solution: (a) uninhibited solution and (b) solution containing 60 ppm β-pinene

3.4. Contact Angle Measurements

The wettability of the carbon steel surface after immersion in 1 M HCl solution in the absence and presence of 60 ppm β-pinene was evaluated by contact angle measurements, and the results are presented in Figure 6. The contact angle of the uninhibited steel surface was 37.4°, indicating a highly hydrophilic surface as a consequence of severe corrosion in the acidic medium. In the presence of 60 ppm β-pinene, the contact angle increased to 47.7°, demonstrating a decrease in surface wettability.

The increase in the contact angle suggests that β-pinene adsorbs onto the carbon steel surface, forming a protective organic layer that reduces the affinity of the surface toward water [7]. Although the increase is moderate, it is consistent with the electrochemical and SEM results, confirming the formation of a protective film that limits the interaction between the steel surface and the corrosive environment.

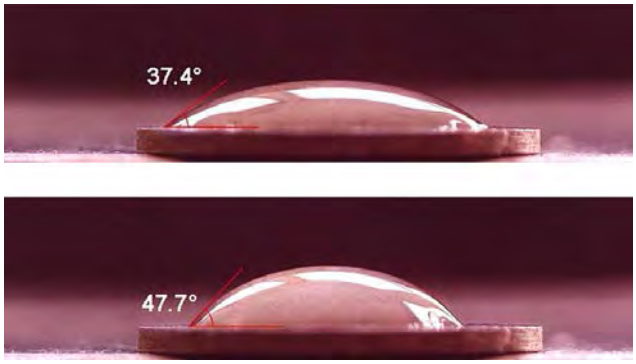

Figure 6. Contact angle measurements of carbon steel after immersion in 1 M HCl solution: without inhibitor (upper image) and in the presence of 60 ppm β-pinene (lower image)

4. CONCLUSION

The present study demonstrated that β-pinene effectively inhibits the corrosion of carbon steel in 1 M HCl, with inhibition efficiency increasing with inhibitor concentration. EIS measurements showed an increase in polarization resistance from 23.4 Ω cm² for the blank solution to 292.2 Ω cm² at 60 ppm β-pinene, corresponding to an inhibition efficiency of 92.0%. Potentiodynamic polarization measurements confirmed the protective effect, with the corrosion current density decreasing from 173.0 to 19.2 μA cm^{-2} and an inhibition efficiency of 88.9% at 60 ppm. The polarization results indicate that β-pinene acts as a mixed-type inhibitor with a predominant cathodic effect. SEM observations revealed substantially lower surface damage in the presence of β-pinene, while the increase in contact angle from 37.4° to 47.7° further supports the formation of a protective organic layer. Overall, the results confirm that β-pinene is a promising environmentally friendly corrosion inhibitor and may represent an important active phytochemical contributing to the protective properties of β-pinene-containing essential oils.

Abstract: *Friction Stir Welding (FSW) and Friction Stir Spot Welding (FSSW) are solid-state joining processes in which bonding occurs below the melting temperature of base materials. These techniques are increasingly applied to non-ferrous metals such as aluminum, titanium, magnesium, and copper, as well as to dissimilar material combinations like Al-Ti and Al-Mg. Their growing use is driven by industrial demands, particularly in the aerospace and automotive sectors, where high strength and low weight are essential. This paper presents an overview of conventional and advanced FSW techniques, focusing on the mechanical and microstructural properties of the resulting joints. Experimental studies and industrial applications demonstrate that high-quality joints in aluminum and titanium alloys can be achieved through proper selection of process parameters and tool geometry. Due to the complex thermomechanical and metallurgical processes involved, careful control of welding parameters such as tool rotational speed, welding speed, and dwell time is crucial. These parameters significantly influence joint quality and the formation of intermetallic compounds, such as Ti_3Al. FSW continues to attract research interest because of its efficiency and potential in joining light metal alloys. Additionally, it is an energy-efficient and environmentally friendly process, contributing to sustainable engineering practices.*

Keywords: *Friction Stir Welding (FSW), Friction Stir Spot Welding (FSSW), aluminum, titanium.*

1. INTRODUCTION

Friction Stir Welding (FSW) is an advanced solid-state joining technology that has gained increasing importance across a wide range of industrial applications. This process enables the reliable joining of materials while providing superior joint properties in both similar and dissimilar metal combinations. FSW was invented and patented by The Welding Institute (TWI), United Kingdom, in 1991, and was initially developed as an alternative to conventional fusion welding for aluminum alloys. The technology was rapidly adopted in the aerospace industry, including NASA space programs, where weight reduction and high structural integrity are of primary importance. Over time, the application of FSW has expanded beyond aluminum alloys to include titanium, magnesium, copper, nickel, lead, zinc, and even steels, demonstrating its versatility for joining a broad range of engineering materials [1].

The development and industrial implementation of FSW have been predominantly associated with the welding of aluminum and its alloys, accounting for approximately 99% of its applications. Butt joints represent the majority of FSW joints because of their excellent mechanical properties, as demonstrated by numerous studies [2]. The weldability of aluminum alloys by conventional fusion welding processes is often limited; however, FSW has provided an effective solution for joining these alloys and related materials. Aluminum alloys, particularly those of the 2xxx, 5xxx, 6xxx, and 7xxx series, are widely used in various industrial sectors, including the automotive, aerospace, space, shipbuilding, construction, bridge engineering, and military industries. Their widespread application is primarily attributed to their low density, favorable mechanical properties, and excellent corrosion resistance [3].

The increasing demand for advanced engineering structures has created a growing need for joining both similar and dissimilar materials. In particular, combinations such as Al-Ti, Al-Mg, Cu-Al, and Al-steel have attracted considerable attention due to their potential for achieving an optimal balance between mechanical

DOI: 10.5937/OTEH26117R

performance, weight reduction, and functional properties. However, joining materials with significantly different melting temperatures by conventional fusion welding processes remains a major challenge. High-strength aluminum and titanium alloys, which are widely used in aerospace applications, are particularly difficult to join using fusion welding because of the metallurgical incompatibilities and defects associated with melting-based processes.

The continued development of FSW has led to significant advances in a number of process variants, including multi-pass FSW, multi-tool FSW, tandem friction stir welding, and Friction Stir Spot Welding (FSSW). These developments have expanded the capabilities of the process and improved its applicability to a wider range of engineering materials and joint configurations. This paper provides an overview of these FSW techniques and discusses their main characteristics. Their implementation has resulted in improved joint performance and significantly broadened the range of compatible alloy systems that can be successfully joined using friction stir welding.

2. FUNDAMENTALS OF THE FSW PROCESS

Friction Stir Welding (FSW) differs from conventional friction welding in that it employs a non-consumable rotating tool to produce the joint. For this reason, FSW is often referred to as tool-assisted friction welding. Unlike conventional fusion welding processes, FSW is a solid-state joining process in which the base materials are joined without melting. During the process, the rotating tool generates frictional heat and severe plastic deformation, softening the material around the tool and enabling its plastic flow. The tool performs a combined rotational and translational motion (Fig. 1). It rotates about its own axis while simultaneously traversing along the joint line, which may be either straight or curved, depending on the joint geometry.

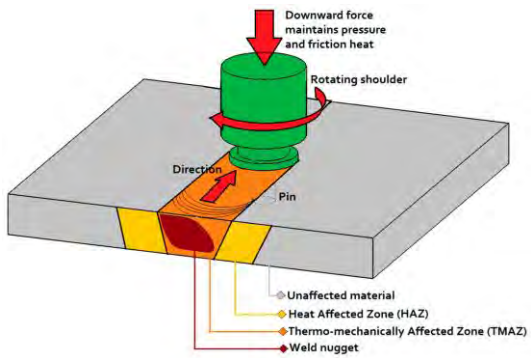

Figure 1. Schematic illustration of the Friction Stir Welding (FSW) process [4]

During the welding process, frictional heat is generated, raising the temperature of the material to approximately 0.8 of its melting temperature, which is sufficient to promote plastic deformation without melting. For most aluminum alloys, the maximum process temperature does not exceed 450 °C [5]. The FSW tool consists of two main components: a shoulder and a pin (Fig. 2). The threaded pin promotes continuous stirring and plastic flow of the softened material around the rotating tool, while the rotating tool typically operates at rotational speeds ranging from 100 to 1500 rpm.

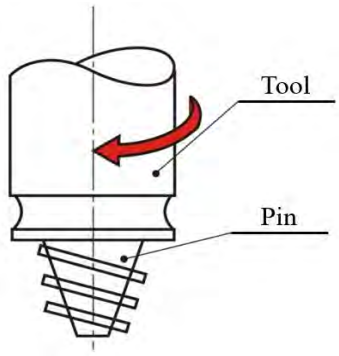

Figure 2. Schematic illustration of the FSW tool [6]

As the tool traverses along the joint line, the softened material undergoes intense plastic deformation and is transported from the leading edge to the trailing edge of the tool. Upon cooling, the plastically deformed material consolidates, forming a sound solid-state joint. At the beginning of the welding process, the tool pin penetrates the workpieces until the tool shoulder comes into contact with the upper surface of the material. After tool withdrawal, a characteristic exit hole, commonly referred to as the keyhole, remains at the end of the weld. The primary function of the shoulder is to apply forging pressure, contain the softened material within the welding zone, and generate the majority of the frictional heat. Tools with profiled shoulder surfaces, such as concentric grooves, spiral features, or scrolls, enhance heat generation and material flow. These surface features facilitate the transport of softened material around the tool, thereby improving material flow, joint formation, and the overall weld quality.

3. FSW-BASED TECHNIQUES

Over a relatively short period, the development of Friction Stir Welding (FSW) has led to the emergence of a broad family of friction stir-based technologies that continue to evolve. These developments have expanded the application of FSW not only as a joining technology but also as a material processing technique. The continuous development of new process variants has expanded the application of FSW to increasingly complex joint geometries and diverse engineering applications. In addition, advances in tool design have contributed to higher process efficiency, improved joint quality, and increased productivity.

The most widely used FSW-based technologies include:

- ✓ Friction Stir Lap Welding (FSLW);
- ✓ Friction Stir Processing (FSP);
- ✓ Friction Stir Dovetailing (FSD);
- ✓ Friction Stir Spot Welding (FSSW);
- ✓ Refill Friction Stir Spot Welding (Refill FSSW);
- ✓ Stationary Shoulder Friction Stir Welding (SSFSW);
- ✓ Underwater Friction Stir Welding (UFSW);
- ✓ Friction Stir Deposition (FSD),

as well as numerous other variants of friction stir-based processing and joining technologies.

Friction Stir Lap Welding (FSLW) is a solid-state joining process primarily used for lap joints in lightweight materials, including aluminum and magnesium alloys, as well as certain polymers [7].

Friction Stir Processing (FSP) is a versatile solid-state processing technique used to refine the microstructure and improve the mechanical properties of metallic materials. It is widely employed in the fabrication of surface composites and has also been successfully combined with ultrasonic vibration-assisted processing to enhance alloying and material modification [8].

Friction Stir Dovetailing (FSD) is a recently developed joining technique for dissimilar materials, particularly aluminum and steel. The incorporation of an aluminum alloy interlayer (AA6061) has been shown to improve the mechanical performance of the joint by increasing both load-bearing capacity and ductility, thereby effectively suppressing the formation of brittle intermetallic compounds [8].

Friction Stir Spot Welding (FSSW) (Fig. 3) is a solid-state spot joining process developed as an alternative to resistance spot welding. The technology is capable of producing high-quality spot welds through precise control of the process parameters and provides excellent mechanical performance, particularly in terms of joint strength. Consequently, FSSW has found widespread application in the automotive and aerospace industries [9].

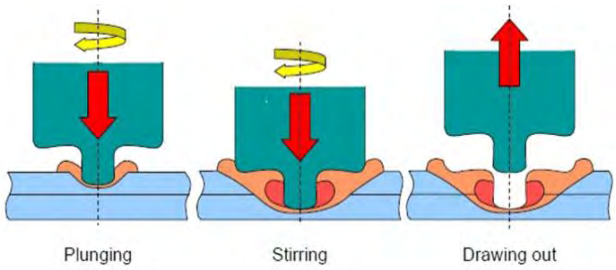

Figure 3. Schematic illustration of the Friction Stir Spot Welding (FSSW) process [10]

Stationary Shoulder Friction Stir Welding (SSFSW) has been shown to provide improved mechanical properties and a more refined microstructure compared with conventional FSW. Owing to its ability to reduce heat input while maintaining excellent joint quality, SSFSW is considered a promising technique for manufacturing lightweight structures [8].

Underwater Friction Stir Welding (UFSW) is an emerging variant of FSW in which the welding process is performed in a water environment. The presence of water creates unique thermal boundary conditions that promote rapid heat dissipation, resulting in a finer microstructure and enhanced joint strength [11]. Owing to these advantages, UFSW has recived increasing attention for joining materials that are difficult to weld using conventional fusion welding processes.

The continuous development of FSW has been driven not only by the need to improve joint quality but also by the demand for higher process efficiency, increased productivity, reduced energy consumption, and greater process flexibility. Consequently, several innovative process configurations have been developed, including multi-tool and double-sided FSW techniques.

Double-sided FSW employs two tools positioned on opposite sides of the workpiece with a slight offset in the welding direction (Fig. 4). Simultaneous counter-rotating operation offers several advantages, including reduced reaction torque and improved weld symmetry. Although the tool pins do not necessarily come into contact, they are positioned sufficiently close to promote effective material flow and mixing throughout the thickness of the joint, ensuring complete weld formation. This configuration also minimizes the asymmetry of lateral forces, resulting in improved process stability and tool balance. Double-sided FSW has been successfully applied to the welding of plates with thicknesses of up to 100 mm.

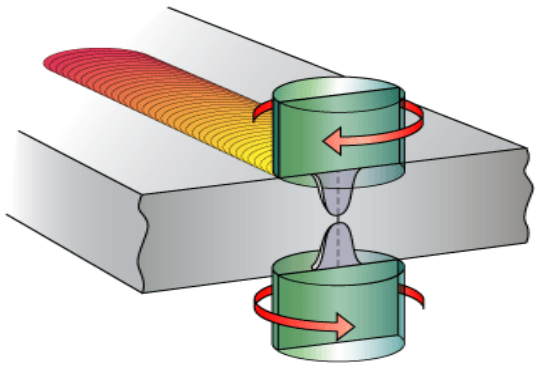

Figure 4. Schematic illustration of the double-sided FSW process [12]

Multi-tool Friction Stir Welding (FSW) enables the simultaneous joining of multiple plates, thereby increasing process productivity and efficiency (Fig. 5).

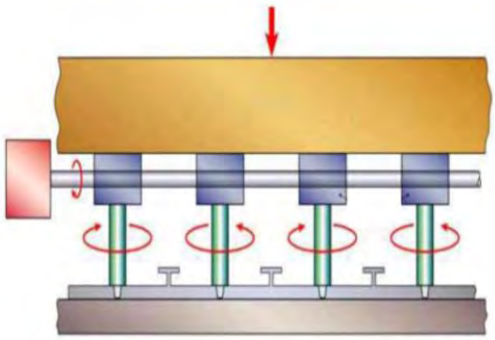

Figure 5. Schematic illustration of the multi-tool FSW process [13]

Several dual-tool FSW configurations have been developed to improve productivity, weld quality, and process efficiency. The three most common configurations are:

1. Parallel twin-tool FSW;
2. Tandem FSW;
3. Staggered twin-tool FSW.

The parallel twin-tool FSW configuration employs two tools that travel simultaneously along parallel welding

paths. This arrangement enables higher welding speeds, threby improved productivity by reducing the overall welding time. Figure 6 illustrates the schematic configuration of this process applied to a lap joint.

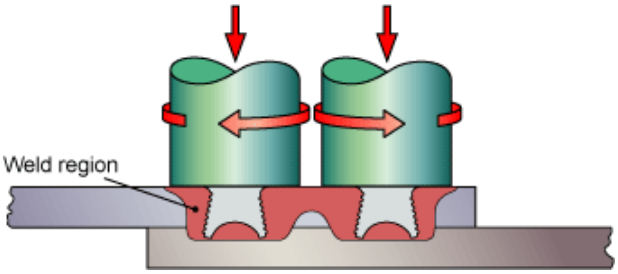

Figure 6. Schematic illustration of the parallel twin-tool FSW configuration [13]

Tandem FSW employs two or more tools positioned sequentially along the welding direction (Fig. 7). The leading tool generates the initial heat input and performs the primary plasticization and stirring of the material while overcoming most of the mechanical resistance. The trailing tool subsequently traverses the softened material, promoting additional material mixing, disrupting residual oxide layers, and refining the weld microstructure. In tandem FSW, the tools are commonly counter-rotating to reduce reaction torque and improve process stability.

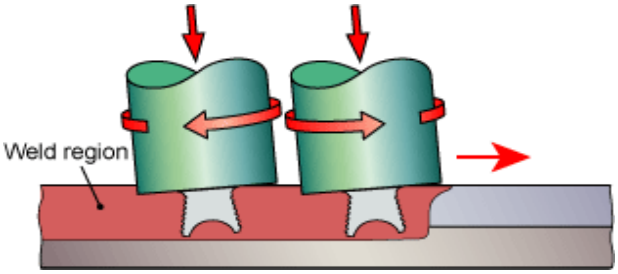

Figure 7. Schematic illustration of the tandem FSW configuration [13]

Tandem FSW has found widespread application in high-performance industries, including aerospace, automotive, and railway engineering. Typical applications include the fabrication of aircraft fuselage panels, rocket propellant tanks, battery enclosures for electric vehicles, and large extruded aluminum profiles used in high-speed railway vehicles [13]. The process is primarily employed for joining aluminum, magnesium, and copper alloys. In shipbuilding, for example, tandem FSW is used for welding thick aluminum alloy plates, particularly those of the 5xxx, 6xxx, and 7xxx series, with thicknesses exceeding 20 mm.

The staggered twin-tool FSW configuration utilizes two tools positioned sequentially with a lateral offset, allowing the second tool to partially overlap the weld produced by the first tool (Fig. 8). This arrangement creates a wider weld region, making it particularly suitable for lap joints where higher joint strength is required. Furthermore, the second tool promotes additional fragmentation and dispersion of residual oxide layers while improving material flow within the thermo-mechanically affected region. Another important advantage of this configuration is its ability to compensate for local thickness reduction that may occur during the first welding pass.

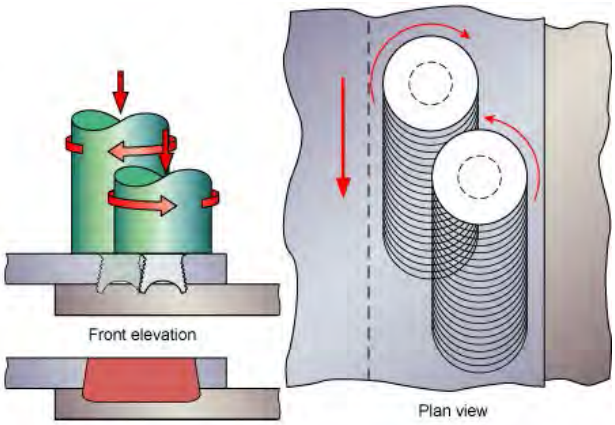

Figure 8. Schematic illustration of the staggered twin-tool FSW configuration [13]

4. WELDABLE MATERIALS

In principle, Friction Stir Welding (FSW) can be applied to joining of nearly all engineering metals, ranging from low-melting-point materials such as aluminum and magnesium to high-melting-point metals including titanium, copper, nickel, and steels. Successful welding depends primarily on the appropriate selection of process parameters and tool geometry, which largely determines the versatility and broad industrial applicability of the process.

Aluminum and its alloys are by far the most extensively welded materials using FSW. All major aluminum alloy series can be successfully joined, making aluminum the primary material group for which FSW was originally developed and remains the most widely adopted in industrial applications.

Magnesium alloys are also highly suitable for FSW. Aluminum-zinc alloys of the AZ series, particularly AZ31 and AZ91, exhibit excellent weldability and are widely used in the automotive and aerospace industries. Similarly, zinc-zirconium alloys of the ZK series produce high-quality welds. FSW has been successfully applied to magnesium components ranging from thin sheets with a thickness of approximately 1 mm to thick plates exceeding 20 mm.

FSW of titanium and its alloys offers an effective joining solution for aerospace, biomedical, and defense applications. Although FSW generally provides superior joint quality compared with conventional TIG and, in some cases, even laser welding, its widespread industrial implementation remains limited because of severe tool wear and the high cost of tool materials. FSW tools for titanium welding are typically manufactured from tungsten-based alloys, tungsten carbide, or polycrystalline cubic boron nitride (PCBN) due to the demanding processing conditions [14].

Compared with other non-ferrous metals, titanium presents unique challenges for FSW because of its high melting temperature and relatively low thermal conductivity. Consequently, lower tool rotational and

welding speeds are generally required to control heat input and minimize tool wear. In the study reported in [15], the mechanical properties and microstructure of the Ti-6Al-4V alloy were investigated using scanning electron microscopy (SEM) and electron backscatter diffraction (EBSD). Microstructural analysis of specimens produced under different processing conditions revealed significant grain refinement and a homogeneous microstructure within the stir zone.

Owing to its excellent biocompatibility, titanium is one of the most important materials for biomedical implants. Consequently, various FSW-based techniques have been developed for fabrication and joining titanium components intended for medical applications.

5. MICROSTRUCTURE OF FSW JOINTS

Owing to the unique characteristics of the FSW process, which combines frictional heating with severe plastic deformation, FSW joints exhibit an asymmetric and highly heterogeneous microstructure. A typical FSW joint consists of four distinct regions: the Base Material (BM), the Heat-Affected Zone (HAZ), the Thermo-Mechanically Affected Zone (TMAZ), and the Stir Zone (SZ), also referred to as the Weld Nugget (WN) (Fig. 9).

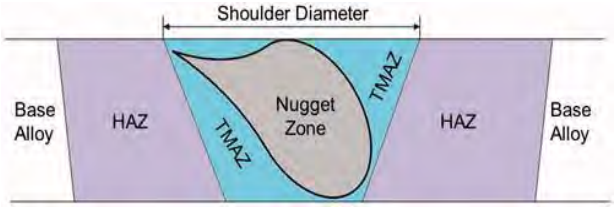

Figure 9. Schematic illustration of the microstructural regions in an FSW joint [16]

The extent of the Heat-Affected Zone (HAZ) depends primarily on the thermal cycle imposed on by the material, particularly the peak temperature and exposure time. In the Thermo-Mechanically Affected Zone (TMAZ), the material undergoes significant plastic deformation combined with elevated temperatures; however, complete recrystallization generally does not occur. The Stir Zone (SZ), located at the center of the weld, experiences the highest levels of plastic deformation and frictional heating. Consequently, extensive dynamic recrystallization occurs within this region, producing a fine equiaxed grain structure.

The boundary between the Stir Zone and the surrounding TMAZ is usually well defined in aluminum alloys because of the distinct difference in recrystallization behavior. In contrast, many other metallic materials exhibit a more gradual transition between these regions. For example, in Ti-6Al-4V and commercially pure copper, the boundaries between the HAZ, TMAZ, and SZ are often less pronounced owing to their different thermomechanical responses during welding.

The Stir Zone is characterized by a fine-grained microstructure, with grain sizes typically ranging from 2 to 10 µm, depending on the alloy system and welding conditions [17]. Figure 10 presents the microstructure of an FSW joint produced in AlMg2.5Cr0.2 aluminum alloy with a plate thickness of 2 mm, illustrating the characteristic microstructural regions.

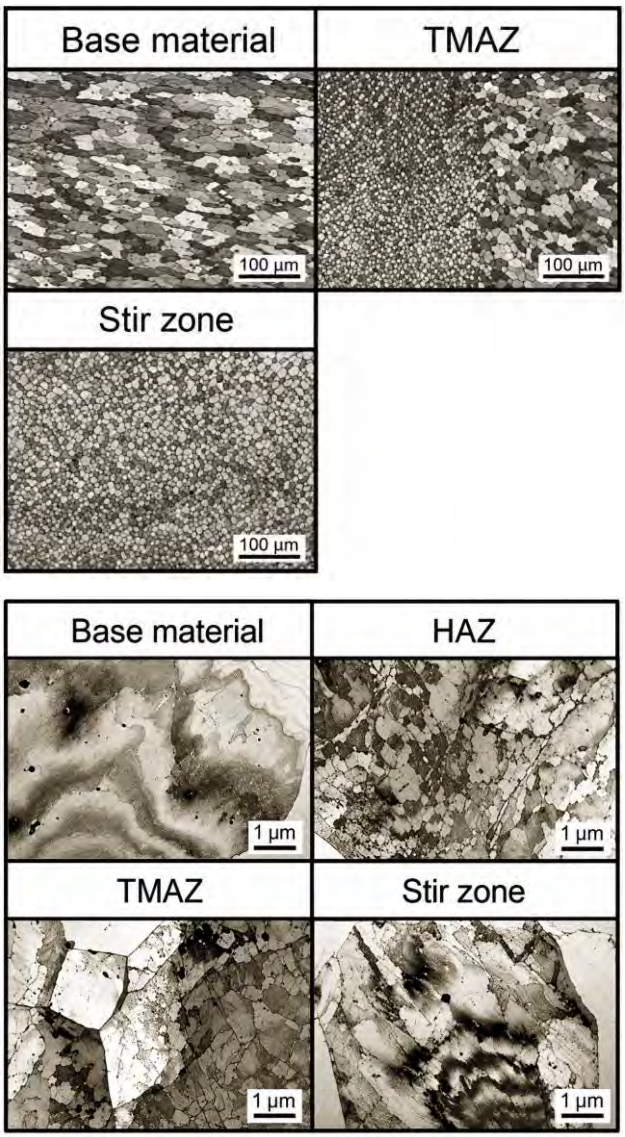

Figure 10. Microstructure of an FSW joint in AlMg2.5Cr0.2 aluminum alloy showing the characteristic microstructural regions [17]

The microstructural evolution during FSW depends strongly on the material being welded and is governed by the combined effects of severe plastic deformation and frictional heating. Dynamic recrystallization occurs within the Stir Zone, leading to the transformation of the original coarse grains into fine equiaxed grains. In aluminum alloys, this process is predominantly associated with geometric dynamic recrystallization. Outside the Stir Zone, where both the deformation and temperature are lower, the grains generally retain their elongated morphology, while dislocations rearrange to form subgrain structures.

Different strengthening mechanisms influence the microstructural evolution of aluminum alloys. In precipitation-hardened alloys, such as AA5052, AA6061, and Al-Mg-Si alloys, the thermal cycle during FSW promotes precipitate dissolution within the Stir Zone, followed by precipitate coarsening during cooling. This

phenomenon is considered one of the primary causes of the localized reduction in hardness. In magnesium alloys, which possess a hexagonal close-packed (HCP) crystal structure with a limited number of slip systems, elevated temperatures activate additional slip systems and deformation twinning. Consequently, dynamic recrystallization becomes more pronounced, often resulting in improved mechanical properties, particularly near the interface between the Stir Zone and the TMAZ [18].

During the FSW of dissimilar light-metal alloys, intense plastic deformation and material flow produce a characteristic swirl-like microstructure. The principal metallurgical challenge in such joints is interfacial diffusion, which may promote the formation of brittle intermetallic compounds. For example, Al-Mg joints typically contain a bilayer intermetallic region composed of Al_3Mg_2, formed adjacent to the aluminum side, and $Al_{12}Mg_{17}$, formed adjacent to the magnesium side. Similarly, a thin $TiAl_3$ intermetallic layer commonly develops at the interface of Al-Ti joints. Therefore, careful control of welding parameters, particularly welding speed and tool geometry, is essential for minimizing the thickness of these intermetallic layers and preserving joint integrity [18].

6. CONCLUSION

Over the past three decades, Friction Stir Welding (FSW) has evolved into one of the most advanced solid-state joining technologies owing to its ability to produce high-quality joints while offering high energy efficiency and excellent environmental sustainability. Nevertheless, further research is required to expand its application to a broader range of engineering materials, complex joint geometries, and dissimilar material combinations.

Although considerable progress has been achieved, several aspects of FSW and Friction Stir Spot Welding (FSSW) remain insufficiently understood. In particular, the joining of dissimilar materials, such as aluminum and titanium, continues to present significant scientific and technological challenges. A deeper understanding of material flow, interfacial reactions, and the formation of intermetallic compounds is essential for further improving joint quality and process reliability.

For lightweight alloys, FSW has become not only an attractive alternative to conventional fusion welding but, in many applications, the only technically feasible and economically viable joining process capable of producing high-quality solid-state joints. Future developments should therefore focus on improving tool materials and extending tool life, particularly when welding high-strength and high-melting-point alloys, where severe tool wear remains one of the primary limitations to large-scale industrial implementation.

The microstructure developed during FSW plays a decisive role in determining the final mechanical performance of the joint. Dynamic recrystallization within the Stir Zone (SZ) produces a refined equiaxed grain structure, resulting in enhanced fatigue resistance, increased hardness, and improved overall mechanical properties.

Further advances in FSW technology will rely on the integration of automation, robotics, digital manufacturing, and numerical simulation. Within the framework of smart manufacturing, virtual process simulation and digital optimization of welding parameters prior to production are becoming increasingly important for improving process efficiency, weld quality, and process repeatability. Consequently, future research should increasingly focus on the development of intelligent process monitoring and control systems to support the wider industrial adoption of FSW technologies.

Finally, one of the most significant advantages of FSW is its environmental sustainability. Since the process is performed entirely in the solid state, it does not require filler materials or shielding gases and produces no harmful fumes, spatter, or intense radiation typically associated with conventional fusion welding. These characteristics make FSW an environmentally friendly and resource-efficient manufacturing process that is widely recognized as a green technology with significant potential for future sustainable industrial applications.

Abstract: *Organophosphate removal is crucial for protection of human health, preservation of biodiversity, and prevention of long-term contamination of soil and water systems. Organophosphate removal using carbon-based materials is widely investigated and employed because these materials are widely available, low-cost, and simple to use, making them practical for treating contamination under diverse conditions. The density functional theory (DFT) is a common tool of computational chemistry to assess the molecular aspects of the interaction between organic molecules and ordered supports such as graphene and modified graphene, including: adsorption geometry, adsorption energetics, nature of interaction (chemisorption of physisorption), and mechanistic insights. On the other hand, such task becomes more complex when the adsorbate and the support are rich in functional groups and diverse in steric properties. This contribution deals with the DFT investigation of adsorption of several selected and commonly used organophosphate model molecules on graphene oxide. The goal was to find the optimal binding geometry among several selected input positions and to find energetically most stable orientations. The obtained output geometries were further analyzed and discussed in order to design more precise carbon-based materials for advanced purposes, such as reusable adsorbents or catalysts for irreversible organophosphate hydrolysis.*

Keywords: *density functional theory, adsorption, organophosphate, graphene oxide.*

1. INTRODUCTION

Organophosphorus molecules, including warfare agents and pesticides, are highly toxic compounds that can pose serious risks to human health and the environment, including neurotoxicity and contamination of water resources, so their efficient removal is important for environmental priority, as well as for removal of warfare agents in defensive technologies. The study on the impact of graphene-based material structure shows that adsorption performance depends strongly on the nature of the graphene surface, which makes graphene-based materials promising candidates for removing these pollutants from wate [1].

Graphene oxide-based materials have attracted considerable attention for removing organophosphorus pesticides from water because their adsorption behavior depends strongly on surface structure, oxidation state, and the preservation of the sp^2 carbon network. In particular, oxidized graphene surfaces favor adsorption of more polar aliphatic compounds such as dimethoate, while graphene basal planes with a more ordered π-electron system are more suitable for aromatic pesticides such as chlorpyrifos.

Recent review work on graphene oxide (GO)-based materials for neurotoxic organophosphates also emphasizes that GO and GO composites are highly effective because their oxygen-containing functional groups, defects, and tunable surface chemistry enabl multiple interaction pathways, including hydrogen bonding, electrostatic attraction, π–π interactions, and complexation. These features make GO a versatile platform for both adsorption and remediation of organophosphate pollutants in aqueous systems [2].

Besides experimental studies, density functional theory (DFT) can also be used to investigate these systems at the molecular level. DFT helps explain adsorption energies, charge transfer, preferred binding sites, and the role of functional groups and defects, which makes it a useful complement to experiments when interpreting why some graphene-based materials remove organophosphates more efficiently than others [3].

The goal of the work was to establish a simple, general DFT-based methodology for investigation of adsorption of organophosphate molecules on graphene oxide, including warfare agents and pesticides. Tabun, as the representative of warfare agents, and dimethoate and malathion, as the representatives of pesticides, were selected for this investigation This is expected to provide insight into the general features and adsorption properties for structurally similar compounds.

2. CALCULATION DETAILS

Density functional theory (DFT) calculations were used to investigate the interaction between the organophosphate

Corresponding author: D. Vasić Anićijević

DOI: 10.5937/OTEH26118V

molecule and the graphene oxide (GO) surface at the molecular level. The computational approach was chosen to provide insight into the adsorption mechanism, the strength of interaction, and the role of oxygen-containing functional groups and surface defects in stabilizing the adsorbate on the GO sheet.

DFT calculations were performed using DFTB+ code [4] using 3ob-3-1basis set. The calculation procedure began with the construction of the isolated GO model, the isolated organophosphate molecule, and the combined adsorbate–adsorbent system. Graphene oxide was modelled as a 128-atom graphene slab with 8 oxygen atoms in epoxy positions and 8 OH-groups in C-top positions to simulate oxygen-rich environment. At least 30 angstroms of vacuum above the slab were provided to minimize interactions between periodic images. All structures were then geometry optimized to obtain the most stable configuration and to ensure that the total energy corresponded to a minimum on the potential energy surface. All atoms were moved through relaxation and 300 geometry optimization steps were allowed. During optimization, the electronic convergence criteria10^{-6} eV and force thresholds 5×10^{-3} eVA^{-1}) were applied to guarantee reliable structural and energetic results.

After geometry optimization, the adsorption energy was calculated according to the following expression:

$$E_{ads}=E_{complex}-E_{GO}-E_{OPs} \quad (1)$$

where $E_{complex}$ is the total energy of the GO–organophosphate system, E_{GO} is the energy of the isolated graphene oxide surface, and E_{OPs} is the energy of the isolated organophosphate molecule. A negative adsorption energy indicates a thermodynamically favorable interaction, while a more negative value corresponds to stronger binding between the molecule and the GO surface.

3. RESULTS AND DISCUSSION

Optimized adsorption geometries os DMT, MLT and GA on GO are represented in Figures 1-3. Multiple input molecular orientations were selected to favorize the potential interaction between heteroatom moieties of organophosphate molecules (P=S, N-H and O-H binding), as well as large surface contact areas (Van der Wals forces). Structurally, the GO lattice remains intact across the configurations, preserving its hexagonal carbon framework and the distribution of hydroxyl, epoxy, and carboxyl groups that facilitate adsorption. Across all tested organophosphorus compounds (dimethoate (DMT), malathion (MLT), and tabun (GA)), the adsorption energies (E_{ads}) reveal a consistent trend of strong binding to the graphene oxide surface. Each molecule exhibits negative adsorption energies, confirming thermodynamically favorable interactions.

Stable adsorption is attributed both to physical (hydrogen bonding, Van der Wals, electrostatic) and chemical interactions (S-O and N-H binding between substrate and adsorbate). Furthermore, all three compounds demonstrate multiple stable adsorption configurations with similar adsorption energetics, highlighting the structural flexibility of GO in accommodating different orientations and binding modes.

Despite these commonalities, notable differences emerge in adsorption strength and orientation (**Table 1**). Dimethoate (DMT) shows the most stable adsorption overall, with DMT-3 reaching the lowest energy (−294.55 kJ mol^{-1}), indicating strong surface coupling through both N-H-O and C-O-H interactions (hydrogen bonding). In case of MLT-2, S-O binding is the most obvious in adsorption geometry. Malathion (MLT) exhibits weaker adsorption in MLT-1 and MLT-2 (−217.43 and −213.62 kJ mol^{-1}), but achieves significantly stronger binding in MLT-3 (−264.12 kJ mol^{-1}), suggesting the significant contribution of hydrogen binding and Van Der Wals interactions to the overall binding energy. Similarly, Tabun (GA) presents the widest variation upon the change of adsorbate-to-substrate contact area: GA-1 shows the weakest adsorption (−186.97 kJ mol^{-1}), while GA-2 demonstrates a much stronger interaction (−266.18 kJ mol^{-1}), reflecting how positional differences (flat vs. upright orientation) drastically alter binding affinity.Collectively, these results underscore that adsorption energy is highly sensitive to molecular geometry, with DMT generally outperforming MLT and GA in stability, while GA exhibits the largest configurational variability.

Table 1. Adsorption energies (E_{ads}) of malathion, dimethoate and tabun on graphene oxide, for investigated adsorption geometries.

OPs		E_{ads} (kJ mol^{-1})
dimethoate	DMT-1	-285,39774
	DMT-2	-255,07476
	DMT-3	-294,55398
malathion	MLT-1	-217,43244
	MLT-2	-213,61734
	MLT-3	-264,11796
tabun	GA-1	-186,96816
	GA-2	-266,18094

Table 1 presents the adsorption energies (Eads) of three organophosphorus compounds: dimethoate (DMT), malathion (MLT), and tabun (GA) in different adsorption configurations on graphene oxide (GO). All values are negative, confirming that the adsorption processes are thermodynamically favorable.

Optimized adsorption geometries of DMT, MLT and GA on graphene oxide are represented in **Figures 1-3**.

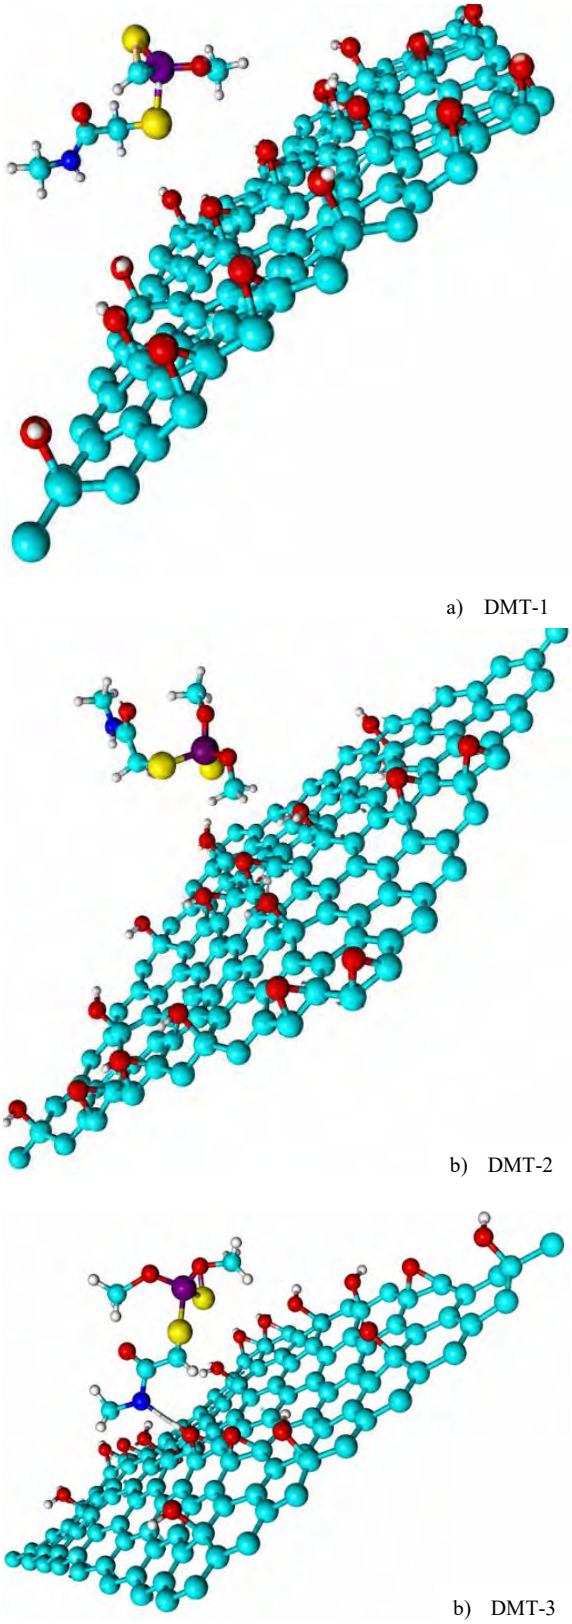

Figure 1. Optimized adsorption geometries of DMT on graphene oxide

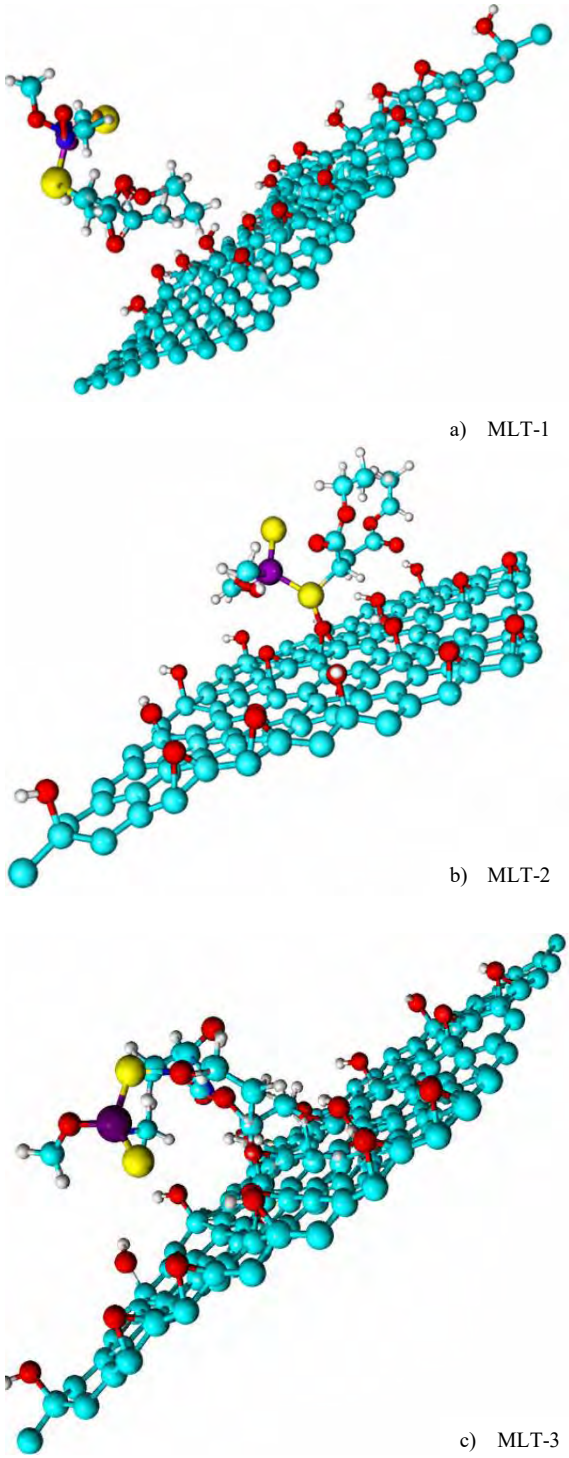

Figure 2. Optimized adsorption geometries of MLT on graphene oxide

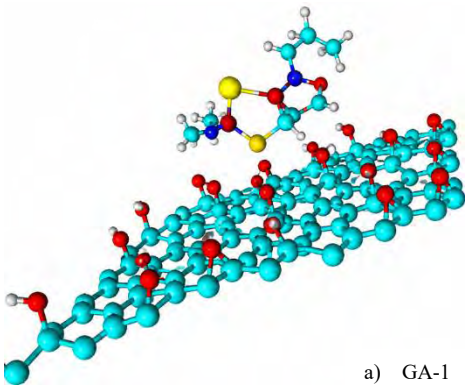
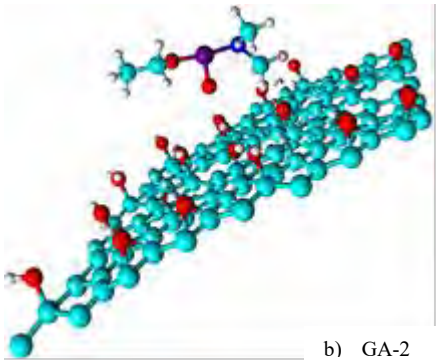


a) GA-1



b) GA-2

Figure 3. Optimized adsorption geometries of GA on graphene oxide

4. CONCLUSION

The results presented in Table 1 and illustrated in Figures 1–3 clearly demonstrate that adsorption of organophosphorus compounds on graphene oxide is energetically favorable, with all calculated adsorption energies being negative. Among the studied systems, dimethoate (DMT) exhibits the strongest and most stable adsorption, particularly in configuration DMT-3, highlighting the importance of molecular orientation in maximizing surface interactions. Malathion (MLT) shows moderate adsorption energies, with a significant increase in stability in MLT-3, confirming that steric effects and binding geometry strongly influence adsorption strength. Tabun (GA) displays the widest variability, ranging from weak adsorption in GA-1 to markedly stronger binding in GA-2, underscoring the sensitivity of this compound to configurational changes.

Overall, the combined numerical and structural analyses indicate that graphene oxide provides a versatile platform for binding organophosphorus agents, with adsorption strength governed primarily by the spatial arrangement of phosphorus and sulfur centers relative to oxygen rich functional groups. These findings emphasize the potential of GO as an effective adsorbent material for environmental remediation and decontamination applications.

Abstract: *Military industries operate with many opportunities, but also face obstacles in the form of political, economic or security restrictions. This paper analyzes additive manufacturing, or 3D printing, as a technology which can provide more resilient production, development, and sustainability of military capability for small states. By analyzing open-source strategic reports and scientific studies, the paper identifies three interlinked dimensions in which 3D printing can contribute to sustainable military production under various political and security conditions: security resilience, economic efficiency and environmental responsibility. The findings show that additive manufacturing can reduce dependence on imports of different components, which can mitigate challenges related to international sanctions, export restrictions or supply chain disruptions. Analyzed sources indicate that 3D printing can offer greater adaptability, lower cost, and a faster development process for small scale production. It can reduce material waste, energy consumption, transportation costs and carbon emissions. The global trends, opportunities and present risks, such as patent rights, cybersecurity and arms proliferation control are taken into consideration. Policy recommendation includes establishment of 3D printing hubs, product modification strategies and the adoption of energy efficiency and ecology standards. Overall, 3D printing can provide a higher degree of autonomy and resilience in military production for small states.*

Keywords*: additive manufacturing, 3D printing, military industry, production sustainability, small states, production efficiency.*

1. INTRODUCTION

Nowadays, military industries are frequently hit by political disturbances, economic obstacles, security threats, and ecological catastrophes. These constraints are usually expressed in forms of political requests, international sanctions, weapon embargoes, or trade tariffs.

Production of military weapons and equipment in small states is usually based on massive imports of different components and spare parts. The supply is relied on long-distance supply chains, centralized supply routes, suppliers from various countries, and a long time for execution. These characteristics make the supply very sensitive to any possible constraints.

The military industry can use developed technology of additive printing (AM) or 3D printing, as a national defense strategy policy to establish operational resilience under disruptive conditions [1]. This technology offers opportunities for locally produced components, in small series with small-scale material stocks, using universal 3D printers and DIGITAL FILE models. It constructs objects by adding material layer by layer, with minimal leftover. Modern technology produces very complex components technology can produce very complicated components, consisting of different materials, depending on printing technology [2].

According to open-source strategic reports and case studies, AM contributes to the resilience of military production in small states through three areas: security resilience, economic efficiency, and environmental responsibility.

Along the positive sides of AM technology, the paper discusses critical risks, focusing on the patent rights, cybersecurity, arms proliferation control, and required precondition for locally 3D printing of spare parts [3].

In conclusion, the paper translates findings into several policy recommendations, including the establishment of regional 3D printing hubs, on-site modification workshops, and the implementation of material recycling standards in manufacturing.

2. BASIC CONCEPTS: ADDITIVE MANUFACTURING, MILITARY INDUSTRY, AND INTERNATIONAL TRADE CONTROLS

Characteristics of AM, the production of weapon systems, and international trade conditions are in correlation to component supplies. Each domain introduces analytical categories that are essential for interpreting empirical evidence presented in subsequent sections of this paper.

2.1. Additive Manufacturing: Definition, Processes, and Characteristics

Additive manufacturing (AM) is an innovative technology where the object creation is based on layer-by-layer material addition, in contrast to conventional manufacturing, where the object creation is based on removing excess material.[2].

For small series component production, AM offers several advantages over conventional manufacturing: almost no material waste, easy fabrication, minimal human work, little post-processing, and energy efficiency. [4]

These properties make 3D printing relevant for production in the military industry, for small-scale production, where availability of components is crucial, the time of supply is essential, and the cost reduction is fundamental. The Peace Research Institute Frankfurt characterizes AM as "key for the development of future military capabilities" and notes that the technique "produces objects layer by layer according to a digital 3D model" [5].

According to the American Society for Testing and Materials (ASTM) classification, AM processes are divided into seven main categories [4]: Stereolithographic (SL), the earliest process, introduced and patented by Charles Hull in 1984; Fused Deposition Modelling (FDM), developed by Stratasys; Powder Bed Fusion (PBF), encompassing Selective Laser Sintering (SLS), Electron Beam Melting (EBM), and Selective Laser Melting (SLM); Binder Jetting, developed at MIT; Direct Energy Deposition (DED), specifically employed for repair and maintenance rather than new-part fabrication; and Laminated Object Manufacturing (LOM), commercialized by Helisys Inc. in 1991. Every AM technology has different characteristics and fields of application.

2.2. Technological Framework

Additive manufacturing is strongly connected with industrial development aligned with Industry 4.0. Raja Santhi, A. and Muthuswamy, P. [6] describe Industry 4.0 as an industry transformation based on digital connection and data-driven processes, focused on automation, interconnectivity, and real-time process optimization. In this environment, leading technologies are the Internet of Things (IoT), Machine Learning (ML), Artificial Intelligence (AI), Cyber-Physical Systems (CPS), Cloud Computing, Additive Manufacturing, Digital Twins, and Cybersecurity. All of these technologies from Industry 4.0 create a manufacturing ecosystem that is interconnected and data-driven [6].

On the other hand, military industry production has always been expensive, involved high technology, complicated product development, and secrecy. In the era of globalization, the costs of development and production have been reduced by outsourcing some work or by buying some components from the main world producer. Such a solution leads to many challenges: trade barriers, disruption of supply-chains, security challenges, time for delivery, quality control, etc. In some cases, for high-tech systems, for small-scale production, the low price is not the main goal, but the availability of components on time.

2.3. International Trade Controls, Sanctions, and Trade Barriers

Hirbu [7] provides a foundational definition: "A trade restriction is defined as any government policy that limits the free flow of goods and services across borders. The main goal of trade restrictions is to protect domestic industries from cheap imports from other countries".

Of greater relevance to the military-technological context is the author's typology of four categories of formal trade barriers: Voluntary Export Restraints, Regulatory Barriers, Anti-Dumping Duties, and Subsidies [7]. Beyond formal tariff barriers, the literature identifies non-tariff measures as increasingly central instruments of trade governance. Hirbu [7] notes that "non-tarife barriers are way to restrict trade using trade barriers in a form other than a tariff ... There are different types of non-tariff measures, such as quotas, sanctions, import deposits, licenses, embargoes, etc."

Monadjemi and Lodewijks [8] highlight the strategic, power-political dimension of trade restrictions: "There is a literature on strategic trade policy, and this appears a power play to reduce market access to improve a bilateral trade deficit." This insight is relevant for understanding how sanctions and export controls function, not merely as regulatory instruments but as tools of geopolitical competition, directly affecting the availability of advanced manufacturing technologies, including AM systems, to states subject to such measures.

3. METHODOLOGY AND ANALYSIS OF THE THREE CORE DIMENSIONS

3.1. Security Resilience

The primary utility of AM within a small state's defense strategy is its capacity to transform a physical, vulnerable logistics pipeline into an anti-fragile, digital asset protection network.

Traditional weapons embargoes and economic sanctions rely on physical interdiction at critical geographical choke points such as maritime ports, airspace corridors, and border crossings. Additive manufacturing fundamentally alters this interdiction dynamic by digitizing the transaction layer, and they become invisible to traditional

maritime blockades and customs border checks [9].

Field data from international deployments confirms that the speed of local component execution acts as a major resilience factor during active disruptions. In expeditionary or isolated defensive settings, standard logistical transport pipelines typically feature severe vulnerabilities due to damaged local infrastructure or a lack of secured transport [2].

3.2. Economic Efficiency

Military supply chains during operations differ from civilian supply chains in ways that amplify the vulnerabilities of smaller states. Den Boer et al. [2] identify three distinguishing features: the primary focus is not on financial efficiency but on advancing the operational effectiveness of deployed troops; the circumstances in which troops operate are of considerably greater variety; and during military and humanitarian operations, the supply chain frequently encounters damaged infrastructure, lack of transport, loss of governmental functions, threat or physical violence, and the presence of many injured and traumatized individuals.

Westerweel et al. [16] conclude that on-site 3D printing can help to solve some of the biggest issues. It is presented the new model formulation in which a 3D printer can be used to resolve spare parts shortages. The benefits of on-site printing are demonstrated via a case study based on actual Royal Netherlands Army operations in Mali. The results prove that RNLA greatly benefits from on-site printing, much more than from a conventional expediting option. It shows a reduction in operational costs of 47% across 14 components, and inventory storage space for regular spare parts is reduced by 72%. Those benefits are achieved with a relatively simple general-purpose printer against small investments in on-site raw material [16].

3.3. Resource saving and recycling

The military industry is structurally optimized for weapon production, where the raw material is optimized for subtractive production, ignoring ecological costs of raw material extraction, scrap generation, and intercontinental transportation loops [10]. In conventional subtractive production, up to 80% to 90% of the raw material is ground away into unrecyclable shavings, which becomes a massive waste footprint for premium, energy-intensive materials [1].

Additive manufacturing has different material processing based on different technology [12]. 3D printers build components layer-by-layer, using the precise volume of printing powder required for the component's geometry [13]. Any unspent material powder surrounding the build chamber is vacuum-reclaimed, sieved, and recycled into subsequent production runs, capping net material waste below 5% to 10% [13]. For a small state facing import restrictions, this 90% reduction in material scrap ensures that precious stocks of national raw metals are preserved rather than lost to factory floor waste.

Official field deployment records for the Dutch troops in the UN mission in Mali indicate that over 51% of all freight cargo delivered to remote military bases consists of single-use packaging materials, polymer containers, and protective sealing foils, with less than 0.1% of these materials ever returned to the home country [2].

By deploying ruggedized shredders and compact filament extruders within the base infrastructure, single-use polymer packaging can be processed locally into technical-grade printing filaments [2]. Processing the baseline 51% packaging waste stream available on-site drops external supply dependency down to 56.65%, proving that on-site circular recycling acts as a strategic buffer [2]. This transformation turns military production into a localized, self-sustaining loop, significantly reducing the carbon footprint of transport vehicles while securing parts supply without drawing on external resources [11].

4. GLOBAL TRENDS, RISKS, AND CHALLENGES

4.1. Resilience policy trends in study cases

The case of the Royal Netherlands Army is particularly instructive as an example of how a small but technically advanced NATO member has approached the AM-logistics nexus. Den Boer et al. document that "the Dutch Army has been going through several budget cuts in the last decade. It has caused the military to be feeding off reserves, both financially and physically in spare parts and material. These budget cuts have led to situations in which availability requirements of materials and spare parts for certain units were not met, in turn affecting preparatory activities for missions and on combat power during missions themselves" [2].

The institutional response was equally significant: "As part of the government strategic plan, the Dutch Ministry of Defense is supposed to reduce primary raw material use by 50%" [2]. This commitment simultaneously addresses economic, environmental, and operational objectives, with AM as the enabling technology.

The most extreme contemporary illustration of AM as a supply chain resilience instrument under conditions of acute disruption is provided by the Ukrainian wartime context. Suckau describes how "both industrial actors and private citizens form nodes in a crowdsourced supply network that supplies the army. As such, it not only shows how lethal effects are achieved, compared to industrial applications' simpler 3D printing, but also exemplifies the professionalization and adaptation of an ad hoc innovation that initially responded to a lack of materials and supply. Besides polymer-based products, replacement parts for conventional armaments have been printed with machines provided through international military assistance".[5] This case transcends the conventional state-centric model of military logistics, demonstrating that under conditions of extreme supply chain disruption, AM enables decentralized, distributed production networks involving civil society actors.

The author appropriately notes the epistemological

limitation of this case: "It is too early to assess the impact on Ukrainian military capabilities" [5]. Nevertheless, the case provides a documented illustration of the mechanisms through which AM can substitute for or supplement conventional supply chains when those chains are partially or fully disrupted.

4.2. Intellectual Property (IP) and Legal Vulnerabilities

When there are supply chain disruptions, regardless of whether they are political isolation, embargoes, or blockades, it immediately affects military production and defense forces readiness [2]. To keep weapon production and maintenance alive by using reverse engineering and locally 3D printing components without authorization from foreign original equipment manufacturers. This can be an immediate solution for defense capabilities, but long-term it can induce problems with contractual and guarantee breachs, but also can cause additional diplomatic countermeasures.

As documented by defense logistics reviews, utilizing self-produced spare parts instead of OEM-certified components routinely invalidates overall system warranties. This can lead to intense legal disputes regarding liability if a system fails during operations [2].

The international community and companies will not look favorably on the infringement of patent rights, such as the mass production of parts without a license. This will have as a consequence secondary economic sanctions, further trade restrictions, or military actions in some cases, which can be extremely harmful for the military structures of small states.

4.3. Cyber-Physical Security Vulnerabilities

AM infrastructure is relying on digital design files, which opens up for hostile cyber operations [9], especially when the CAD software and 3D printers are usually produced by global foreign companies. In some cases, 3D printers are connected to the Internet to their producer, from whom the printing file has to be received. Adversaries can use these facts to cyber-physically sabotage.

Cyber attackers do not need to destroy a network or prevent printing components. Instead of that, the printing file can be intercepted, and the component registries can be changed. These changes can lead to small changes in design or printing quality, which can have an impact on printed component function [3].

These compromised parts will visually pass field inventory checks, only to suffer catastrophic failure under operational stress (e.g., a drone propeller snapping at high RPM or a missile casing rupturing upon ignition), rendering the weapon system ineffective at a critical moment.

4.4. Technical Omissions and Quality Control

Maintaining consistent mechanical properties across distributed, forward-deployed 3D printers remains a difficult engineering challenge. In centralized mass production, quality control is maintained through tightly regulated factory conditions [1]. On the field, however, AM systems must operate in harsh, volatile environments. Institutional reports from the U.S. GAO and the NATO STO [14] mention uncontrolled changes in humidity, and fluctuations in electrical grids, but also the quality of trained personnel.

Uncontrolled changes in humidity, ambient temperature, and dust contamination can degrade raw metal powders and technical polymers [1]. For example, nylon and advanced polyamides are highly sensitive to moisture, and poor storage conditions can lead to porous, brittle prints [2].

Fluctuations in electrical grids or rough physical handling of machines can throw off optical laser calibration or extrusion precision [1]. This can affect the precision of the production head, which can be a big problem for high-precision military systems [2].

The problem of trained personnel who are responsible for printing components or quality control is problematic because usually it’s their additional job, and the different components have different requirements. It’s difficult to train personnel for every possible situation.

4.5. Arms Control and Proliferation Challenges

Today, 3D printing is a widely spread technology, with very capable 3D printers available for a relatively low price. If CAD printing file reach a person with criminal intentions, they can easily produce components of highly capable weapon systems. Traditional arm control systems are based on tracking physical components, and they aren’t successful. Tracking digital files is much harder, and it’s dangerous.

UNIDR [3] highlights that AM deconstructs this framework by separating the design of a weapon from its material execution. Unindexed weapon designs, modular CAD frameworks for improvised explosive devices (IEDs), and components for autonomous kamikaze drones can be shared globally across untraceable digital networks.

This digital transfer makes it increasingly difficult for international bodies to enforce traditional export controls or verify non-proliferation treaties. This environment allows both non-state actors and domestic criminal enterprises to establish covert, localized manufacturing cells that bypass all conventional border and customs checkpoints [9].

5. POLICY RECOMMENDATIONS

It isn’t possible to set one solution for building resilience of military industry production in small states, considering global trade market disturbances. To get the most from AM and mitigate the system risks, the best solution for small states is to establish national policies, with the aim to build military industry, including AM as integrated technology. That will include the establishment of regional 3D printing hubs, product development aiming to design for 3D printing and required ownership of data

files, production standardization, and required procedures for material recycling, storage, and testing.

5.1. Establishment of Sovereign and Secure 3D Printing Hubs (AM Hubs)

Small states should avoid fragmented, ad-hoc adoption of AM by civilian operators and instead build a centralized network of secure, military-controlled Additive Manufacturing Hubs (AM Hubs) [3]. These installations must serve as the primary repositories for national digital inventory data, technical materials, and industrial-grade printing systems (e.g., Wire Arc Additive Manufacturing - WAAM and Selective Laser Melting - SLM) [12].

AM Hubs should be built as production facilities with big data centers and different printing material reserves. It should operate as a service center for small-scale production where other types of production would demand too many operations or be too costly. As a production line, there should be many different 3D printers for printing all kinds of materials. For military purposes, this kind of facility can be built in cargo containers, and it could be set for expeditionary purposes.

As a data center for CAD file storage, this hub has to be protected from different cyber-physical vulnerabilities, so it has to be built with high network protection from physical impact and cyberattacks.

To insulate these hubs from the cyber-physical vulnerabilities detailed in Chapter 4, they must adhere to rigid network isolation criteria.

First, all computer-aided design (or other types of digital files) stations, slicing engines, and industrial printers must be completely disconnected from public internet routing and unclassified defense networks.

Data transfer from the main digital registry to forward-deployed or mobile printing modules must utilize high-level, end-to-end encryption protocols with hardware-token validation to prevent malicious code modifications or file interception.

Hubs should establish cooperation with national technology research centers and technical universities to provide an environment for technical improvement, material development, and 3D printing localization, but also to ensure a continuous pool of certified operators and design engineers without relying on foreign technical support.

5.2. Adoption of "Design-for-AM" and Digital Procurement Protocols

3D printing requires digital files, which are usually intellectual property and should be solved before the need for printing arises. Small states must pivot toward data-centric purchasing frameworks [2].

Future procurement contracts signed by small states with foreign original equipment manufacturers (OEMs) should mandate the following provisions: contractual technical data packages (TDPs), "Design-for-AM" optimization, and certified third-party service escrows.

Tenders must require that international suppliers include fully documented CAD files, material performance criteria, and localized printing rights for non-structural, high-wear components as part of the base purchase agreement.

Domestic defense industries must design native military equipment to prioritize the use of modular, standardized components that are explicitly optimized for on-demand 3D printing, reducing the need for specialized external tooling [1].

To protect against situations where an OEM goes bankrupt or imposes a political cutoff, agreements should place critical design blueprints in secure digital escrows managed by neutral international bodies or verified domestic service providers.

5.3. Codification of Digital Quality and Ecological Standards

For decentralized designing and manufacturing components

that will meet required structural performance and quality, but also the resource efficiency and ecological standards, small states must enforce strict, standardized quality controls [15].

Any critical component printed at a forward-deployed location must undergo strict verification protocols (e.g., ultrasonic scanning or industrial computed tomography) to check for internal microstructural voids and layer alignment anomalies before field installation [1].

Mobile, containerized printing labs must be equipped with active environmental control systems to manage internal moisture, temperature, and dust levels. This ensures raw metal powders and technical polyamides do not degrade before printing [1].

Small states should mandate for hubs to use high-efficiency machinery and compulsory recycling of unspent metal powders and single-use polymer packaging within tactical zones [11]. Standardizing on-site filament extrusion processes allows small states to transform base waste streams into functional defense assets, ensuring long-term resource independence under blockade [2].

6. CONCLUSION

Additive manufacturing is a disruptive technology, which can cause a structural shift in how small states design and maintain their defense capabilities and sustain national interests under geopolitical constraints. As global supply chain disruptions, caused by international sanctions, wars, export controls, or resource constraints, threaten the continuity of military industry production and degrade the defense capabilities of small countries. Conventional centralized supply models, characterized by long lead times and high inventory dependencies, increasingly fail to guarantee operational readiness.

This paper has evaluated the impact of 3D printing on small states military industry and defense capability.

Changing from physical import to transfer of encrypted digital data protects small states from physical supply chain breaks and embargoes, effectively bypassing traditional geographical choke points. AM excludes upfront tooling costs in conventional manufacturing and enables the financially viable production of rare, customized, and small-batch components, reducing weapon system downtime by over 90%. Building components layer-by-layer cuts net raw material waste below 10%, while localized circular loops (such as converting single-use base packaging waste into raw printing filament) allow outposts to sustain manufacturing needs without drawing new external resources.

Building a military industry around AM technology, it has its negative sides. The digitalization of supply chains is an opportunity for hostile actors to change printing files to cause undetected structural weapon malfunction. Unauthorized component replications have intellectual property and warranty challenges. For security reasons, the digitalization of weapon designs can cause severe problems for non-proliferation hurdles for global arms control.

Successful implementation of AM depends on proactive public policies. By establishing AM hubs, requiring digital data rights in procurement contracts, establishing strict control standards, and recycling and ecology standards, small states can mitigate these risks. Then, AM becomes an essential, sustainable ecosystem that provides small states with the operational flexibility, economic sustainability, and long-term autonomy required to survive in a volatile global arena.

Abstract: *Electrochemical methods are widely used for evaluating corrosion behavior of structural steels in aggressive environments; however, their mutual consistency and practical applicability under varying conditions remain critical challenges. In this study, the corrosion behavior of X12CrMoWVNbN10-1-1 steel was investigated in 0.1 M NaCl solutions at different pH values (2.9, 6.5, and 10.3) using electrochemical impedance spectroscopy (EIS), linear sweep voltammetry (LSV), and potentiodynamic polarization (PDP), complemented by scanning electron microscopy (SEM). The results reveal a pronounced influence of pH on both corrosion rate and degradation mechanism. Acidic conditions promote active dissolution with high corrosion current density, while neutral and alkaline environments enable passive film formation, resulting in significantly improved corrosion resistance. A combined analysis of electrochemical techniques indicates good agreement between EIS and LSV in less aggressive conditions, whereas notable deviations were observed in acidic media due to accelerated corrosion kinetics and interfacial instability. PDP measurements further confirm enhanced resistance to pitting corrosion at higher pH values. Surface analysis supports the electrochemical findings, showing severe degradation in acidic solution and compact, stable surfaces in neutral and alkaline environments. The study demonstrates that the combined application of electrochemical and surface characterization methods provides a reliable framework for corrosion assessment and highlights the importance of method selection in engineering practice.*

Keywords: *electrochemical impedance spectroscopy; linear sweep voltammetry; potentiodynamic polarization; pH effect.*

1. INTRODUCTION

Corrosion of structural steels operating in chloride-containing environments remains one of the major challenges in engineering practice because it directly affects the reliability, service life, and maintenance costs of critical components [1,2]. Chloride ions are particularly aggressive since they promote passive film breakdown and initiate localized corrosion, while environmental pH strongly influences both the corrosion rate and the stability of protective oxide layers [3,4].

Electrochemical techniques are among the most effective tools for evaluating corrosion behavior because they provide rapid, quantitative, and non-destructive information on metal degradation [5,6]. Electrochemical impedance spectroscopy (EIS), linear sweep voltammetry (LSV), and potentiodynamic polarization (PDP) are widely employed for determining corrosion resistance, corrosion kinetics, and susceptibility to localized corrosion under various environmental conditions [5,7-9]. However, each technique characterizes a different aspect of the electrochemical process, and their combined interpretation often provides a more reliable assessment than the application of a single method [6,8].

Ferritic–martensitic steels are extensively used in thermal power plants and other high-temperature engineering systems owing to their excellent mechanical properties and satisfactory corrosion resistance. Among them, X12CrMoWVNbN10-1-1 steel is widely applied for components operating under demanding service conditions [10]. Although its corrosion behavior has been investigated in different environments, studies comparing

DOI: 10.5937/OTEH26120V

the complementary application of electrochemical techniques for corrosion assessment under varying pH conditions remain limited [11,12].

The objective of the present study is therefore not only to evaluate the corrosion behavior of X12CrMoWVNbN10-1-1 steel in chloride solutions with different pH values, but also to compare the information obtained by EIS, LSV, and PDP measurements and correlate these findings with scanning electron microscopy observations. Particular attention is devoted to the complementary role of the applied techniques in assessing general and localized corrosion, with the aim of establishing an integrated electrochemical assessment strategy applicable to engineering practice.

2. EXPERIMENTAL

2.1 Material and Test Solutions

The investigated material was ferritic-martensitic steel X12CrMoWVNbN10-1-1 (EN 1.4906), commonly used for high-temperature components in thermal power plants because of its excellent mechanical properties and good corrosion resistance. Prior to electrochemical testing, the specimens were mechanically ground using SiC abrasive papers up to 1500 grit, degreased with ethanol, rinsed with distilled water, and dried in air.

Corrosion tests were performed in 0.1 M NaCl solution under three different environmental conditions: acidic (pH 2.9), neutral (pH 6.5), and alkaline (pH 10.3). The pH values were adjusted using diluted hydrochloric acid or sodium hydroxide solutions and verified before each experiment.

2.2 Electrochemical Measurements

Electrochemical measurements were carried out using a Gamry Reference 620 potentiostat/galvanostat in a conventional three-electrode electrochemical cell consisting of the steel specimen as the working electrode (1 cm² exposed area), a saturated calomel electrode (SCE) as the reference electrode, and a platinum mesh as the counter electrode. All experiments were conducted after stabilization of the open-circuit potential at room temperature.

Electrochemical impedance spectroscopy (EIS) measurements were performed by applying a sinusoidal perturbation of ±10 mV around the open-circuit potential over the frequency range from 100 kHz to 0.01 Hz. The impedance spectra were analyzed using an equivalent electrical circuit to determine the polarization resistance and parameters describing the electrochemical interface.

Linear sweep voltammetry (LSV) measurements were performed at a scan rate of 0.5 mV s^{-1} over the potential range of ±0.2 V with respect to the corrosion potential. The obtained polarization curves were used to determine the corrosion current density and corrosion rate by Tafel extrapolation.

The resistance of the investigated steel to localized corrosion was evaluated by potentiodynamic polarization (PDP). The measurements were carried out using the same electrochemical cell and scan rate, while the pitting potential and passive current density were determined from the anodic polarization curves.

All electrochemical measurements were repeated three times to verify the reproducibility of the obtained results.

2.3 Surface Characterization

After electrochemical testing, the morphology of the steel surface was examined using scanning electron microscopy (SEM). The observations were performed in order to correlate electrochemical parameters with the corresponding corrosion damage and to identify the characteristic features of passive film stability and localized corrosion under different pH conditions.

3. RESULTS AND DISCUSSION

3.1 Electrochemical assessment of general corrosion

The corrosion behaviour of X12CrMoWVNbN10-1-1 steel was evaluated by combining electrochemical impedance spectroscopy (EIS) and linear sweep voltammetry (LSV). Although both techniques are widely used for corrosion assessment, they provide complementary information on electrochemical processes occurring at the metal/electrolyte interface. EIS primarily characterizes the electrochemical response of the passive surface layer through impedance parameters, whereas LSV directly evaluates the kinetics of anodic dissolution and enables determination of corrosion current density.

EIS diagrams for X12CrMoWVNbN10-1-1 steel in 0.1 M NaCl solutions at different pH values are presented in Figure 1.

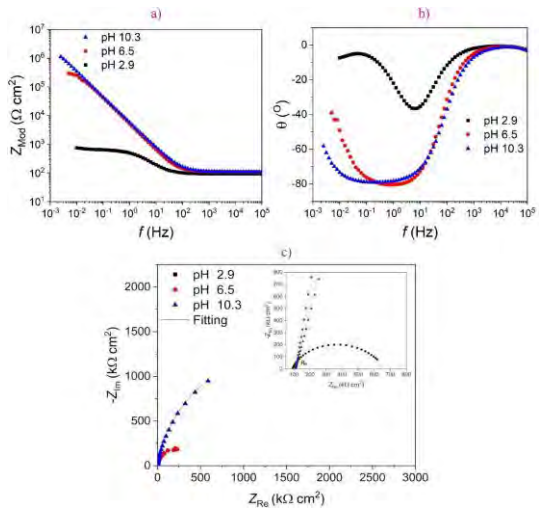

Figure 1. EIS diagrams for X12CrMoWVNbN10-1-1 steel in 0.1 M NaCl solutions at different pH values (pH 2.9, 6.5, and 10.3): (a) Bode modulus, (b) Bode phase, and (c) Nyquist plots

The impedance spectra obtained in chloride solutions (Figure 1) clearly demonstrate the strong influence of

solution pH on the corrosion resistance of the investigated steel. The acidic environment (pH 2.9) produced the lowest impedance modulus and polarization resistance, indicating rapid charge transfer and active metal dissolution. In contrast, both neutral and alkaline solutions exhibited considerably higher impedance values, reflecting the formation of a protective passive layer. The highest polarization resistance was obtained in the alkaline solution, confirming the beneficial effect of hydroxide ions on passive film stability.

The corrosion parameters obtained by LSV (Figure 2) followed the same overall trend of markedly higher corrosion resistance in neutral and alkaline solutions compared with the acidic environment. The highest corrosion current density was measured in the acidic solution, while corrosion rates decreased markedly in neutral and especially alkaline media. These results confirm that increasing pH significantly suppresses the general corrosion process by promoting passivation of the steel surface [4,12].

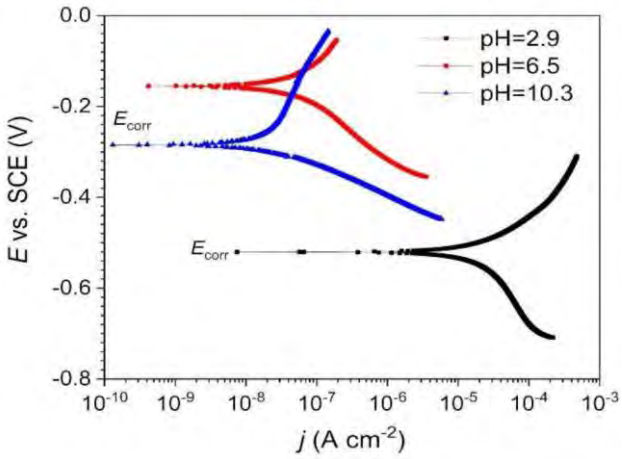

Figure 2. Tafel polarization curves for X12CrMoWVNbN10-1-1 steel obtained in acidic (pH 2.9), neutral (pH 6.5), and alkaline (pH 10.3) 0.1 M NaCl solutions

The polarization resistance values obtained from EIS and LSV are summarized in Table 1.

Table 1. Polarization resistance values obtained by EIS and LSV at different pH values.

Technique	R_p (kΩ cm^2)		
	pH 2.9	pH 6.5	pH 10.3
EIS	0.557	418.5	3051
LSV	2.391	507.7	1042

According to the presented results, both techniques yielded the lowest resistance in the acidic solution, confirming the substantially higher corrosion activity at pH 2.9. In neutral solution, the values were relatively close. In alkaline solution, however, a more pronounced difference was observed. Thus, the two methods agree in identifying the acidic environment as the most aggressive condition and the neutral and alkaline environments as considerably more protective, although they do not provide identical quantitative values or the same relative ranking of the neutral and alkaline conditions.

Such deviations originate from the different physical principles of the two methods [8,9]. While EIS evaluates the impedance response over a wide frequency range under near-equilibrium conditions, LSV determines corrosion parameters from polarization behavior during potential scanning. Consequently, LSV becomes more sensitive to rapid anodic dissolution occurring in highly aggressive acidic environments, whereas EIS reflects the overall electrochemical properties of the metal/electrolyte interface [5,6]. The comparison therefore indicates that the methods provide consistent information on the major differences in corrosion resistance, while their quantitative results should be interpreted as complementary rather than directly interchangeable.

The comparison of EIS and LSV results indicates that neither method alone provides a complete description of corrosion behaviour. Instead, their combined interpretation considerably improves the reliability of corrosion assessment, particularly under conditions where passive film stability strongly depends on environmental pH.

3.2 Evaluation of pitting susceptibility

General corrosion parameters alone are insufficient for evaluating the long-term performance of structural steels exposed to chloride-containing environments. For this reason, potentiodynamic polarization measurements were performed to assess the susceptibility of X12CrMoWVNbN10-1-1 steel to localized corrosion.

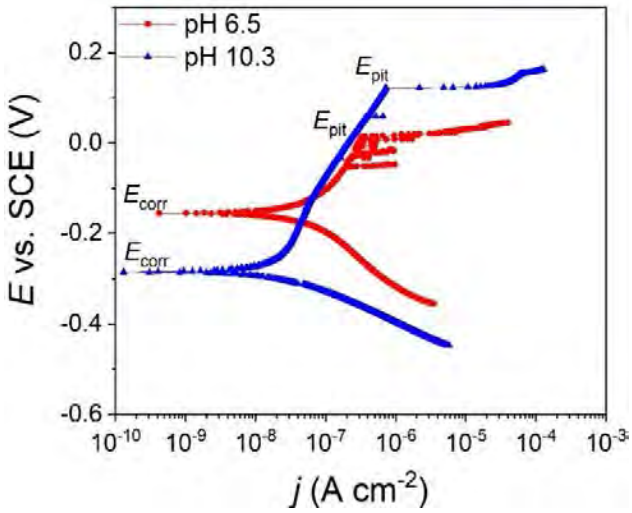

Figure 3. Potentiodynamic polarization (PDP) curves for X12CrMoWVNbN10-1-1 steel in neutral (pH 6.5) and alkaline (pH 10.3) 0.1 M NaCl solutions

The polarization curves (Figure 3) revealed a pronounced influence of pH on passive film stability and pit initiation [3,4]. In the acidic solution, active dissolution dominated throughout the anodic polarization range, indicating the absence of an effective protective film. Under these conditions, localized attack rapidly developed following continuous metal dissolution.

In neutral solution, the steel exhibited stable passivation over a broad potential interval before localized breakdown occurred. The passive region became even

more pronounced in the alkaline environment, where the highest pitting potential and the lowest passive current density were obtained. These findings demonstrate that alkaline conditions significantly increase the resistance of the investigated steel to chloride-induced pitting corrosion.

The PDP measurements complement the information obtained by EIS and LSV. Whereas EIS and LSV primarily quantify the intensity of general corrosion, PDP provides additional information regarding passive film stability and resistance to localized degradation. The combination of these electrochemical techniques therefore enables simultaneous evaluation of both uniform and pitting corrosion processes.

3.3 Correlation between electrochemical measurements and SEM observations

Electrochemical measurements provide quantitative information regarding corrosion kinetics and passive film behavior; however, direct observation of the exposed surfaces is essential for verifying the corresponding corrosion mechanisms. For this reason, SEM examination was performed after electrochemical testing.

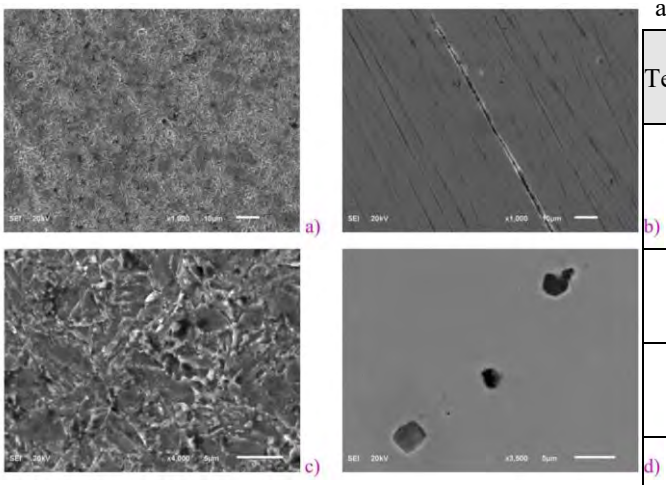

Figure 4. SEM micrographs of the X12CrMoWVNbN10-1-1 steel surface after exposure to 0.1 M NaCl: (a) pH 2.9 (×1000); (b) pH 6.5 (×1000); (c) pH 2.9 (×4000); (d) pH 6.5 (×3500)

The SEM micrographs (Figure 4) showed excellent agreement with the electrochemical results. Severe surface degradation was observed after exposure to the acidic chloride solution, where extensive dissolution and irregular corrosion features confirmed the high corrosion current density measured by LSV and the low polarization resistance obtained by EIS. These observations clearly indicate unstable electrochemical conditions associated with active corrosion.

Conversely, specimens exposed to neutral and alkaline solutions exhibited substantially less surface damage. In neutral solution, only isolated pits were detected, indicating localized passive film breakdown. The alkaline environment produced the most compact surface morphology, confirming the formation of a stable passive layer responsible for the highest polarization resistance and the lowest corrosion rate among the investigated conditions.

The close agreement between electrochemical parameters and SEM observations demonstrates that electrochemical measurements reliably describe the degradation processes occurring on the steel surface [13]. While EIS characterizes passive film resistance, LSV quantifies corrosion kinetics and PDP evaluates susceptibility to localized attack, SEM provides direct morphological confirmation of the electrochemical findings. Their combined application therefore represents a comprehensive methodology for corrosion assessment of structural steels operating in chloride-containing environments. Rather than identifying a superior technique, the present results demonstrate that reliable corrosion assessment is achieved through the complementary integration of EIS, LSV, PDP, and SEM, with each method contributing unique information on the corrosion process.

The complementary information provided by the applied corrosion assessment techniques is summarized in Table 2.

Table 2. Complementary information provided by the applied corrosion assessment techniques

Technique	Primary output	Information obtained	Role in corrosion assessment
EIS	Polarization resistance (R_p)	Passive film stability and corrosion resistance	Early evaluation of protective behavior
LSV	Corrosion current density (j_{corr})	General corrosion kinetics	Quantitative estimation of corrosion rate
PDP	Pitting potential (E_{pit})	Susceptibility to localized corrosion	Assessment of passive film breakdown
SEM	Surface morphology	Verification of corrosion mechanisms	Confirmation of electrochemical interpretation

4. CONCLUSIONS

The present study demonstrates that reliable corrosion assessment of X12CrMoWVNbN10-1-1 steel in chloride-containing environments requires the complementary application of several electrochemical techniques rather than reliance on a single measurement method. Although all investigated techniques consistently identified the beneficial effect of increasing pH on corrosion resistance, each method provided different but mutually complementary information on the corrosion process.

Electrochemical impedance spectroscopy proved particularly effective for evaluating passive film stability through polarization resistance measurements, while linear sweep voltammetry enabled quantitative determination of corrosion kinetics and corrosion rate. Potentiodynamic polarization provided additional information regarding the susceptibility of the investigated steel to localized corrosion by identifying

changes in pitting resistance under different environmental conditions. Scanning electron microscopy confirmed the electrochemical interpretation by revealing characteristic surface degradation features corresponding to the measured corrosion parameters.

From an engineering perspective, the obtained results demonstrate that acidic chloride environments promote active steel dissolution, whereas neutral and especially alkaline solutions significantly improve corrosion resistance through passive film stabilization. The excellent agreement between electrochemical measurements and surface observations confirms the reliability of the applied methodology.

Overall, the combined use of EIS, LSV, PDP, and SEM provides a comprehensive strategy for corrosion assessment of structural steels exposed to chloride environments and represents a practical approach for selecting appropriate evaluation methods in engineering applications.

Abstract: *Mechanical activation is widely used to induce solid-state reactions; however, distinguishing between structural disordering and true chemical transformation remains a key challenge. This study proposes a combined methodological approach based on X-ray diffraction (XRD) and atomic absorption spectroscopy (AAS) for evaluating the progress of mechanochemical processes in the MgO-TiO_2 system. Mechanical activation was performed in a high-energy vibration mill, and the evolution of the system was monitored at different time intervals. XRD analysis revealed a gradual decrease in the intensity and broadening of diffraction peaks, indicating significant structural disordering and near-complete amorphization of the starting components. However, no new crystalline phases corresponding to magnesium titanate were detected. Complementary AAS results confirmed that the chemical composition of the system remained unchanged throughout the activation process, indicating the absence of a measurable reaction extent. The combined interpretation of structural and chemical data demonstrates that mechanical activation led predominantly to amorphization rather than to synthesis. The results highlight the importance of integrating multiple analytical techniques to reliably assess mechanochemical processes and avoid misinterpretation based on a single method. The proposed approach provides a practical framework for distinguishing between activation-induced structural changes and actual phase formation in solid-state systems.*

Keywords: *mechanical activation; XRD; AAS; amorphization; MgO-TiO_2 system.*

1. INTRODUCTION

Mechanochemical methods have attracted considerable attention as an efficient route for inducing solid-state reactions, particularly in the synthesis of advanced functional materials. Mechanical activation enables the transfer of energy into solid systems through repeated deformation, fracture, and cold-welding processes, leading to the accumulation of structural defects, reduction of crystallite size, and increased reactivity of the treated materials [1]. In recent years, mechanochemistry has emerged as a versatile and sustainable approach for material synthesis, offering reduced solvent usage and improved energy efficiency, and is increasingly recognized as a new frontier in chemical processing [2-4].

Among various solid-state systems, mixtures of alkaline earth metal oxides and titanium dioxide have been extensively studied due to their potential to form technologically important titanates with dielectric, catalytic, and electronic applications [5-9]. In such systems, mechanochemical synthesis is often considered a promising alternative to conventional high-temperature processing routes. Recent advances further demonstrate the applicability of mechanochemical methods in the synthesis of advanced materials, including catalysts and energy-related systems [10,11].

However, despite the theoretical feasibility of these reactions based on thermodynamic considerations, the actual occurrence of mechanochemical synthesis strongly depends on kinetic factors, including the amount of energy introduced into the system, milling conditions, and intrinsic material properties [12-15]. In particular, the

Corresponding author: M. Vlahović;
E-mail: m.vlahovic@ihtm.bg.ac.rs;
DOI: 10.5937/OTEH26121D

MgO-TiO_2 system represents a challenging case, as the formation of $MgTiO_3$ is associated with relatively low driving force compared to other alkaline earth titanates, making the reaction difficult to achieve under purely mechanochemical conditions [16].

A key challenge in the study of mechanochemical processes is the reliable evaluation of reaction progress. Structural characterization techniques, such as X-ray diffraction (XRD), are widely used to monitor phase evolution and crystallographic changes during mechanical activation. However, peak broadening and intensity reduction, commonly observed during high-energy milling, may arise from amorphization and defect formation rather than from the formation of new phases, which can lead to ambiguous interpretation of results.

Complementary chemical analysis methods, such as atomic absorption spectroscopy (AAS), provide quantitative information on the composition of the system and enable estimation of reaction progress. Nevertheless, these techniques do not provide direct insight into structural transformations at the crystallographic level.

Recent studies emphasize the importance of combining multiple analytical approaches in order to obtain a comprehensive understanding of mechanochemical processes and to avoid misinterpretation based on a single technique [17-19].

The aim of this study was to assess the applicability of a combined XRD-AAS approach for evaluating mechanochemical reaction progress and distinguishing activation-induced structural disordering from true mechanochemical synthesis, using the MgO-TiO_2 system as a model case.

2. EXPERIMENTAL

2.1. Materials

Magnesium oxide (MgO) and titanium dioxide (TiO_2) of analytical grade purity (p.a., Merck, Germany) were used as starting materials. The powders were mixed in a stoichiometric ratio corresponding to the formation of $MgTiO_3$.

The initial mixture was prepared using 0.5 mol of each component, resulting in a total mass of approximately 60 g. Prior to mechanical treatment, the powders were homogenized to ensure uniform distribution of components within the reaction system.

2.2 Mechanical activation

Mechanical activation of the MgO-TiO_2 system was performed in a high-energy vibration mill (type MH954/3, KHD Humboldt Wedag, Germany). The milling process was carried out under ambient conditions.

Samples were collected at selected time intervals (60, 180, 330, and 1000 min) in order to monitor the evolution of the system during mechanical activation. The mass of the processed material and milling conditions were adjusted according to the operational characteristics of the mill to ensure efficient energy transfer.

2.3. Characterization methods

X-ray diffraction (XRD)

Structural characterization of the starting materials and mechanically activated samples was performed using X-ray diffraction (XRD) analysis (Philips PW-1700 diffractometer, Netherlands) with Cu Kα radiation. The measurements were carried out over an appropriate 2θ range to identify phase composition and monitor structural changes during activation.

Atomic absorption spectroscopy (AAS)

Chemical analysis of the system was conducted using atomic absorption spectroscopy (AAS) (Analyst 300, PerkinElmer, USA). Prior to analysis, the samples were dissolved in a 10% acetic acid solution.

The obtained concentrations of magnesium and titanium were used to evaluate the progress of the mechanochemical reaction.

Reaction progress evaluation

The mechanochemical reaction progress was estimated based on the results of chemical analysis using a relation derived from the stoichiometry of the MgO-TiO_2 system:

$$S = \left(1 - \frac{0.25\,(c - bc_{Ti})}{c_0 w}\right)100 \qquad (1)$$

where c represents the concentration of magnesium in the solution, c_0 is the initial sample mass, c_{Ti} is the concentration of titanium, w is the mass fraction of magnesium in the initial mixture, and b is the stoichiometric coefficient related to the formation of $MgTiO_3$.

3. RESULTS AND DISCUSSION

3.2 Structural evolution during mechanical activation (XRD analysis)

The structural evolution of the MgO-TiO_2 system during mechanical activation was monitored by X-ray diffraction (XRD) analysis at different milling times. The corresponding diffraction patterns are presented in Figure 1.

The diffraction patterns of the mixture after 60 min of activation show well-defined peaks corresponding to crystalline MgO and TiO_2. With increasing activation time, a gradual decrease in peak intensity and simultaneous peak broadening are observed. These changes indicate progressive reduction in crystallite size and accumulation of lattice defects, which are typical consequences of high-energy mechanical treatment. Such structural evolution is commonly observed during high-energy mechanical activation and is generally attributed to defect accumulation and progressive amorphization of the crystalline phases [17–19].

After prolonged activation (1000 min), the diffraction peaks become significantly broadened and reduced in

intensity, suggesting near-complete amorphization of the system. Importantly, no new diffraction maxima corresponding to magnesium titanate ($MgTiO_3$) or any other reaction products are detected throughout the entire activation period.

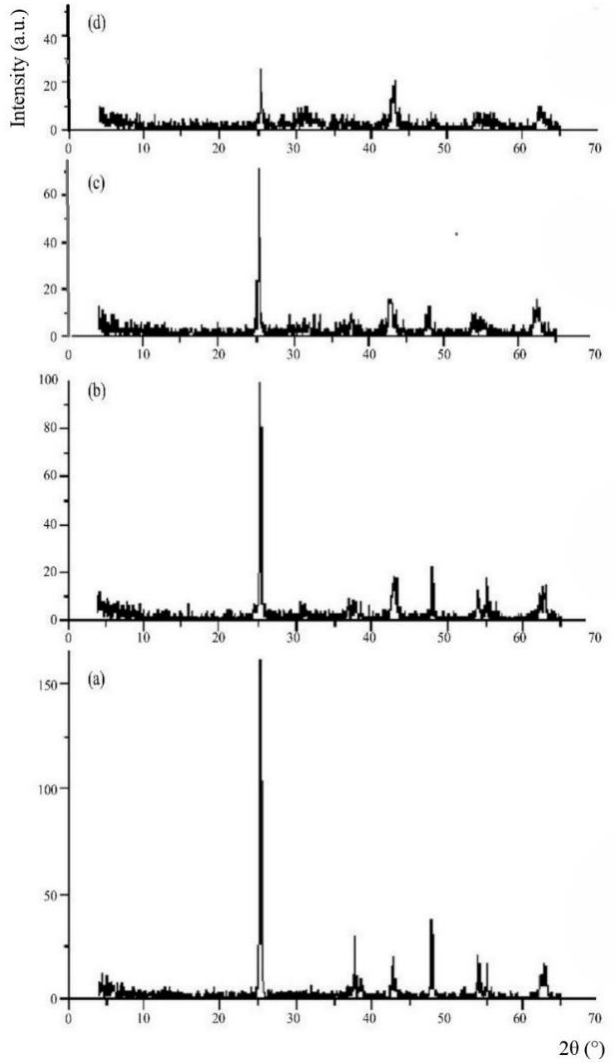

Figure 1. XRD patterns of the MgO-TiO_2 system during mechanical activation:a) 60 min, b) 180 min, c) 330 min, and d) 1000 min

The absence of new crystalline phases, despite intensive structural disordering, indicates that mechanical activation under the applied conditions leads predominantly to structural transformation rather than to the formation of a new compound. Therefore, XRD results clearly demonstrate that the process is governed by amorphization and defect generation, without evidence of mechanochemical synthesis. Similar observations have been reported for oxide systems in which mechanical activation promotes structural disordering without providing sufficient energy for complete solid-state reaction [12,14].

3.2. Chemical analysis and evaluation of reaction progress (AAS)

To complement the structural analysis, the chemical composition of the system during mechanical activation was evaluated using atomic absorption spectroscopy (AAS). The calculated reaction progress as a function of activation time is presented in Figure 2.

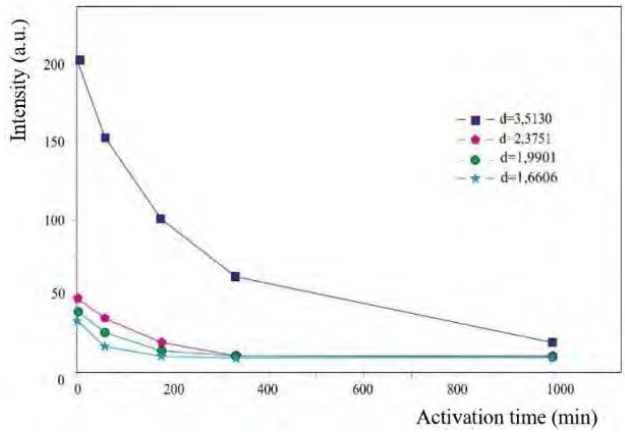

Figure 2. Mechanochemical reaction progress in the MgO-TiO_2 system as a function of activation time, calculated from AAS data

The results show that the concentrations of magnesium and titanium in the analyzed samples remain essentially unchanged throughout the entire duration of mechanical activation. Accordingly, the calculated reaction progress remains negligible, indicating that no measurable chemical transformation occurs within the system. The absence of measurable compositional changes confirms that structural disordering alone should not be interpreted as evidence of mechanochemical reaction, highlighting the importance of complementary chemical analysis.

These findings are consistent with the XRD results, confirming that the observed structural changes are not accompanied by chemical reaction leading to the formation of magnesium titanate. The absence of compositional variation demonstrates that the system remains in its initial chemical state, despite undergoing significant structural disordering.

Thus, AAS analysis provides quantitative confirmation that the mechanochemical reaction progress is effectively zero under the applied experimental conditions.

3.3 Methodological validation of the combined XRD-AAS approach

The obtained results highlight the importance of employing a combined analytical approach for reliable evaluation of mechanochemical processes. When used independently, each method provides only partial insight into the system evolution. This observation is consistent with previous studies emphasizing that reliable interpretation of mechanochemical processes requires complementary analytical techniques [18,19].

XRD analysis alone reveals significant structural changes, such as peak broadening and intensity reduction, which may be misinterpreted as indicators of mechanochemical reaction progress or phase transformation. However, without complementary chemical information, it is not possible to distinguish between amorphization and the actual formation of a new phase.

On the other hand, AAS analysis provides accurate information on the chemical composition and enables quantification of reaction progress, but does not offer insight into structural transformations occurring at the crystallographic level.

The combined application of XRD and AAS overcomes these limitations by integrating structural and chemical perspectives. The combined interpretation of structural and chemical data is schematically presented in Figure 3, illustrating the methodology for distinguishing amorphization from mechanochemical reaction progress.

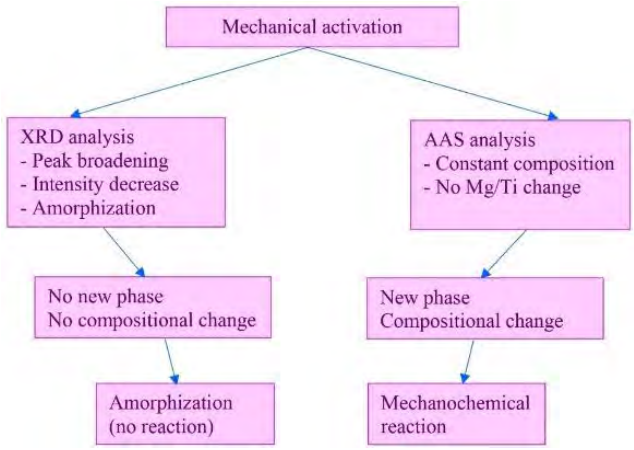

Figure 3. Schematic representation of the combined XRD-AAS methodology for evaluating mechanochemical reaction progress and distinguishing amorphization from mechanochemical synthesis

In addition to the experimentally observed case, the schematic also includes a general scenario in which the combined XRD-AAS approach confirms the occurrence of a mechanochemical reaction, thereby demonstrating the broader applicability of the proposed methodology.

In the present study, this approach clearly demonstrates that intensive mechanical activation leads to pronounced amorphization without any detectable mechanochemical reaction.

The proposed methodology enables reliable discrimination between structural disordering and true mechanochemical reaction progress, thereby reducing the risk of misinterpretation of experimental results. This is particularly important in systems where reaction kinetics are limited or where high-energy input predominantly induces structural defects rather than chemical transformation.

4. CONCLUSION

In this study, the progress of mechanochemical processes in the MgO-TiO_2 system was evaluated using a combined XRD-AAS approach. The results show that intensive mechanical activation leads to significant structural disordering and near-complete amorphization of the starting components, as evidenced by XRD analysis. However, no formation of new crystalline phases was detected.

Complementary AAS analysis confirmed that the chemical composition of the system remained unchanged throughout the activation process, indicating that no measurable mechanochemical reaction occurred.

The combined interpretation of structural and chemical data demonstrates that mechanical activation, under the applied conditions, induces predominantly amorphization rather than mechanochemical synthesis.

The proposed XRD-AAS methodology enables reliable evaluation of mechanochemical reaction progress and provides a practical framework for distinguishing structural disordering from true chemical transformation. This approach reduces the risk of misinterpretation when relying on a single analytical technique and is applicable to a wide range of solid-state systems. The presented approach is particularly valuable in systems with limited reaction kinetics, where distinguishing between activation-induced structural changes and true reaction progress is essential.

Abstract: *This paper aims to show how different designs of igniter charges affect interior ballistic properties. Different geometries were achieved with 3D printed technology. All igniter charges were prepared with an identical number and amount of pyrotechnic compositions to ensure consistency in released chemical energy. The experiments were conducted in experimental rocket motor with fixed and identical free volume as a flight rocket motor. To accurately monitor combustion behavior, operating pressures were measured at two points with the test setup using calibrated pressures transducers. The collected data were analyzed to assess the influence of geometric variations on ignition efficiency, pressure increase time and maximum pressure values.*

Keywords: *igniters, 3D printing technology, rocket motor*

1. INTRODUCTION

With the development of new additive manufacturing technologies, particularly 3D printing [1-2], it has become possible to create components with complex geometries that were previously economically viable only in mass production. Traditional manufacturing methods often required expensive tooling for each geometry, making small-batch or prototype production inefficient. In contrast, 3D printing allows rapid prototyping and cost-effective fabrication of custom parts without the need for molds or tooling, making it especially valuable in research and development environments. Ideas can be quickly transformed into physical components, tested, and iterated with minimal delay.

Additive manufacturing is increasingly utilized in the defense and aerospace industries across the globe [3-4]. In modern warfare conditions, 3D printing enables field-level production of urgently needed components, directly supporting operational readiness and logistical flexibility. Rapid on-site fabrication reduces downtime and increases system reliability in mission-critical applications.

One of the most critical components in a solid rocket propulsion system [5] is the igniter housing. The igniter must ensure precise and consistent initiation of combustion without damaging the propellant grain or nozzle throat [6]. Therefore, the housing must be mechanically robust, thermally stable, and capable of withstanding a wide range of environmental stressors—such as impact, vibration, and thermal cycling—that occur throughout the rocket's operational life cycle [7].

Another essential requirement for igniter housings is hermetic sealing and safe handling. In large-scale production scenarios, igniters are assembled and installed by trained personnel under standardized procedures. Therefore, the housing must not only guarantee performance but also meet stringent safety standards during storage, transport, and integration.

Before finalizing a design for mass production, several iterative prototypes must be tested under identical operating conditions to those of the final application. For this purpose, all igniters in this study were tested in experimental rocket motor with a fixed and controlled internal free volume.

Additive manufacturing enables the use of a wide range of materials with varying densities, thermal tolerances, and mechanical strengths [8-9].

In this work, igniter housings were produced using a Creality K1C 3D printer (Figure 1), capable of printing high-performance polymers reinforced with carbon fiber, and supporting extrusion temperatures up to 300°C. The printer's build volume is 220 × 220 × 250 mm, with a maximum print speed of 600 mm/s, allowing for rapid and scalable prototyping.

Figure 1. Creality K1C 3D printer

2. DESIGN

Two different igniter housing models were designed using SolidWorks. Each housing consisted of three separate parts to allow for easy loading of pyrotechnic compositions and visual inspection before final sealing. The STL models were processed in the Creality slicing software (Figure 2), where part orientation, material selection, layer thickness, and print resolution were configured. Based on the slicing parameters, the estimated print time for a complete igniter housing was approximately 45 minutes. The selected material was 1.75 mm PLA filament, with a temperature resistance of up to 260°C.

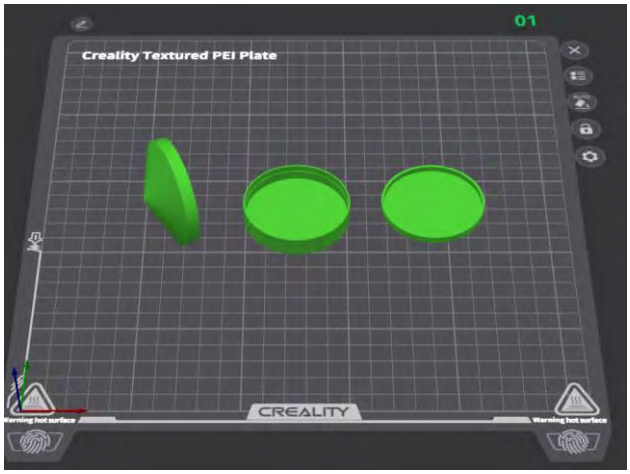

Figure 2. Creality slicing software – geometry 1

Both housing designs featured identical internal free volume to allow consistent loading of pyrotechnic compositions [10]. A total of six igniters were fabricated, with three for each housing geometry. All igniters were hermetically sealed and subjected to dimensional and mass control verification.

The internal architecture of each housing consisted of a primary cylindrical chamber (60 mm diameter) containing the initial ignition mixture—black powder with a pyrotechnic initiator cap and Composition No. 1. To this base structure, a second modular chamber of varying geometry was added. In Geometry 1 (Figure 3), this second chamber took the form of a regular conical shape containing Composition No. 2.

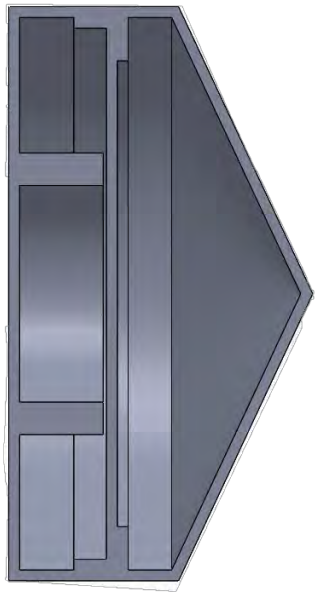

Figure 3. Geometry 1

In Geometry 2 (Figure 4), the second chamber featured an inverted conical cavity with a 60-degree angle, also housing Composition No. 2.

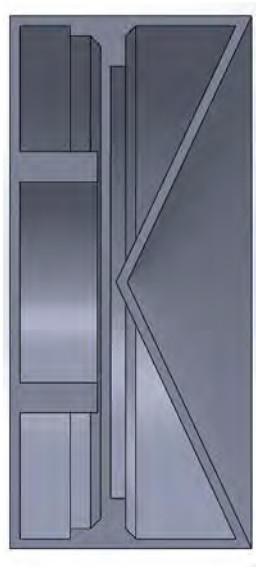

Figure 4. Geometry 2

The wall thickness of all printed housings was 1 mm. The free volume of Chamber 1 was 0.026 dm^3, while Chamber 2 had a volume of 0.042 dm^3.

For the third test configuration, the same pyrotechnic composition was loaded into an ethyl cellulose pouch, without a rigid printed housing structure. This configuration served as a control to observe the ignition behavior of the composition in a less confined environment. The results were not presented in this paper.

The used pressure transducers are designed for measuring static and dynamic liquid and gas pressures. They are available in various measuring ranges, from 1 to 3000 bar. Transducers with the 0 to 3000 bar measuring ranges work according to the strain gage principle. The strain gage application is located on the side of the tube away from the measurement medium in a hermetically sealed reference chamber. This protects it from environmental influences.

3. EXPERIMENT

All igniter charges were tested in experimental rocket motor (Figure 5) equipped with a calibrated pressure transducers P3IC up to 200 bar.

The transducers housings are made from stainless steel and hermetically seal the measurement system to protect it against any harmful external influences, so that even if the operating conditions continue to be rough, the reliability and precision of the transducer are not impaired.

The resulting data were acquired and visualized as pressure-time (P-t) diagrams. Accurate pressure measurement is important in interior ballistic testing, and uncertainty was minimized through calibration, thermal compensation, and signal filtering. Remaining uncertainties were evaluated using standard measurement uncertainty analysis.

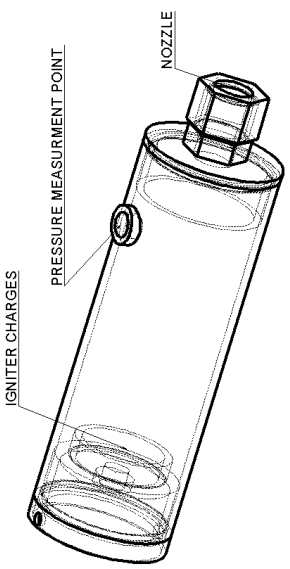

Figure 5. Experimental rocket motor

The pressure-time diagram for Geometry 1 (Figure 6) shows a maximum pressure of approximately 31 bar (y-axis), with moderate variation between trials.

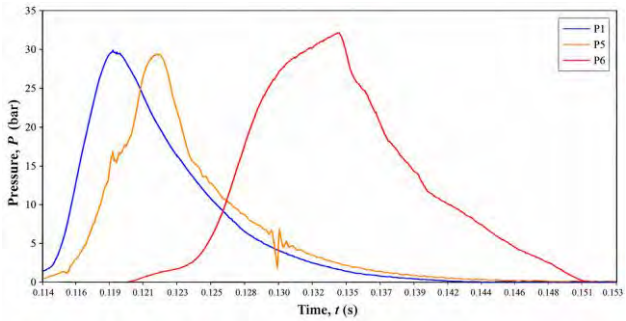

Figure 6. The pressure-time diagram for Geometry 1

The results presented in Table 1 include the maximum pressure and effective operating time.

Table 1. Geometry 1 test results

Igniter #	P	P (bar)	t (s)
#1	P1	30	0.014
#2	P5	29.8	0.013
#3	P6	31.6	0.016

The corresponding diagram for Geometry 2 (Figure 7) reveals a slightly higher maximum pressure—around 10% higher than Geometry 1—under otherwise identical conditions.

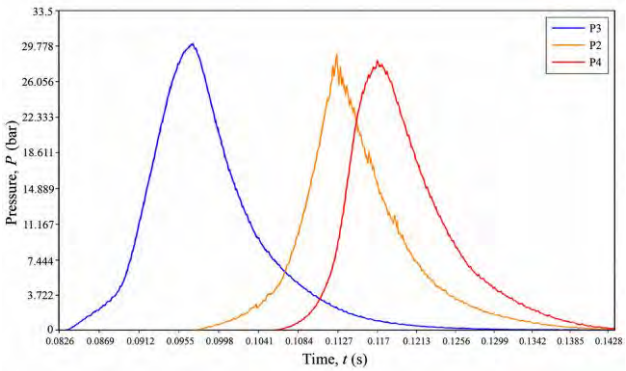

Figure 7. The pressure-time diagram for Geometry 2

The results presented in Table 2 include the maximum pressure and effective operating time.

Table 2. Geometry 1 test results

Igniter #	P	P (bar)	t (s)
#4	P2	27.5	0.014
#5	P3	29.8	0.015
#6	P4	27.3	0.014

These results show that internal geometry, even with identical pyrotechnic mass and free volume, can significantly affect pressure generation and combustion dynamics. The effect is likely related to localized flame propagation, gas flow paths, and the surface-area-to-volume ratio, all of which influence the rate of pressure increase.

Furthermore, the study demonstrates the efficiency and repeatability of 3D printing in the design, fabrication, and testing of igniter housings. Additive manufacturing offers a rapid and cost-effective method for prototyping and even low-rate production of components with complex internal geometries. It enables functional validation before mass production, reduces lead times, and allows for immediate modifications.

3. CONCLUSION

The results of this study confirm that internal geometry of igniter housing has a significant role in effect on interior ballistic behavior, even when the pyrotechnic composition and free volume remain constant. Among the tested configurations, Geometry 2—featuring a recessed conical cavity—demonstrated a ~10% increase in maximum pressure compared to Geometry 1. While the overall impulse remained comparable across designs, the rate of pressure increases and flame propagation dynamics were noticeably affected by structural differences.

These findings validate the hypothesis that optimized igniter geometry can enhance ignition efficiency and combustion control in solid rocket motors. Moreover, the successful application of 3D printing technology for rapid prototyping of complex igniter housings highlights its practical value in both research and low-volume production environments. The use of carbon-fiber-reinforced and high-temperature-capable filaments provides an adequate balance of mechanical strength, thermal stability, and manufacturing speed.

Future work will focus on numerical simulations (finite element methods or CFD analysis) of thermal and gas-dynamic processes within the igniter chamber to correlate experimental findings with predictive models. Additionally, further optimization of geometry, material selection, and surface finish could lead to improved safety, repeatability, and ignition performance under operational conditions.

Abstract: *The ethanol electrooxidation reaction is a key process in direct ethanol fuel cells. However, its practical application is hindered by catalyst poisoning and limited stability. In this work, Pd–Sb electrocatalysts (Pd@Sb/GC) were synthesized via a two-step electrodeposition route. The Pd/Sb ratio was fixed at 80:20, while the total metal loading was systematically varied. The catalytic activity toward ethanol oxidation in alkaline media was evaluated using cyclic voltammetry and chronoamperometry. All samples exhibited the characteristic dual-peak behavior associated with ethanol oxidation and the removal of adsorbed intermediates. The Pd@Sb/GC catalyst with a metal loading of 4.41 µg Pd demonstrated the highest activity, achieving a peak current density of 600 mA mg^{-1}. In addition to the highest current density, it showed a more negative onset potential, indicating enhanced catalytic performance. This improvement is attributed to the formation of well-dispersed Pd islands. At higher Pd loadings, increased agglomeration led to a decrease in mass activity. The Pd@Sb/GC (4.41 µg Pd) also exhibited the highest jf/jb ratio, close to 2, along with a smaller peak separation, indicating improved resistance to poisoning and enhanced reaction reversibility.*

Keywords: *Palladium-based catalyst, catalyst poisoning tolerance, surface morphology effect, electrocatalytic stability*

1. INTRODUCTION

Ethanol is primarily utilized as a fuel in direct ethanol fuel cells (DEFCs) [1]. This growing interest stems from the urgent global demand to transition away from fossil-fuel-dependent energy systems. The high theoretical energy density of ethanol (8.0 kWh kg−1), combined with its low toxicity and ease of storage as a liquid, makes it an ideal candidate for sustainable power generation. These specific advantages give it a distinct edge over alternative fuels like methanol or compressed hydrogen. Besides that ethanol is applied in proton exchange membrane (PEM) electrolyzers to produce hydrogen at lower cell voltages (<1 V) compared to water electrolysis (> 1.8 V), often yielding high-value chemical byproducts like acetic acid [2]. This approach not only reduces the energy footprint of green hydrogen production but also integrates chemical synthesis into the electrochemical cycle. Consequently, a highly favorable dual benefit of clean energy production and chemical manufacturing is realized simultaneously. Likewise, well known are ethanol biosensors for amperometric determination of ethanol in alkaline media with the aid of enzymes (e.g., Alcohol Oxidase - AOX) or Ni-based catalysts (e.g., Ni-Schiff base complexes), measuring the generated current to determine concentration in applications like breathalyzers [3]. The development of non-enzymatic sensors, in particular, has gained traction due to their superior thermal stability and longer shelf life compared to biological recognition elements. This makes them ideal for demanding point-of-care testing and long-term industrial monitoring.

Ethanol is a key organic molecule in electrochemistry, and Pd is acknowledged as one of the most effective metal for the ethanol electrooxidation reaction (EOR) [1, 4]. In alkaline environments, Pd exhibits faster kinetics for C–H bond activation and higher CO-tolerance than platinum-based benchmarks. However, several key factors hinder its practical use, primarily related to catalytic deactivation, inefficient reaction pathways, and stability issues. The accumulation of strongly adsorbed carbonaceous intermediates, such as COads and CHx,ads, often blocks the active Pd sites and leads to a rapid decay in current density. As a result, a dramatic loss in overall cell efficiency occurs over extended operating periods. To address these challenges, research is focused on alloying Pd with other metals (e.g., PdAg, PdNi, PdAu, PdSn) to modify the electronic structure, improve C–C bond cleavage, and promote the formation of OH– species for better CO oxidation [1, 4]. These promoters typically

Corresponding author: M. Košević;

DOI: 10.5937/OTEH26123K

operate via the bifunctional mechanism, where the second metal provides oxygen species at lower potentials to facilitate the oxidative removal of poisons from the Pd surface. This cooperative interaction continually regenerates the active metal sites. While transition metals have been extensively studied as promoters, the exploration of main-group metalloids like antimony (Sb) remains limited. This is an oversight, as antimony has a unique potential to favorably tune the electronic states of noble metals while altering surface oxophilicity.

In this work, a bimetallic Pd-on-Sb catalysts were synthesized by electrodeposition of Pd on pre-prepared Sb nanoparticles using chronopotentiometry. This sequential deposition strategy was employed to create a specific surface architecture where Pd "islands" are anchored onto Sb sites. This arrangement maximizes the synergistic interaction between the two metals. This specific architecture ensures that a high number of active boundary zones are exposed. The electrocatalytic behavior of Pd-on-Sb catalysts, with different amount of electrodeposited Pd and Sb and constant Pd/Sb ratio, was systematically investigated toward EOR using cyclic voltammetry and chronoamperometry, allowing for a clear comparison with the performance of pure Pd. Special attention was paid to the effect of total metal loading on the mass activity and the jf/jb ratio, providing insights into how catalyst dispersion influences poisoning resistance. Ultimately, this approach provided new insights into how the spatial arrangement of the Pd-Sb interface influences reaction reversibility.

2. EXPERIMENTAL

Preparation and characterization of the catalysts

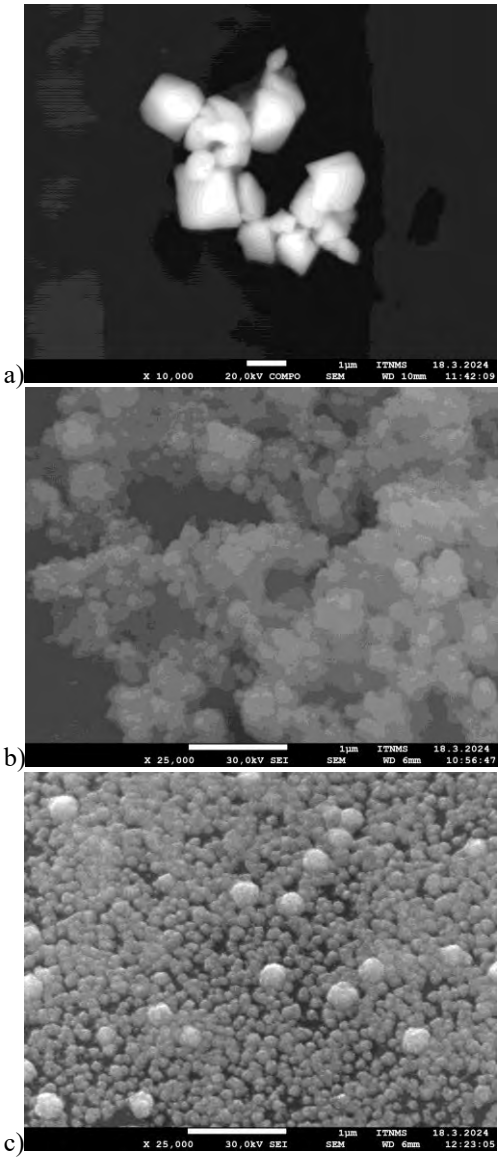
The Pd-on-Sb (designated as Pd@Sb/GC) catalysts were synthesized using a two-step electrodeposition method as was previously described [5]. The Pd@Sb/GC catalysts with a constant atomic ratio of 20 at.% Sb-80 at.% Pd was obtained by controlling the deposited charge of Sb (3, 6, and 12 mC) and Pd (8, 16, and 32 mC). The electrocatalysts are designated as Pd1@Sb/GC, Pd2@Sb/GC and Pd3@Sb/GC, respectively. For accurate comparison, a Pd electrode was constructed utilizing the same deposition parameters corresponding to one for bimetallic electrode. The current densities were normalized by the mass of Pd, and the calculated metal loadings were 4.41 µg, 8.82 µg, and 17.64 µg for Pd1@Sb/GC, Pd2@Sb/GC and Pd3@Sb/GC, respectively.

Morphologies of electrodeposited Sb, Pd and Sb–Pd catalysts were characterized by the technique of scanning electron microscopy (SEM) – model JEOL JSM-7001F.
Electrochemical experiments were in a standard three compartment electrochemical glass cell with Pt wire as the counter electrode and Ag/AgCl/3.5 M KCl as the reference electrode.

3. RESULTS AND DISCUSSION

3.1 Characterization of the Sb, Pd and Sb–Pd catalysts by the SEM technique

Morphology of Sb, Pd and Sb–Pd obtained by galvanostatic regime of the electrodeposition is shown in Fig 1.



Morphology of a) Sb, b) Pd and c) Sb–Pd catalysts

3.2 Ethanol oxidation reaction on the Pd@Sb catalysts

Electrochemical examination of electrodeposited catalysts in EOR was started by CV measurements. Figure 1 shows the voltammetric responses of Pd@Sb/GC catalysts in 1 M NaOH + 1 M C_2H_5OH. A summary of key CV features related to ethanol oxidation revealed two anodic peaks. The forward scan peak is ascribed to the oxidation of chemisorbed ethanol species. Due to the formation of the oxide layer at higher potentials the electrocatalytic activity decrease. The electrode reactivates during the reverse scan after the oxide is removed from its surface, resulting in a second oxidation peak. The backward scan

peak indicates the removal of carbonaceous species that can form on the Pd catalyst surface but remain incompletely oxidized during the forward scan [6].

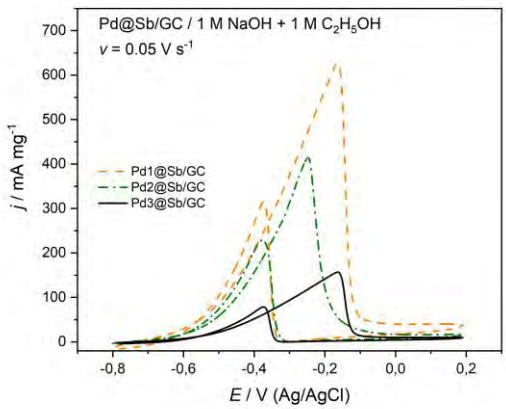


Fig. 2. CVs for the oxidation of 1 M C_2H_5OH recorded on Pd@Sb/GC catalysts in 1 M NaOH. Scan rate: 0.05 V s^{-1}.

According to Fig. 2, the most active Pd@Sb/GC catalyst toward EOR is Pd1@Sb/GC, showing the highest reaction currents in forward and backward direction, along with the shift of the initial potential of the reaction toward more negative values. The observed behavior is explained by the different surface morphology i.e. size effect of Pd islands [7]. An increase in Pd loading resulted in a subsequent decrease in mass activity as the palladium surface changed from isolated Pd nanoparticles to Pd agglomerates. It can be said that the catalytic activity is not directly proportional to surface area, as a higher surface area does not necessarily provide more active sites.

The ratio of the forward anodic peak current density (jf) to the backward anodic peak current density (jb), as well as potential peak separation between the forward and backward scans are crucial indicators of the susceptibility to carbonaceous intermediates that accumulate on the catalyst surface during the EOR. The j_f/j_b ratio of Pd@Sb/GC is measured to be 2, 1.8 and 1.72 for Pd1@Sb/GC, Pd2@Sb/GC, and Pd3@Sb/GC, respectively. The potential peak separation increase in order Pd2@Sb/GC<Pd1@Sb/GC< Pd3@Sb/GC. Reduced peak separation and higher j_f/j_b ratio signifies that the oxidation of intermediate species during the reverse scan occurs closer to the potential of the initial oxidation, indicating better efficiency and less irreversible poisoning. The obtained results are in accordance with chronoamperometric measurements (Fig. 3).

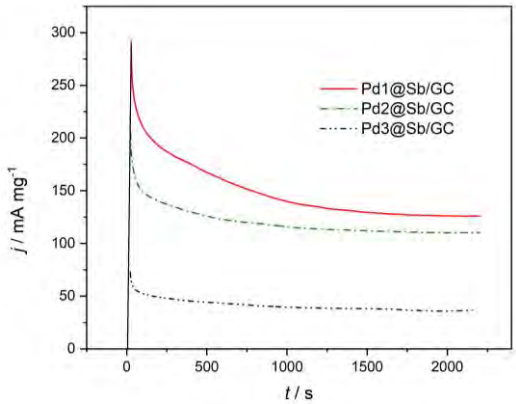

Fig 3. Chronoaperometric curves obtained at E = – 0.35 V for the oxidation of 1 M C_2H_5OH on Pd@Sb/GC.

4. CONCLUSION

The catalytic activity towards the EOR was examined on a catalyst system constructed by the electrochemical deposition of Sb on GC followed by the electrochemical deposition of Pd. According to electrochemical measurements, catalytic performance is heavily dependent on surface morphology rather than total surface area alone. Among the tested samples, the highest performance was delivered by the catalyst with a lower metal loading (4.41 µg Pd, designated as Pd1@Sb/GC). A peak current density of 600 mA mg−1 was achieved by this sample, alongside a significantly more negative onset potential. This enhanced activity is driven by the formation of well-dispersed, isolated Pd islands. Conversely, nanoparticle agglomeration was triggered by higher metal loadings, causing mass activity to be severely restricted.

Beyond high current densities, stable operation was demonstrated by the optimized Pd1@Sb/GC catalyst. The highest jf/jb ratio of approximately 2 and a tightly reduced potential peak separation were yielded. This proves that highly reversible reactions are undergone by the material and a strong resistance to carbonaceous poisoning is possessed. Ultimately, the vital importance of controlling mass loading in bimetallic designs is underscored by these findings, allowing this optimized Pd–Sb configuration to be positioned as a viable anode candidate for next-generation direct ethanol fuel cells.

Abstract: *Ceramics are essential for lightweight armor systems, utilizing high hardness and compressive strength to shatter projectiles and absorb impact energy. Key materials include boron carbide (B_4C), silicon carbide (SiC), and alumina (Al_2O_3), commonly used in personal body armor and vehicle shielding to counter high-velocity ballistic threats. Bulletproof materials, more accurately termed bullet-resistant or ballistic materials, are specialized materials designed to stop or significantly decrease the penetration of munitions. They function by absorbing, dispersing, or breaking up the bullet's kinetic energy through layered, high-strength structures like Kevlar, ceramic, steel, or polycarbonate, rather than being completely impervious. These materials work by either deforming the bullet upon impact with a rigid surface (e.g., ceramics, metals) or capturing the projectile through a dense, flexible weave (e.g., aramid fibers) that distributes energy. In this paper, the most commonly used ceramic materials for armor applications will be discussed; these are: alumina (Al_2O_3), silicon carbide (SiC), and boron carbide (B_4C). Armor functions related to ceramic materials, as well as ceramic applications, will be presented, along with performance considerations related to their strengths and weaknesses.*

Keywords: *bulletproof material, ceramic materials, Boron Carbide (B_4C), Silicon Carbide (SiC), Alumina (Al_2O_3)*

1. INTRODUCTION

Materials for military applications are highly specialized materials engineered for extreme conditions and performance, such as durability and lightweight strength, designed to withstand combat, high temperatures, and harsh environments. Key materials include different materials, including metals, ceramics, and composite materials. Some of the most used belongs to the groups of: titanium and aluminum alloys for aerospace, carbon fiber composites, high-performance ceramics for armor, tungsten, and critical rare earth elements for electronics and propulsion [1,2].

One of the interesting applications of materials, or military application are materials with high resistance to impact, "Bullet-Resistant" or "Bulletproof" materials. While commonly called "bulletproof," most materials are only *bullet-resistant*, meaning their effectiveness depends on the bullet type, caliber, velocity, and distance, often categorized by protection levels [3-5].

Compared with traditional steel bulletproof materials, ceramic materials are lighter in weight and have superior protective performance. They have gradually become the first choice material for lightweight protection.

Most used bulletproof ceramic materials are:

- Alumina Ceramic (Al_2O_3)
- Silicon Carbide Ceramics (SiC)
- Boron Carbide Ceramics (B_4C)

In this paper, the focus will be on the main characteristics of the ceramics, their strengths and weaknesses as bullet-resistant materials, and possible applications.

During ballistic impact, extremely high strain rates occur at the point of contact, while strain rates decrease with the distance from the impact site (Figure 1). In these lower-strain regions, quasi-static fracture behavior becomes relevant and can provide insight into failure mechanisms [3-12]. Generally, materials exhibit more brittle behavior at higher strain rates.

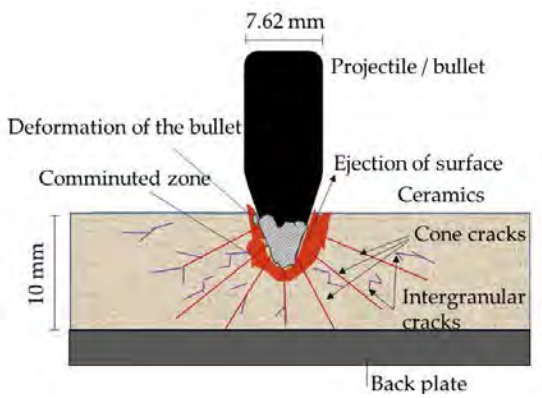

Fig.1. Deformation of the bullet and ceramic tile during ballistic impact. [13]

Relationships between material properties, microstructure, processing conditions, failure mechanisms, and ballistic

DOI: 10.5937/OTEH26124V

performance in order to provide critical discussion of the reasons for different ballistic behavior of selected ceramics [14-19].

- **Material Properties → Microstructure**

Density, hardness, and fracture toughness are direct outcomes of the ceramic's grain size, porosity, and phase composition.
Example: Boron carbide's extreme hardness comes from its crystal structure, but its brittleness is linked to localized amorphization under stress.

- **Microstructure → Processing Conditions**

Hot pressing, sintering temperature, and additives control grain boundaries and porosity.
Alumina processed at lower purity has larger pores, reducing ballistic efficiency compared to high-purity alumina.

- **Processing Conditions → Failure Mechanisms**

Improper sintering can leave residual stresses or weak grain boundaries, leading to crack propagation.
SiC produced via liquid-phase sintering achieves higher flexural strength, delaying catastrophic fracture.

- **Failure Mechanisms → Ballistic Performance**

Ceramics defeat projectiles by shattering or eroding them, but cracks and fragmentation reduce multi-hit capability.
Alumina: fails by brittle fracture, but cost-effective.
SiC: resists armor-piercing rounds but cracks after repeated hits.
B_4C: amorphization reduces effectiveness after localized impact.

2. MATERIALS

2.1. Alumina Ceramic(Al_2O_3)

Alumina provides the best cost-benefit ratio among advanced ceramics, due to the excellent mechanical properties, such as high modulus of elasticity, high refractoriness, high hardness, and relatively lower cost compared to other advanced ceramics. Weaknesses of the alumina-based ceramics are related to the low fracture toughness and low flexural strength. Due to the mechanical properties, the ballistic performance of alumina is lower when compared to SiC and B_4C [8]. The ballistic properties of alumina could be improved by using zirconia or by manufacturing CMCs. This approach could increase fracture toughness and flexural strength by introducing tetragonal zirconia particles or ceramic fibers [9,10].

Some of the relevant mechanical properties of alumina are given in Table 1.

Table 1. Mechanical properties of alumina [7-11]

Properties	Value
Density	3.6-3.95 g/cm³
Flexural strength	200-400 MPa
Hardness	HRA90
Fracture toughness	3.0-4.5 MPa·m$^{1/2}$

Advantages and Properties

Cost-Effectiveness: More economical than alternatives like silicon carbide or boron carbide.
Hardness: High hardness (HRA 90) enables breaking, fracturing, and eroding projectiles.
Durability: Offers excellent chemical stability, corrosion resistance, and heat dissipation, making it suitable for harsh environments.
Performance: High-purity (99%) alumina offers better weight reduction and reliable ballistic results compared to lower purity options.
Key Application Areas include [6,7,11,12]:
Personal Body Armor**:** Used as rigid inserts (plates) in vests for military personnel and police forces to protect against rifle fire.
Vehicle Armor**:** Applied as armored panels in light military vehicles, armored cars, and aircraft, often designed with concave/convex edges to improve joints.
Structural Protection**:** Utilized in security shielding for vital facilities or VIP vehicles.
Composite Structures**:** Frequently bonded with backing materials like fiber-reinforced polymers or UHMWPE (ultra-high molecular weight polyethylene) to increase strength and reduce weight

2.2. Silicon carbide ceramics (SiC)

Silicon carbide ceramics are currently the highest level of bulletproof ceramics. Its special crystal structure forms a diamond-like tetrahedral structure, which gives it extremely high hardness and strong mechanical properties.

Silicon carbide is second only to diamond and boron carbide in hardness and is very light, with a density about 18% lower than that of alumina. Silicon carbide ceramics are mainly used in high-end military equipment, such as special forces bulletproof equipment and key protective parts of armored vehicles.

Table 2. Mechanical properties of silicon carbide ceramics (SiC) [6,13]

Properties	Value
Density	3.10-3.15 g/cm³
Flexural strength	400-730 MPa
Hardness	≥HRA92
Fracture toughness	5.0-5.5 MPa·m$^{1/2}$

Key Performance Benefits

High Hardness: SiC is one of the hardest known materials, second only to diamond and boron carbide. This extreme hardness allows it to erode or "shatter" the hardened steel cores of armor-piercing bullets upon impact.

Lightweight Efficiency: It has a density approximately 18% lower than alumina and 2.5 times less than steel. This reduction in weight is critical for maintaining user mobility without sacrificing protection.

Protection Levels: SiC plates are typically used to achieve NIJ Level III and IV protection standards,

meaning they can stop high-velocity rifle rounds, including .30-06 M2 armor-piercing (AP) threats.

- Thermal & Chemical Stability: The material remains stable at temperatures up to 1600°C/(depending on atmosphere (oxidizing vs. inert), since oxidation can degrade performance) and is highly resistant to corrosion and wear.

The performance of ceramic armor materials depends not only on intrinsic properties but also on processing conditions, microstructure, test configuration, and environment. Similarly, NIJ Levels III and IV describe the ballistic rating of complete armor systems, not the ceramic alone; SiC or B_4C must be integrated with backing materials to achieve these standards. Ballistic efficiency is therefore a system-level outcome, influenced by sintering method, grain size, porosity, and environmental exposure, rather than a single material property.

Ballistic Performance Features:

- **Shock Resistance:** Excellent thermal shock resistance and thermal conductivity prevent premature failure during high-energy impacts.
- **Phase Composition:** Often produced via hot pressing or liquid-phase sintering to optimize microstructure for superior flexural strength.
- **Applications:** Widely utilized in high-end military equipment, such as personal body armor and vehicle armor, owing to its combination of low density and high destructive energy capability.

Critical Limitations

- **Brittleness:** Like all ceramics, SiC is brittle. While it effectively stops initial impacts, it is prone to cracking and may lose effectiveness if subjected to multiple closely spaced hits or "multi-hit" scenarios without specialized backing.
- **Cost:** It is more expensive to produce than alumina due to the complex sintering processes required.
- **Brittle Fracture:** It cannot withstand heavy, sustained gunfire as effectively as some composite or metal-backed systems might, as the entire plate can fail after its structural integrity is compromised.

2.3. Boron Carbide Ceramics (B_4C)

Boron carbide ceramics are known as the “lightest bulletproof ceramics”. Its density is only 2.45-2.52 g/cm³ (about 20% lighter than SiC). $B_{11}C$ has a unique rhombus crystal structure. C-B-C is connected by covalent bonds and has a very stable spatial structure. It is also one of the lightest known superhard materials [14-16].

Boron carbide is mainly used in situations where weight and protection are high, such as air force pilot seat protection, special forces lightweight bulletproof equipment, etc. In addition, it also has good neutron absorption ability and can be used for nuclear protection.

Table 3. Mechanical properties of boron carbide ceramics [11-14]

Properties	Value
Density	2.45-2.52 g/cm³
Flexural strength	200-500 MPa
Hardness	28-35 GPa
Fracture toughness	2.0-4.7 MPa·m$^{1/2}$

Key Advantages in Ballistic Armor

Lowest Density: It is the lightest bulletproof ceramic, with a density of ~2.52 g/cm³. It is roughly 20% lighter than silicon carbide (SiC) and 40% lighter than alumina.

Extreme Hardness: Its high Vickers hardness (~28-35 GPa) allows it to effectively shatter high-velocity armor-piercing (AP) projectiles on impact.

Rifle-Rated Protection: It is a primary component in NIJ Level IV plates, designed to stop .30-06 Springfield M2 armor-piercing rounds.

Weight Sensitivity: Because of its lightness, it is the preferred choice for elite military gear, air force pilot seat protection, and specialized lightweight vests where mobility is critical.

Limitations & Trade-offs

Brittleness & Multi-Hit Performance: It is more brittle than other ceramics. Upon impact, it can suffer localized "amorphization," where its crystal structure breaks down, potentially reducing its effectiveness against subsequent hits in the same area.

Higher Cost: Due to complex manufacturing requirements-needing temperatures above 2000°C for sintering-it is significantly more expensive than alumina or silicon carbide.

Composite Requirement: It is rarely used alone. It is bonded to a ductile backing material (like Kevlar or UHMWPE) to catch the shattered fragments of the ceramic and the bullet.

3. COMPARISON OF THE SELECTED CERAMICS

Some of the relevant properties are listed in Table 4. Representing strengths and weaknesses in comparison of selected ceramics for bulletproof applications.

The ballistic performance of ceramics is not only determined by their intrinsic properties (density, hardness, fracture toughness) but also by their microstructure and processing conditions. For example, high-purity alumina with fine grains exhibits improved hardness and reduced porosity, enhancing its ability to erode projectiles. Silicon carbide, when hot-pressed or liquid-phase sintered, achieves superior flexural strength due to optimized grain boundaries, delaying brittle fracture. Boron carbide’s extreme hardness allows it to shatter armor-piercing rounds, but localized amorphization of its crystal structure under impact reduces multi-hit capability. These failure mechanisms-cone cracking, fragmentation, and amorphization-explain why ceramics must be paired with

backing materials (e.g., UHMWPE, Kevlar) to absorb residual energy and maintain structural integrity. Thus, processing and microstructural control are as critical as the inherent properties in defining the real-world ballistic efficiency of ceramic armor.

Table 4. Comparison of the selected ceramics [11-14, 19-22]

Properties	Value		
	Alumina (Al_2O_3)	Silicon carbide (SiC)	Boron carbide (B_4C)
Density	3.6-3.95 g/cm³	3.10-3.15 g/cm³	2.45-2.52 g/cm³
Flexural strength	200-400 MPa	400-730 MPa	200-500 MPa
Hardness	HRA90	≥HRA92	29-35 GPa
Fracture toughness	3.0-4.5 $MPa \cdot m^{1/2}$	5.0-5.5 $MPa \cdot m^{1/2}$	2.0-4.7 $MPa \cdot m^{1/2}$
Relative cost	medium	low	high

Ceramic armor protects by breaking and eroding projectiles through extreme hardness, while simultaneously dissipating impact energy via fracture and fragmentation. Upon impact, a compressive stress wave forms, causing cone cracking and radial/circumferential cracks that spread through the ceramic. The projectile is blunted or shattered, but the ceramic itself undergoes brittle fracture or localized amorphization (in B_4C). Backing materials (e.g., UHMWPE, Kevlar) are essential to capture fragments and absorb residual energy. Thus, the physical protection mechanism is a combination of projectile defeat and controlled ceramic failure, designed to prevent penetration while sacrificing the ceramic layer.

The ballistic efficiency of ceramics is strongly influenced by processing and microstructural control. Hot pressing and liquid-phase sintering of SiC improve grain boundary cohesion, increasing flexural strength and delaying brittle fracture. In alumina, higher purity and finer grain size reduce porosity, enhancing hardness and projectile erosion capability. Boron carbide requires sintering above 2000 °C, where microstructural defects or amorphization zones can reduce multi-hit performance. Thus, sintering method, grain size distribution, and porosity are critical factors that determine whether ceramics achieve their theoretical mechanical properties in real ballistic tests.

4. CONCLUSIONS

In this paper, some of the most used ceramics as bulletproof materials were presented. Some of the key applications, as well as the mechanical properties, were discussed. Based on the literature data, some strengths and weaknesses of the selected ceramics were highlighted.

Abstract: *In the last decade, the expansion of industrial and agricultural activities has led to the significant rise of organic pollutants, contributing to serious environmental contamination. Biochar has received considerable attention as a low-cost and environmentally friendly adsorbent for a wide range of pollutants. In this paper, waste sour cherry stones, originating from the local fruit industry, were used as a raw material for biochar production via slow pyrolysis. The obtained biochar was characterized by SEM-EDX analysis, which revealed a porous and irregular surface morphology. The adsorption of the cationic dye Malachite green (MG) onto biochar was investigated in stirred batch system at pH 6, 25 °C, adsorbent dosage of 2 g/L, initial dye concentration of 15-400 mg/L for 24 h. To assess the adsorption capacity of biochar for MG, the experimental data were analyzed by non-linear fitting of the Langmuir, Freundlich, and Sips adsorption isotherm models. The maximum adsorption capacity of 116.33 mg/g was obtained by Sips model, indicating combined adsorption on heterogeneous surfaces. The utilization of waste sour cherry stones for biochar production offers an effective approach for reducing waste disposal problems and producing a novel and sustainable adsorbent with promising potential for removal of organic pollutants from aqueous solutions.*

Keywords: *lignocellulosic waste, pyrolysis, dye removal, isotherms*

1. INTRODUCTION

Global population growth, urbanization, industrial expansion, and evolving lifestyles have contributed to the growing release of potentially polluting substances into the environment, placing considerable strain on water resources. Worldwide assessments indicate that water pollution is a critical environmental challenge, with repercussions felt globally, posing severe threats to human health, food security, and ecosystem functioning [1]. Of particular concern are organic pollutants, whose persistent nature allows them to remain in water systems for extended periods. These pollutants include a wide range of compounds such as pharmaceuticals, dyes, pesticides, and industrial chemicals, as well as hazardous organic substances that may originate from the chemical industry and military activities. Due to their toxicity, persistence, semi-volatile nature, and resistance to natural biodegradation, these compounds pose significant risks to both ecosystems and human health [2,3]. Furthermore, the persistence of organic pollutants can lead to their bioaccumulation and biomagnification through food chains [4].

Among these contaminants, organic dyes constitute a significant class of pollutants due to their widespread industrial use and direct release into aquatic systems. In particular, Malachite Green (MG) has been extensively studied as a model dye, owing to its high toxicity, chemical stability, complex structure and resistance to conventional degradation processes. This dye is widely used in the textile industry, as a therapeutic agent in aquaculture, and for food-related applications [5]. Prolonged exposure to this dye has been associated with potential carcinogenic and mutagenic effects [6]. In order to effectively remove MG from contaminated water, various treatment technologies have been developed, among which adsorption has been widely recognized as one of the most effective methods due to its cost-effectiveness, simplicity, and operational flexibility [2,6].

In recent decades, various materials have been investigated as adsorbents for organic pollutants, while

DOI: 10.5937/OTEH26125A

biochar has emerged as a promising material for environmental applications. Biochar is a stable carbon-rich material produced through the pyrolysis of biomass under oxygen-limited conditions, which is widely recognized for its low cost, abundant feedstock availability, and versatile applications in environmental remediation [7,8]. Due to the highly porous structure, large specific surface area, and diverse surface functional groups (hydroxyl, phenolic and carboxyl groups), biochar exhibits excellent adsorption capacity toward various organic and inorganic contaminants [5,8].

Despite these advances, there is a growing need to develop feedstock-specific biochars that align with the principles of green chemistry and circular economy, transforming local agricultural by-products into high-value environmental solutions. In the present study, biochar produced from fruit waste industry was evaluated as a low-cost and sustainable adsorbent for the removal of MG from aqueous solutions and represents a basis for further investigations aimed at developing cost-effective and efficient adsorbents for organic pollutant removal. The results provide a basis for further research on the application of the obtained biochar for the removal of other organic pollutants, such as fuel residues and pesticides, from water contaminated by military activities.

2. MATERIALS AND METHODS

Sour cherry stones (*Prunus cerasus L.*) were obtained from the local fruit processing company "Fruvita", where they are generated as a waste by-product. The collected stones were separated from fruit residues, thoroughly washed with tap water, and dried at room temperature prior to further processing. The dried material was subsequently pyrolysed to produce biochar. Pyrolysis was carried out in a Nabertherm 1300 muffle furnace (Nabertherm, Germany) at 500 °C for 90 minutes under an argon atmosphere. After cooling, the produced biochar was ground and sieved to obtain a particle size fraction between 0.1 and 0.5 mm.

The yield of produced biochar is calculated according to the following Equation (1):

$$Yield(\%) = \frac{mass\ of\ pyrolised\ sampel\ (g)}{mass\ of\ raw\ sampel\ (g)}\ x\ 100 \qquad (1)$$

Produced biochar was characterised by using the SEM-EDX analysis by JEOL JSM-6610 LV SEM (JEOL Ltd., Japan). Prior to analysis, the samples were coated with a thin layer of gold. EDX measurements were conducted at an accelerating voltage of 20 kV, a probe current of approximately 13 nA, a working distance of 10 mm, a magnification of 500×, and an acquisition live time of 100 s. The elemental composition obtained by EDX analysis was expressed as weight percentages (wt. %).

Malachite green, also known as Basic Green 4 was supplied by Sigma-Aldrich, (USA) and used as received without further purification. A stock solution (1000 mg/L) was prepared by accurately dissolving the required amount of dye in distilled water, and working solutions of different concentrations were subsequently obtained by serial dilution of this stock solution.

The adsorption isotherms were performed in batch mode at 25 °C. Briefly, 0.1 g of biochar was added to 50 mL of MG solutions with initial concentrations ranging from 15 to 400 mg/L. The systems were equilibrated for 24 h, after which the residual dye concentration was determined spectrophotometrically by measuring the absorbance by UV/VIS spectrophotometer (Spekol 1300, Analytik Jena, Germany) at 614 nm. The adsorption capacity q (g/mg) was calculated using Equation (2):

$$q_e = \frac{V\ x\ (C_i - C_f)}{\mathrm{m}} \qquad (2)$$

where C_i and C_f are the equilibrium and initial concentrations of dye (mg/L), respectively, V is the volume of dye solution (L) and m is the amount of the sorbent (g).

The equilibrium data were analyzed using Langmuir, Freundlich, and Sips isotherm models, which are described in detail in our previous study [7]. The best fitting model was determined by the highest correlation coefficients (R^2) and the lowest chi-squared value (χ^2).

3. RESULTS AND DISCUSSION

Schematic illustration of the adsorbent preparation and adsorption experiment is provided in Figure 1.

Figure 1. Schematic diagram of the experiment

The obtained biochar yield was 26.73%, which is typical for biochar produced from fruit stones [9,10].

To investigate the surface morphology and elemental composition of the biochar, SEM–EDX analysis was performed and presented in Figure 2. The biochar exhibited irregular and heterogeneous morphology with visible pores of different sizes and shapes. The observed porous features may be associated with the thermal decomposition of lignocellulosic components, including cellulose and hemicellulose, during pyrolysis. The decomposition of these components is accompanied by the release of volatile compounds, which may contribute to the formation of voids and channels within the carbon matrix [11]. The EDX analysis indicated that carbon was the dominant element in the biochar (81.37%), followed by oxygen (18.44%). These results are in agreement with the study by Lopičić et al., [12] who investigated the SEM–EDX characteristics of biochar derived from plum stones.

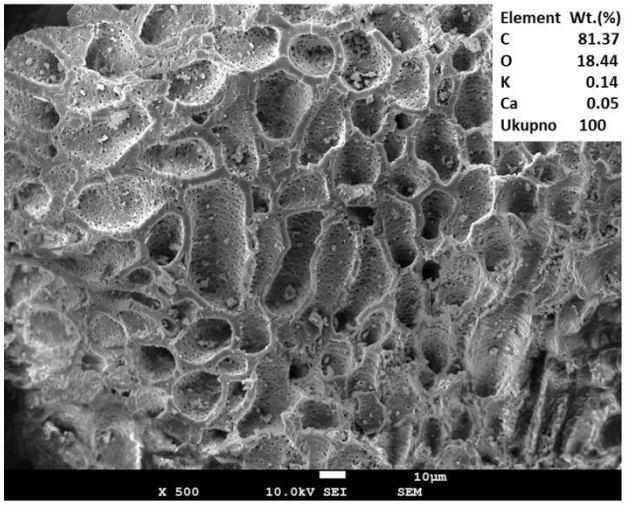

Figure 2. SEM-EDX micrographs of the biochar from Sour cherry stone

To elucidate the nature of the interaction between MG and biochar, adsorption isotherm analysis was performed. The experimental data were fitted using the Langmuir, Freundlich, and Sips isotherm models and presented in Figure 3, while the corresponding parameters are listed in Table 1.

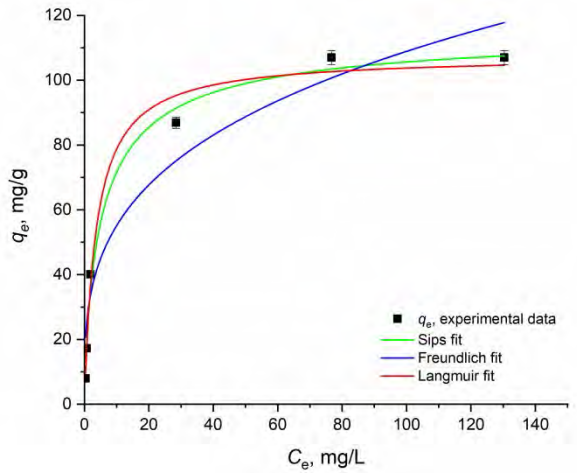

Figure 3. Isotherm model fitting of MG adsorption on biochar

The suitability of the applied isotherm models for describing MG adsorption was evaluated using the correlation coefficient (R^2) and chi-square (χ^2) values as statistical criteria. According to the data presented in Table 1, the Sips model provided the best fit for MG adsorption onto biochar. The Sips model exhibited the highest R^2 value (0.991) and the lowest χ^2 value (2.657), indicating that MG adsorption onto biochar occurs on heterogeneous surface sites with varying energies. The Sips heterogeneity parameter s was 0.791, which confirms a heterogeneous adsorption surface with non-uniform binding energies. The maximum predicted adsorption capacity obtained from the Sips model was 116.332 mg/g. Das et al., [5] reported the similar adsorption capacity of 120.50 mg/g for MG removal by NaOH-activated biochar derived from agricultural waste. Considering that the biochar used in this study was not activated, the obtained results highlighting the potential of the biochar derived from waste sour cherry stones for further optimization and application in the removal of organic pollutants from aqueous solutions. Future studies should evaluate the applicability of the biochar in real water matrices, where competing dissolved components may affect the adsorption process. The desorption of the adsorbed dye, together with the regeneration and reuse of the biochar, should also be evaluated to determine the potential for repeated application and the economic feasibility of the adsorption process. In addition, the obtained biochar may be further investigated as a low-cost adsorbent for the treatment of contaminated water resulting from military activities, particularly where locally available waste-derived materials may be advantageous.

Table 1. Isotherm parameters for the adsorption of MG onto biochar

Isotherm model	Parameter	Value
Langmuir	q_e, mg/g	107.551
	K_L	0.273
	R^2	0.985
	$\chi 2$	7.374
Freundlich	K_F	27.904
	n	0.296
	R^2	0.931
	χ^2	9.696
Sips	q_e, mg/g	116.33
	K_S	0.259
	s	0.791
	R^2	0.991
	χ^2	2.657

4. CONCLUSION

This study demonstrates that biochar derived from agro-industrial waste can be used as an efficient, low-cost, and sustainable adsorbent for the removal of organic pollutants from aqueous systems, such as MG. Conversion of fruit industry waste into a functional adsorbent not only provides an effective approach for wastewater treatment, but also contributes to waste valorization and the reduction of environmental burdens in accordance with the principles of the circular economy.

Among the investigated isotherm models, the Sips model showed the best agreement with the experimental data, indicating heterogeneous adsorption behavior, with a maximum adsorption capacity of 116.33 mg/g. The high adsorption capacity may be associated with the porous morphology observed by SEM, which may facilitate the uptake of relatively large dye molecules. These findings provide a basis for future studies focused on the optimization, potential surface modification, and application of biochar derived from sour cherry stones for the removal of organic pollutants from aqueous solutions.

Abstract: *Foam glass is an inorganic insulation material composed of a glassy matrix with gas-filled pores. In this study, it was produced entirely from secondary raw materials: green container glass as the glassy matrix and sugar beet factory lime as the foaming agent. During sintering and foaming, the material expands irregularly, and it should be cut into blocks. Ground and sieved foam glass can be used as an adsorbent. This study investigates the effect of particle size on the adsorption capacity of Brilliant Green (BG). Four particle size fractions were examined (<0.2 mm, 0.2-0.5 mm, 0.5-0.8 mm, and >0.8 mm) and characterized by BET analysis to evaluate the variation of specific surface area with particle size. The adsorption experiments were performed in a batch system at room temperature for 24 h, using an adsorbent dosage of 2 g/L and a BG concentration of 50 mg/L. The smallest particle size fraction (<0.2 mm) showed the highest dye removal efficiency (96%), attributed to its largest specific surface area, while further increases in particle size led to a decrease in removal efficiency. Ground foam glass waste was successfully repurposed as an adsorbent, promoting circular economy principles.*

1. INTRODUCTION

The rapid expansion of industrial activities has led to the increased discharge of synthetic dyes into water systems, posing significant environmental and public health concerns. Dyes are used in textile, paper, leather, printing, pharmaceutical, and cosmetic industries because of their excellent stability, high coloring efficiency, and resistance to degradation. However, these same properties make many dyes persistent pollutants that are difficult to remove by conventional wastewater treatment processes. Even at low concentrations, colored effluents reduce light penetration in water bodies, inhibit photosynthetic activity, disrupt aquatic ecosystems, and negatively affect water quality [1].

Among synthetic dyes, Brilliant Green (BG) has attracted considerable attention due to its widespread use and high toxicity. Brilliant Green is a cationic triphenylmethane dye. It has been widely used as a biological stain, veterinary antiseptic, disinfectant, and colorant in the textile and paper industries. Despite its practical applications, the discharge of BG into water systems represents a serious environmental challenge because of its high chemical stability and poor biodegradability. The dye can persist in water for extended periods, increasing the risk of accumulation in natural ecosystems [2].

The presence of BG in wastewater is associated with numerous adverse effects on living organisms. Exposure to this dye has been reported to cause skin and eye irritation, respiratory disorders, gastrointestinal disturbances, and allergic reactions. Prolonged exposure has been linked to mutagenic, cytotoxic, and potentially carcinogenic effects. In aquatic environments, BG can

Corresponding author: V. Savić;
E-mail: v.savic@itnms.ac.rs
DOI: 10.5937/OTEH26126S

inhibit the growth of algae and microorganisms, disrupt food chains, and reduce dissolved oxygen levels by limiting light penetration and photosynthetic activity. Consequently, the efficient removal of BG from contaminated water has become an important objective in environmental protection and wastewater management [2].

Among the available treatment technologies, adsorption has emerged as one of the most promising methods for dye removal because of its simplicity, high efficiency, ease of operation, and economic feasibility. The adsorption process involves the accumulation of dye molecules on the surface of a solid adsorbent through physical or chemical interactions, allowing rapid and efficient removal even at low pollutant concentrations. Compared with other treatment methods, adsorption offers several advantages, including high removal efficiency, low energy requirements, minimal formation of harmful by-products, operational flexibility, and the possibility of adsorbent regeneration and reuse [1,2].

In recent years, considerable research efforts have focused on the development of low-cost, sustainable, and high-performance adsorbents derived from natural minerals, industrial by-products, and agricultural residues [1]. These materials often exhibit large specific surface areas, abundant active adsorption sites, and favorable surface chemistries. The utilization of waste-derived adsorbents is attractive because it simultaneously addresses wastewater purification and waste valorization, contributing to the principles of circular economy and sustainable resource management.

For dye removal from aqueous solution many types of adsorbents were examined (clays, biochars, etc.), but there is limited research on glass or foam glass application. Foam glass is a highly porous inorganic material consisting of a continuous glassy matrix enclosing a network of gas-filled pores. It is typically produced from finely ground waste glass cullet mixed with a foaming agent, most commonly calcium carbonate ($CaCO_3$), carbon (C) or silicon carbide (SiC). During heat treatment, the glass particles undergo viscous flow sintering while the foaming agent decomposes or reacts to generate gases. The resulting increase in internal gas pressure promotes pore nucleation, growth, and, in some cases, pore coalescence, leading to the expansion of the material [3].

Foam glass exhibits low density, good mechanical strength and excellent thermal insulation properties. In addition, its excellent chemical durability minimizes the release of hazardous substances into the environment during service, contributing to its long-term environmental stability [3].

Application of ground foam glass provides a low-cost and sustainable adsorbent for water purification, thereby integrating waste valorization with environmental remediation. The potential application of foam glass extends beyond dye removal, as its porous structure and surface properties make it a promising adsorbent for the removal of various pollutants from contaminated water. The possible use of ground foam glass may also extend to water treatment following floods or other events associated with water contamination. The aim of the present study is to investigate the feasibility of utilizing ground foam glass as an adsorbent for the removal of BG from aqueous solutions.

2. MATERIALS AND METHODS

Green container glass cullet was initially crushed in an agate mortar and subsequently milled in a Tencan planetary ball mill at 400 rpm for 60 min. Sugar beet factory lime (SBFL), a calcium carbonate-rich industrial by-product, was also crushed in an agate mortar and used as the foaming agent. The glass powder and SBFL were sieved using a No. 300 sieve (48 µm), and only particles smaller than 48 µm were used for foam glass production [3].

The glass powder was mixed with SBFL to obtain a batch containing 2.5wt.% $CaCO_3$. The powder mixture was uniaxially pressed into cylindrical pellets and sintered in a Carbolite CWF 13/13 electric furnace at 800 °C for 30 min using a heating rate of 10 °C/min [3]. After cooling to room temperature, the produced foam glass was crushed and sieved into four particle size fractions: d_1 (<0.2 mm), d_2 (0.2-0.5 mm), d_3 (0.5-0.8 mm), and d_4 (>0.8 mm). These fractions were subsequently used as adsorbents.

The surface area of the samples was analysed using N_2 physisorption at 77 K with an Anton Paar Nova 600. Before the analysis, samples were vacuum-degassed for 1 hour at room temperature, after which the temperature was increased to 100 °C and degassing continued for an additional 2 hour; then the temperature was increased again to 300 °C and degassing continued for 4 hours. When the temperature dropped to room temperature, vacuum degasation continued for additional 2 hours. The specific surface area of the samples was calculated from the linear portion of the adsorption isotherm branch by applying the Brunauer-Emmett-Teller (BET) equation [4-6]. The specific surface area for sample d_4 (>0.8 mm) could not be determined, likely due to its low specific surface area.

Batch adsorption experiments were conducted in 250 mL Erlenmeyer flasks. For each experiment, 0.10 g of foam glass of the selected particle size fraction was mixed with 50 mL of a 50 mg/L BG solution and agitated for 24 h. The pH of dye solution was 6.25. The residual BG concentration in the solution was determined using a UV–Vis spectrophotometer (Spekol 1300, Analytik Jena, Germany) at a wavelength of 625 nm. All experiments were done in doublets and average value is presented. The solution for UV-Vis measurements was sampled after the adsorbent had settled. The adsorption performance was evaluated in terms of the dye removal efficiency (R, %) were calculated using Eq. (1):

$$R(\%) = \frac{C_i - C_f}{C_i} \cdot 100\% \quad (1)$$

where C_i and C_f are the initial and final concentrations of Brilliant Green in the solution (mg/L).

3. RESULTS AND DISCUSSION

Figure 1 shows the SEM micrograph of the foam glass produced using sugar beet factory lime as the foaming agent. The material exhibits a highly porous cellular structure consisting nearly spherical pores embedded within a continuous glassy matrix.

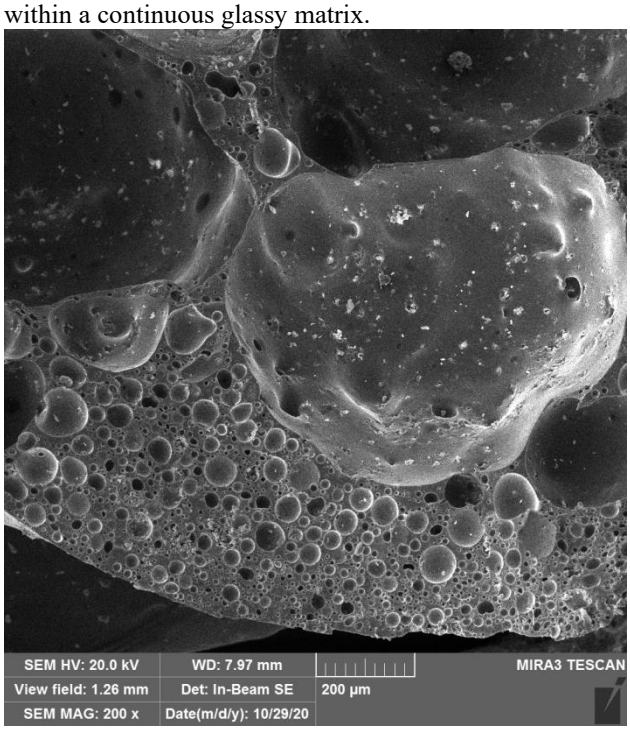

Figure 1. SEM micrograph of foamed glass sample

The pore structure is characterized by a broad pore size distribution. Numerous small pores are present throughout the structure, while larger pores are also observed, indicating that bubble nucleation and growth occurred simultaneously during foaming. The coexistence of pores of different sizes suggests that, in addition to the formation of new gas bubbles, some bubbles continued to grow. Several large pores appear to result from the coalescence of neighboring bubbles following the rupture of thin glass walls [3]. Despite the presence of several large pores, the majority of the cellular structure is composed of fine pores distributed relatively uniformly throughout the sample. The rough internal surfaces and numerous pore openings exposed after crushing are expected to provide accessible adsorption sites and facilitate the diffusion of dye molecules into the porous network.

The specific surface area was calculated from the data of absorption measurements by applying the BET equation (S_{BET}), and it is presented in Table 1.

Table 1. Specific surface area of ground foam glass samples

Sample	S_{BET} (m^2/g)	Correlation coefficient, R^2
d_1	0.194	0.9998
d_2	0.084	0.9999
d_3	0.055	0.9995
d_4	N.D.	N.D.

The BET specific surface area of the foam glass samples ranged from 0.055 to 0.194 m²/g, indicating relatively low nitrogen-accessible surface areas. An increase in particle size resulted in a decrease in the specific surface area. The observed increase in BET surface area with decreasing particle size is attributed to particle fragmentation during crushing, which exposes fresh fracture surfaces and opens previously inaccessible pores. Smaller particles therefore provide a greater external surface area per unit mass and a larger number of accessible adsorption sites. Such values are characteristic of soda-lime glass materials and are consistent with those reported for both waste glass and foam glass in the literature. Papelis et al. [7] reported BET surface areas between 0.0016 and 1.65 m²/g for various natural and manmade glasses, Similarly, Katsuura et al. [8] measured a BET surface area of only 0.04 m²/g for foam glass despite the presence of numerous pores with diameters between 10 and 900 µm. The adsorption performance of the ground foam glass is expected to depend not only on the measured BET surface area but also on factors such as particle size, pore accessibility, surface chemistry, and electrostatic interactions between the glass surface and BG molecules [1,2].

Figure 3 shows removal efficiency of different particle size of ground foam glass of BG.

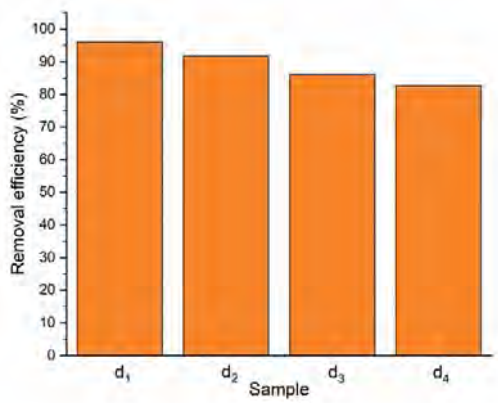

Figure 3. Removal efficiency of BG dye

The highest removal efficiency (96%) was achieved by the smallest particle size fraction (<0.2 mm), whereas progressively lower removal efficiencies were observed for larger particles.

Removal efficiency increase is accompanied by an increase in BET specific surface area from 0.055 to 0.194 m²/g with decreasing particle size, which could indicate that particle comminution increases the surface available for adsorption.

The better removal efficiency of the finest particles can be possibly attributed to their larger external surface area [2]. Crushing the foam glass exposes fresh fracture surfaces and opens previously closed cells, thereby increasing the number of accessible adsorption sites. Although the BET surface area increased with decreasing particle size, the measured values remained relatively low compared with conventional porous adsorbents such as activated carbon or biochar [2].

In addition to the physical characteristics of the adsorbent, electrostatic interactions may likely play an important role in the adsorption mechanism. BG is a cationic dye, whereas the surface of soda-lime glass in aqueous solution is generally negatively charged due to the deprotonation of surface silanol (Si–OH) groups. Attractive electrostatic interactions between the positively charged dye molecules and negatively charged glass surface could possibly be reason for enhanced dye uptake.

5. CONCLUSIONS

Ground foam glass generated was successfully used as a low-cost adsorbent for the removal of BG from aqueous solutions. The foam glass produced from recycled green container glass and sugar beet factory lime exhibited a highly porous cellular structure composed predominantly of macropores formed during the foaming process. The produced grounded foam glass proved to be effective for dye removal, achieving removal efficiencies of 82-96%. The highest removal efficiency was obtained using sample d_1, which also exhibited the largest measured BET surface area. The higher adsorption performance of smaller particles is attributed to the greater accessible surface area, exposure of fresh fracture surfaces during crushing. This study presents preliminary research in which high removal efficiency of dye was achieved, providing a solid foundation for future research. By utilization of ground foam glass material for wastewater treatment, this work contributes to both sustainable waste management and the development of environmentally friendly adsorption technologies.

Abstract: *Environmental radioactivity monitoring includes the assessment of radiation exposure through food consumption, which represents a significant pathway for human intakes. The determination of radionuclide activity concentrations in foodstuffs provides essential data for evaluating background radiation levels and identifying potential contamination originating from anthropogenic sources, including nuclear and other radiation–related facilities .The Radiochemical Laboratory of the Military Technical Institute performs systematic gamma spectrometric measurements of representative food samples obtained from the Military Medical Academy, contributing to the system of radiological protection within the defence sector. This study presents the results of activity concentration measurements in 20 food samples, including dairy products, cereals fruits ,vegetables, eggs, and meat products used in standard daily diet. The analysis was performed using high-resolution gamma spectrometry. The aim of this study is to assess the natural radionuclides activity concentration in commonly consumed food and to evaluate the associated radiological health risk. An overview of monitoring results from 2015 to 2020 is also presented, providing insight into long-term trends and supporting compliance with relevant radiological safety standards.*

Keywords: *radioactivity, food, monitoring, gamma spectrometry, effective dose*

1. INTRODUCTION

The presence of anthropogenic radionuclides in the environment of Serbia is primarily a consequence of the nuclear accident that occurred Chernobyl nuclear power plant accident in 1986. Several decades after this event, the radionuclide ^{137}Cs continues to be detected in various environmental compartments owing to its relatively long half-life of approximately 30 years.

In addition to the consequences of nuclear accidents, numerous anthropogenic activities contribute to increased levels of environmental radioactivity. These include nuclear energy production, nuclear weapons testing, fossil fuel combustion, mining activities, as well as the production and application of phosphate fertilizers. These processes may promote the release and redistribution of naturally occurring radionuclides within the environment.

Among the naturally occurring radionuclides relevant for environmental and food radioactivity monitoring are ^{40}K, ^{232}Th, and ^{238}U. These radionuclides are introduced into ecosystems through the exploitation and utilization of mineral resources, most notably through agricultural practices.

The primary objective of radiological monitoring of the food chain is to determine the occurrence of natural and anthropogenic radionuclides in food products and their transfer to the production environment. Such investigations involve the analysis of soil, animal feed, agricultural crops, milk and dairy products, eggs, meat from domestic and wild animals, as well as fish, in order to assess the potential transfer of radionuclides through the food chain to the final consumers [1].

The presence of naturally occurring radionuclides in the Earth's crust directly influences the food chain. Agricultural crops cultivated on such soils can absorb these radionuclides, leading to their accumulation in food products. Consequently, the consumption of contaminated food may result in internal radiation exposure of the human population. Therefore, monitoring radioactivity levels in food represents a key component in the assessment of the overall radiation exposure associated with daily dietary intake.

2. RADIOACTIVITY IN FOOD PRODUCTS AND MEASUREMENT METHODS

The intake of radionuclides through food represents a significant pathway for long-term exposure to ionizing radiation, potentially affecting various organs. Therefore, assessing the level of radioactive contamination in food products is of great importance for evaluating food safety and the radiological risk to human health.

The high natural abundance of potassium (^{40}K) in soil constitutes the largest contributor to internal radiation exposure in humans. Its beta and gamma emissions

DOI: 10.5937/OTEH26127P

directly increase the level of internal radiation dose following ingestion. In this study, gamma spectrometry was employed to quantify the activity concentrations of naturally occurring radionuclides in various food products used for the preparation of daily meals in the kitchen of the Military Medical Academy.

Sources of radioactivity in food products can be classified into four main categories:

- Naturally Occurring Sources of Radioactivity,
- Industrial and Energy-Related Sources of Radioactivity,
- Radioactivity as consequence of nuclear weapons testing and nuclear accidents.

2.1 Naturally Occurring Sources of Radioactivity

Certain radionuclides represent an integral part of the natural environment. Among them, potassium (^{40}K) is a naturally occurring radioactive isotope of an element essential for biological processes. Uranium, thorium, and their decay progenies are also present in soil, water and the atmosphere. Plants absorb these elements from their surroundings and therefore trace amounts can be detected in fruits, vegetables, cereals, milk and meat. Monitoring natural radiation enables the assessment of population exposure and the timely detection of potential adverse changes. [2]

2.2 Industrial and Energy-Related Sources of Radioactivity

During the operation of nuclear facilities, fuel processing activities, laboratory operations, as well as certain medical procedures, small quantities of radionuclides may be released into the environment. These radionuclides can subsequently be transferred to water, soil, and the food chain. Although, such emissions are generally strictly regulated and maintained at low levels, continuous monitoring remains essential for the protection of human health.

2.3 Radioactivity as a Consequence of Nuclear Weapons Testing and Nuclear Accidents

Nuclear weapons testing during the second half of the 20th century resulted in the global dispersion of radioactive particles. These particles were deposited on soil, vegetation, and in aquatic environments, subsequently entering the food chain and spreading through various components of the environment. Certain radionuclides can still be detected decades after the conducted tests. [2]

2.4 Radioactivity in Food Products

Continuous monitoring of radioactivity in food products enables the timely detection of changes in the environment, the assessment of population exposure, and the implementation of appropriate protective measures if radionuclide concentrations exceed the established reference values. The results of long-term studies indicate that radionuclide activity concentrations in food are generally low in most countries and remain within levels that do not represent a significant risk to public health. Nevertheless, regular monitoring remains an essential component of the food safety system, particularly in the event of nuclear accidents or other emergency situations that may result in environmental contamination.

2.5 The Most Relevant Radionuclides in Food Products

- Radionuclides determined in food products can be classified into naturally occurring and artificial radionuclides. Their importance in environmental monitoring depends not only on their presence in the environment but also on their half-life, pathways of entry into the food chain, chemical properties, and contribution to the total effective radiation dose received by the population.
- Potassium-40 (^{40}K) is the most abundant naturally occurring radionuclide in food. As a naturally occurring isotope of potassium, it is present in all plant- and animal-derived food products. Since potassium is an essential element for the normal functioning of the human body, its concentration in tissues is regulated by physiological mechanisms. Consequently, ^{40}K is a major contributor to natural internal radiation exposure.
- Radium-226 (^{226}Ra) belongs to the uranium-238 (^{238}U) decay series and may be taken up by plants from soil or enter drinking water from geological formations. Its presence is of particular concern in groundwater and in certain food products originating from areas with elevated concentrations of naturally occurring radionuclides.
- Uranium-238 (^{238}U) and thorium-232 (^{232}Th) occur naturally in soils at low concentrations. Their transfer to plants is generally limited; however, elevated activity concentrations may be observed in certain geological regions, which is why these radionuclides are included in environmental monitoring programs.
- Polonium-210 (^{210}Po) is of particular importance in marine ecosystems. This radionuclide can accumulate in fish and seafood and may constitute one of the major sources of natural internal radiation exposure for populations with a high consumption of marine food products. [3]

2.6 Artificial Radionuclides

The most significant artificial radionuclide in food products is caesium (^{137}Cs). Following its release into the environment, it binds strongly to soil particles; however, it can be taken up by plants through their root systems. Its transfer through the food chain depends on soil characteristics, plant species, and climatic conditions. Owing to this, its may remain in the environment for several decades following a nuclear accident.

Strontium-90 (^{90}Sr) enters the human body primarily through the consumption of milk and dairy products because it exhibits chemical behavior similar to that of calcium. After absorption, it is incorporated into bone tissue, making its monitoring particularly important in foods intended for children.

In addition to these radionuclides, **iodine (^{131}I)**, **tritium (^{3}H)**, **plutonium-239 (^{239}Pu)**, and **americium-241 (^{241}Am)** may also be determined under specific circumstances. Although ^{131}I has a relatively short half-life (approximately eight days), it may pose a significant health risk following nuclear accidents because of its accumulation in the thyroid gland. Consequently, milk, drinking water, and leafy vegetables are subject to intensive monitoring immediately after such events.

Table 1. The most relevant radionuclides in food

Radionuclide	Origin	Main Food Products	Monitoring Significance
^{40}K	Natural	Fruits, vegetables, cereals, milk, meat	natural internal radiation exposure
^{226}Ra	Natural	Drinking water, vegetables	assessment of regional geological characteristics
^{238}U	Natural	Drinking water, cereals	assessment of natural radioactivity
^{232}Th	Natural	Plant-based foods	natural background radioactivity
^{210}Po	Natural	Fish and seafood	dietary intake from aquatic ecosystems
^{137}Cs	Artificial	Milk, meat, mushrooms, game meat, cereals	primary indicator of nuclear contamination
^{90}Sr	Artificial	Milk and dairy products	accumulation in bone tissue
^{131}I	Artificial	Milk, leafy vegetables	post-nuclear accident monitoring

The selection of radionuclides included in routine monitoring programs depends on the national monitoring strategy, the contamination history of a particular region, and the assessment of potential risks to the population. Under normal conditions, the greatest emphasis is placed on determining the activity concentrations of ^{40}K and ^{137}Cs, whereas other radionuclides are analyzed as required or within the framework of specialized monitoring and research programs.

2.7 Food Radioactivity Monitoring

Food radioactivity monitoring is an organized and continuous system of sampling, laboratory analysis, and assessment of radionuclide activity concentrations in food products. Its primary objective is to protect public health through the timely detection of potential food contamination and the assessment of exposure to ionizing radiation via dietary intake. In addition to routine surveillance, monitoring enables a rapid response in the event of nuclear or radiological accidents when there is an increased likelihood of radionuclides entering the food chain.

Monitoring programs are based on the recommendations of the International Atomic Energy Agency (IAEA). In the Republic of Serbia, environmental and food radioactivity monitoring is conducted in accordance with the Law on Radiation and Nuclear Safety and Security, as well as the relevant other regulations that define the types of samples, the frequency of testing, and the applicable reference values.

The selection of food products included in monitoring programs is based on their importance in the daily diet of the population, their capacity to accumulate radionuclides, and their suitability as indicators of environmental changes. Particular attention is given to milk, drinking water, cereals, leafy vegetables, and infant foods, as these products may contribute significantly to the overall dietary intake of radionuclides among sensitive population groups.

2.8 Radionuclide Determination Methods

Laboratory analysis of food radioactivity is performed using standardized methods that enable the reliable determination of the activity concentrations of individual radionuclides.

The most commonly used methods include:

- High-resolution gamma spectrometry (HPGe detectors) – used for the determination of gamma-emitting radionuclides such as ^{40}K, ^{137}Cs, ^{60}Co, and ^{131}I. The main advantage of this method is that it allows the simultaneous determination of multiple radionuclides without chemical preparation of the sample.
- Radiometric determination of beta-emitting radionuclides – applied for the determination of ^{90}Sr following appropriate chemical separation procedures.
- Alpha spectrometry – used for the determination of alpha-emitting radionuclides such as ^{210}Po, ^{238}U, and ^{239}Pu.

The types of food products subject to monitoring vary between countries, however, the main categories are generally similar due to their importance in human nutrition and their potential for radionuclide accumulation.

Table 2. Major food groups included in food radioactivity monitoring programs

Food Group	The Most Frequently Monitored Radionuclides	Reason for Inclusion in Monitoring
Milk and dairy products	^{40}K, ^{137}Cs, ^{90} Sr, and ^{131}I	Highly sensitive indicator of contamination;

		important for infant and child nutrition
Cereals and cereal products	^{40}K, ^{137}Cs	Significant contribution to the daily diet
Bread and flour	^{40}K, ^{137}Cs	Control of essential staple foods
Leafy vegetables	^{137}Cs, ^{131}I *, ^{40}K	Direct deposition of radionuclides from the atmosphere
Fruits	^{40}K, ^{137}Cs	Assessment of intake through plant-based foods
Meat from domestic animals	^{40}K, ^{137}Cs	Transfer of radionuclides through animal feed
Fish and seafood	^{210}Po, ^{137}Cs	Monitoring of radioactivity in aquatic ecosystems
Mushrooms	^{137}Cs	High capacity for cesium accumulation
Honey	^{40}K, ^{137}Cs	Indicator of environmental conditions
Drinking water	^{226}Ra, ^{238}U, ^{3}H	Assessment of exposure through drinking water

The results of monitoring are used for the assessment of the annual effective dose received by the population, evaluation of food safety, and planning of protective measures in the event of increased radionuclide activity concentrations.

3. MATERIAL AND METHODS

Monitoring was performed on food product samples obtained through a joint initiative of the Military Technical Institute and the Military Medical Academy. The samples consisted of food items used to prepare daily meals for members of the Serbian Armed Forces, and were included in a comprehensive radiological, chemical, and biological monitoring program.

The study was conducted between 2015 and 2020. The analyzed samples represented a random selection of food products collected as part of the routine monitoring program. Sample preparation was performed at the Military Medical Academy laboratory using standard Marinelli geometry. Moist samples were treated with hydrochloric acid prior to analysis. Following this treatment, the containers were left open for 24 hours before sealing to allow the escape of radon gas. Subsequently, the samples were hermetically sealed with Parafilm®, appropriately labelled, and stored for a minimum of 28 days to establish secular equilibrium between radionuclides of ^{238}U and ^{232}Th and their short-lived decay products. After equilibration, the samples were subjected to gamma spectrometric analysis in the Radiochemistry Laboratory of the Military Technical Institute.

The activity concentrations of radionuclides were determined by high-resolution gamma spectrometry using a high-purity germanium (HPGe) detector with a relative efficiency of 56% and an energy resolution of 1.72 keV for the 1.33 MeV gamma line of ^{60}Co. Gamma-ray spectra were processed using the GammaVision 32 software package. The combined relative uncertainty associated with sample preparation and activity measurements did not exceed 10%.

The activity concentration of ^{134}Cs was determined using the gamma-ray emission lines at 604, 796, and 802 KeV, while ^{137}Cs was quantified using the 661.6 keV gamma line. The activity concentration of ^{40}K was determined from its characteristic gamma-ray emission at 1460 KeV.

3.1 Equipment and calibration

Calibration of the detector for measuring plant samples was done with a reference radioactive material, a matrix of silicone resin in Marinelli geometry. As a calibration source, a 1000ml mix standard of the MBSS 2 type in Marinelli geometry of the Inspectorate for ionizing radiation Czech metrological institute was used - certificate number: Cert.No: 9031-OL-159/08 total activities 41.48 kBq on August 31, 2023 (^{241}Am, ^{109}Cd, ^{139}Ce, ^{57}Co, ^{60}Co, ^{203}Hg, ^{88}Y, ^{113}Sn, ^{85}Sr ^{137}Cs). The time of measuring the samples is 60000 s.

The resolution depends on the energy deposited in the detector, that is, at higher energies, the resolution is better.

The first semiconductor material used for the detection of gamma radiation was silicon (Si), and later germanium (Ge) was used, which had an exceptional energy resolution, which is why it was widely used in spectrometry of photon radiation.In order to improve the performance of germanium detectors, a new material known as high-purity germanium with an active volume about 1 cm wide was obtained. Due to germanium detectors, gamma spectrometry is a widely used measurement technique for determining the concentration of radionuclide activity in various samples.

3.2 Sample Preparation

The selected food samples include cheese, eggs, butter, fruit, vegetables, grains, etc. A total of 20 samples of imported food brands were randomly sourced from local markets. The sample preparation procedure was strictly based on the recommendations of the International Atomic Energy Agency (IAEA). The measurement geometry was chosen based on the sample type; a plastic Marinelli beaker with a volume of 1000 ml was used for non-mineralized plant and meat samples. **[3]**

3.3 Determination of radionuclide activity

Activity Concentration

The activity concentrations of the radionuclides in the samples are calculated from the net area of the corresponding photopeak using the following equation:

$$A = \frac{N_{net}}{\varepsilon \times \gamma \times m \times t_s}$$

– *Nnet* – The net area under the given photopeak of the corresponding gamma energy in the spectrum, calculated as:

$$N_{net} = N_s - N_b \times \left(\frac{t_s}{t_b}\right)$$

Ns – The total area of the photopeak in the sample spectrum.
Nb – The corresponding total area of the photopeak in the background radiation spectrum.
tb – The total time of the background radiation spectrum measurement (s).
ts – The total time of the sample spectrum measurement (s).
ε – The detection efficiency at the specific gamma-ray energy.
γ – The absolute transition probability of the gamma-ray emmision
m – The mass of the sample (kg).

3.4 Assessment of radiological risk from food ingestion

The assessment of radiological risk associated with the consumption of contaminated food is based on internal radiation exposure, as the ingestion of radionuclides results in their distribution within human tissues and the consequent internal irradiation of the body. The annual effective dose for an individual consumer was calculated using the standard equation recommended by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR).

$$E(mSvy^{-1}) = \sum(A_i \times U \times D_{f,i}) \times 10^{-3}$$

Where:

- ***E*** *– annual effective dose due to food ingestion (mSv·y⁻¹)*
- ***Ai*** *– specific activity concentration of the radionuclide (^{226}Ra, ^{232}Th, or ^{40}K) measured in food samples (Bq/kg);*
- ***$D_{f,i}$*** *– standard ingestion dose conversion factor for radionuclide (Sv/Bq);*
- ***10^{-3}*** *– conversion factor used to express the annual effective dose in millisieverts (mSv) rather than sieverts (Sv).*

The standard ingestion dose conversion factors (D_f) for adults, as recommended by the International Atomic Energy Agency (IAEA), represent the committed effective dose per unit intake of a radionuclide and are as follows:

- ^{40}K: 6.2×10^{-9} Sv·Bq⁻¹
- ^{226}Ra: 2.8×10^{-7} Sv·Bq⁻¹
- ^{232}Th: 2.3×10^{-7} Sv·Bq⁻¹

Table 4. Annual Effective Dose from Food Ingestion

Sample Type	Annual consumption U(kg/y)	Dose from ^{238}U (mSv·y⁻¹)	Dose from ^{232}Th (mSv·y⁻¹)	Dose from ^{40}K (mSv·y⁻¹)	Total anual Dose E (mSv·y⁻¹)
Cheese	15	1.72×10^{-7}	8.97×10^{-8}	5.25×10^{-6}	5.51×10^{-6}
Eggs	15	1.93×10^{-6}	4.83×10^{-7}	8.92×10^{-7}	3.31×10^{-6}
Butter	10	1.12×10^{-7}	6.90×10^{-8}	2.18×10^{-6}	2.36×10^{-6}
Hot dogs	20	1.90×10^{-6}	7.36×10^{-7}	1.57×10^{-6}	4.21×10^{-6}
Fruit	40	5.15×10^{-7}	2.85×10^{-7}	2.44×10^{-5}	2.52×10^{-5}
Vegetables	50	3.50×10^{-6}	2.07×10^{-6}	4.44×10^{-5}	5.00×10^{-5}
Corn grits	15	2.60×10^{-6}	1.59×10^{-6}	1.31×10^{-5}	1.73×10^{-5}
Milk powder	5	5.60×10^{-8}	1.84×10^{-7}	1.74×10^{-5}	1.98×10^{-6}
Cocoa	5	3.48×10^{-6}	1.82×10^{-6}	2.58×10^{-5}	3.11×10^{-5}
Cottage cheese	20	1.96×10^{-7}	5.52×10^{-8}	6.13×10^{-6}	6.38×10^{-6}
Rice	25	9.38×10^{-67}	2.30×10^{-6}	1.02×10^{-5}	2.19×10^{-5}
Bacon	15	1.39×10^{-7}	1.79×10^{-7}	1.20×10^{-5}	1.23×10^{-5}
Beans	15	2.67×10^{-5}	2.55×10^{-6}	1.29×10^{-5}	4.22×10^{-5}
Sardines	10	1.05×10^{-5}	3.68×10^{-7}	9.82×10^{-6}	2.07×10^{-5}
Flour	50	1.13×10^{-5}	7.02×10^{-6}	3.79×10^{-5}	5.62×10^{-5}
Salt	2	3.36×10^{-8}	1.38×10^{-8}	1.45×10^{-7}	1.92×10^{-7}
Sugar	10	5.60×10^{-8}	4.60×10^{-8}	3.80×10^{-7}	4.82×10^{-7}
Tea	2	7.28×10^{-8}	1.01×10^{-7}	4.42×10^{-7}	6.73×10^{-7}
Green salad	10	5.4×10^{-7}	2.76×10^{-6}	7.44×10^{-8}	6.16×10^{-7}
Sample 20	3	2.25×10^{-7}	1.15×10^{-6}	3.1×10^{-8}	3.09×10^{-6}

$$Ei = A \times U \times D_f$$

where:
Ei – annual effective dose resulting from the ingestion of radionuclide i (mSv·y⁻¹);
A – activity concentration of the radionuclide in food (Bq·kg⁻¹);
U – annual food consumption per person (kg/y);
Df – ingestion dose conversion factor for the radionuclide of interest (Sv/Bq).

4. RESULTS AND DISCUSSION

4.1 Determination of activity concentration

The activity concentrations of the analyzed radionuclides in the investigated samples of daily meals prepared at the Military Medical Academy are presented as mean measured values. Among the analyzed radionuclides, the naturally occurring radionuclide ^{40}K exhibited the highest activity concentrations in all food samples, ranging from 6.13 to 832.40 Bq·kg^{-1}, with a mean value of 120.19 Bq·kg^{-1}. The highest ^{40}K activity concentration was measured in the cocoa sample, which can be attributed to the naturally high potassium content of this food product.

The activity concentrations of ^{137}Cs were low in all analyzed samples and fell within the range typically reported for food products available on the commercial market. All measured values were below the recommended reference levels. The presence of this radionuclide reflects its long-term persistence in the environment following past nuclear accidents; however, only very low activity concentrations are currently detected in most food products. [4]

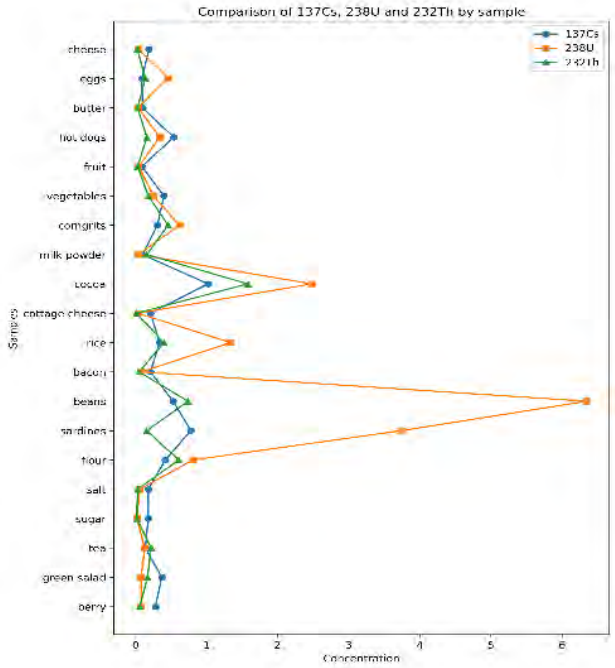

Figure 1. Comparison of Radionuclide Activity Concentrations among Food Groups

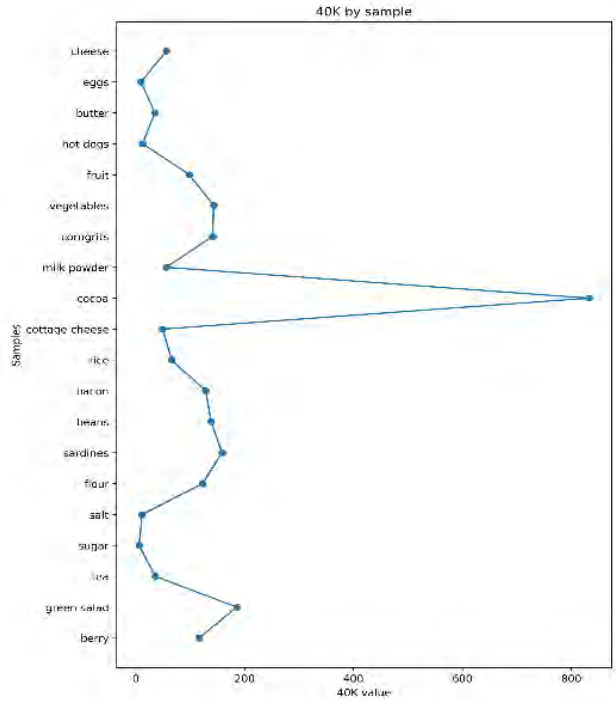

Figure 2. Comparison of the Specific Activity of ^{40}K among Food Groups

The concentrations of the natural radionuclides ^{238}U and ^{232}Th were considerably lower compared with ^{40}K. The highest uranium activity concentration was determined in the bean sample (6.35 Bq·kg^{-1}), while the highest thorium concentration was measured in the cocoa sample (1.58 Bq·kg^{-1}). Both radionuclides were detected at significantly lower levels than ^{40}K.

These results indicate that the influence of geological characteristics of the soil and the availability of specific minerals, represent dominant factors affecting the presence and transfer of radionuclides within the food chain. [5]

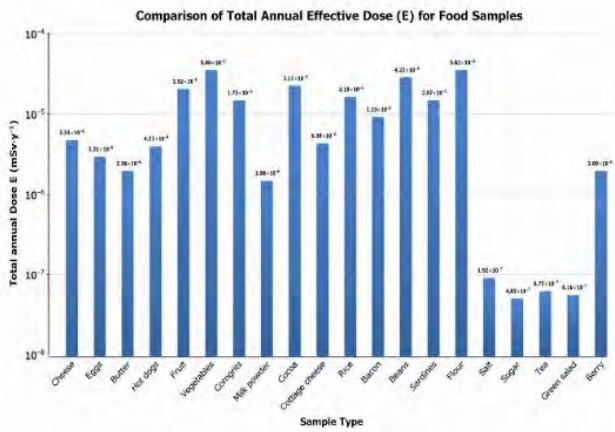

Figure 3. Comparison of the Total Annual Effective Dose for food samples

All obtained results were within the range of recommended values. The findings indicate that the food products analyzed for the assessment of the radiological burden of daily meals prepared at the Military Medical Academy do not represent a significant source of exposure of Serbian Armed Forces personnel to ionizing

radiation. The largest contribution to the total activity originates from the naturally occurring radionuclide ^{40}K, which is an essential component of the normal metabolism of living organisms and does not represent an indicator of radioactive contamination.

5. CONCLUSION

Gamma-spectrometric analysis of selected food products used in meal preparation showed that the activity concentrations of naturally occurring radionuclides (^{226}Ra,^{232}Th,and^{40}K) as well as anthropogenic radionuclide ^{137}Cs were within the ranges reported for similar food products in the available literature.

The estimated annual effective ingestion doses calculated from the measured activity concentrations indicate that consumption of the analyzed food products does not represent a significant source of radiological exposure for members of the Serbian Armed Forces. As expected, the largest contribution to the total annual effective dose originated from naturally occurring radionuclide ^{40}K reflecting its ubiquitous presence in food and its role in normal biological processes.

The obtained results confirm that the analyzed food groups are radiologically acceptable for consumption within the investigated dietary system and provide a reliable baseline for future monitoring of radionuclides in food products used in institutional nutrition.

Abstract: *The commercial AlMg4.5Mn and AlMg6Mn alloys, containing approx. 0.50%Mn both, were subjected to thermomechanical treatments (TMTs) in order to produce different final microstructures with small or large grains. TMT I included: cold rolling with 50% reduction + annealing at 320°C/3h; TMT II included: two-stage annealing (565°C/6h + 450°C/4h), cold rolling with 20% reduction and final annealing. Final annealing for AlMg4.5Mn alloy was 280°C/3h, while for AlMg6Mn alloy was 350°C/3h. Microstructure was evaluated using optical microscopy and quantitative metallography. Microstructure after TMT I route was homogeneous for both alloys, with unimodal distribution around average grain size of 13-14 μm. TMT II route enabled the grain coarsening, but produced less homogeneous microstructure with a grain size in the range of 15-55μm, for both alloys. Final grain structure is attributed to interrelation between cold rolling reduction, chemical composition and annealing conditions.*

1. INTRODUCTION

Aluminum-magnesium alloys are of interest in research for theirs many desirable properties, such as low density, high weight-to-strength ratio, high thermal and electrical conductivities, corrosion resistance, weldability, and relatively high ductility [1].

Aluminum-magnesium alloys sheets are widely used in the aerospace, automotive and ship-building industries and they are subject of continuous research. Military applications such as aircrafts, missiles, vehicle components, ships, boats, underwater weaponry, and light armor also require components that are strong and yet lightweight [2-5]. High strength, heat treatable, aluminum alloys (2xxx, 6xxx and 7xxx series) exhibit problems like consistency of tolerances introduced by quenching. Using non-heat treatable (solid solution hardened) Al-Mg alloys (5xxx series), this problem is eliminated, and additionally, these alloys have better corrosion resistance and good formability.

The strength of Al-Mg alloys is achieved mostly by solid solution strengthening and strain-hardening, and less by precipitation and grain boundary strengthening [6]. The main alloying element - magnesium, provides the most enhancement of strength among all alloying additions in aluminum solid solution, due to its high solubility in solid solution [1]. Hardness and strength of Al-Mg alloys linearly increase with addition of Mg [1]. Even an increase in Mg content above 5 wt% kept in good balance strength and formability [7]. Magnesium also, like the other solute elements, has a strong influence on recrystallization and grain growth, reducing both the rate of growth and the final grain size [8-9]. The addition of Mn in Al-Mg alloys, which have a limited solubility in solid solution, has a minor influence on strength of these alloys, but it has a significant influence on annealing behavior [10]. Mn containing particles usually precipitates during preheating, and inhibits the grain growth [11-12].

The chemical composition and processing parameters affect the development of the microstructure in these alloys. Grain size is known to be important for many properties of Al-Mg alloys, determining their mechanical properties, serrated flow and formability. Thus, controlling and evaluating grain size is important, especially for their formability [13-16]. The effect of applied TMTs on the grain size and its distribution in the past has been rarely discussed, particularly in Al-Mg-Mn alloys with high Mg content and Mn addition. A particular challenge is to increase the grain size due to the presence of Mn containing dispersoids on the grain boundary [17-19]. Additionally, there is lack of data on correlation between grain size and formability by spinning.

The aim of this work was to examine the influence of different thermomechanical treatments (TMTs) on the grain structure development in two Al-Mg-Mn alloys intended for further shear forming processing. This study

DOI: 10.5937/OTEH26128R

was performed in order to obtain fine grained (10-15 µm) and coarse grained structure (40-50 µm), and to evaluate grain size and its distribution that can affect further processing by shear spinning. The selected range of grain size was based on the preliminary research [20].

2. EXPERIMENTAL PROCEDURE

The chemical composition of the as received alloys is given in Table 1.

Table 1. Chemical composition of Al-Mg-Mn alloys

Alloy	Mg	Mn	Si	Cu	Fe	Zn	Ni	Al
AlMg4.5Mn	4.5	0.47	0.16	0.02	0.42	0.02	0.01	Bal.
AlMg6Mn	6.02	0.54	0.12	0.015	0.36	0.07	0.01	Bal.

Two TMTs were applied in an attempt to obtain microstructure with small (10 µm -15 µm) and coarse (40 µm -50 µm) grain, enable for a further sheet forming.

The as received hot rolled 15 mm and 8 mm thick plates of AlMg4.5Mn and AlMg6Mn alloys, respectively, were cold rolled up to 6 mm before TMT I, and up to 3,75 mm before TMT II.

TMT I route included: cold rolling (CR) to 50% reduction and annealing at 320°C/3h followed by air cooling (AC) for both alloys.

TMT II route included: two stage annealing (565°C/6h FC+450°C/4h FC to RT) (FC-furnace cooling, RT-room temperature). Following this process the samples of both alloys were cold rolled to 20 % reduction. Subsequent annealing was applied at 280°C/3h (AC) for AlMg4.5Mn and 350°C/3h (AC) for AlMg6Mn alloy.

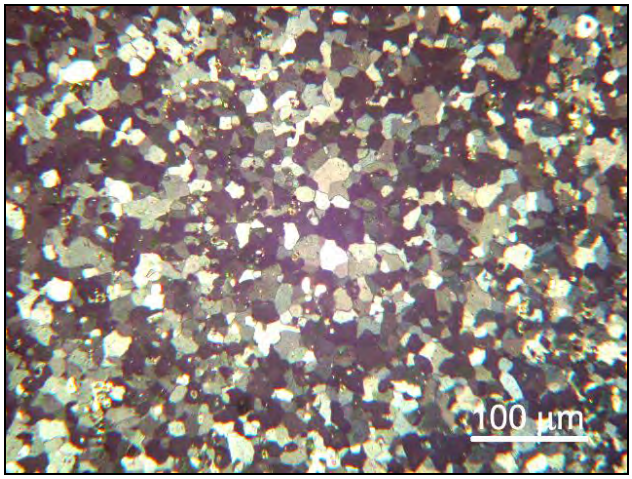
Thermomechanical treatments were determined on the base of published data and previous research [19, 21]. The final thickness of all specimens were 3 mm.

To reveal the grain structure, after electropolishing in perchloric acid, the samples were electrolytically etched in Barker′s solution. The microstructures were observed with a Leitz optical microscope (in polarized light) with a digital camera. Quantitative metallographic analysis was carried out using LAS-Leica Application Suite software V4.3 for image analysis. The grain size was determined by the linear intercept method.

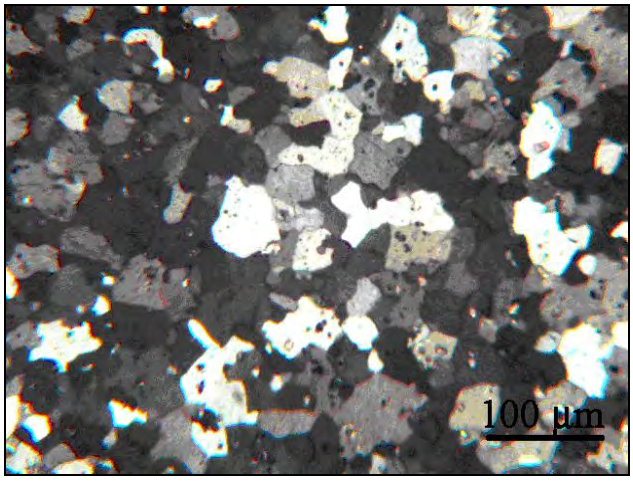
3. RESULTS AND DISCUSSION

Microstructures of Al-Mg-Mn alloys after applied two different TMTs are shown in the Figures 1 and 2. After TMT I microstructures of both alloys are characterized by small, equiaxed, recrystallized grains (Figures 1a and 2a). Observation by optical microscopy also revealed homogenous microstructure of small grain AlMg4.5Mn alloy (Figure 1a) compared to AlMg6Mn alloy (Figure 2a). After TMT II, which included two-stage annealing before cold rolling of 20 % reduction and subsequent annealing, the increase in grain size is achieved in both alloys (Figures 1b and 2b). However, microstructures are not homogenous, concerning the grain size.

Obtained grain size distributions for both examined alloys after applied TMTs are shown in Figures 3 and 4. The grain size distribution of AlMg4.5Mn and AlMg6Mn alloys with small grain are very similar (Figures 3a and 3b). The grain size distribution of AlMg6Mn alloy only exhibits a little longer tail in the coarse grain region compared to AlMg4.5Mn with the same grain size. The both distributions are unimodal, slightly asymmetric on the right. Also, the variation of the grain size is small. The dominant grain size is close to 15 µm for both alloys.



a)



b)

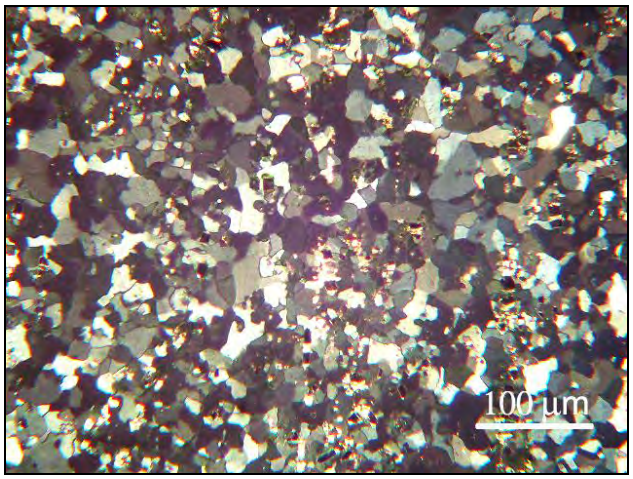
Figure 1. Microstructure of AlMg4.5Mn alloy: a) after TMT I: 50 % CR+320°C/3h AC; b) after TMT II: (565°C/6h FC+450°C/4h FC) + 20 % CR + 280°C/3h.

Cumulative curves show that approximately 90 % and 80 % of grains in small grain sized AlMg4.5Mn and AlMg6Mn alloy, respectively, are up to 20 µm. These results confirmed the microstructure homogeneity observed by optical microscopy.

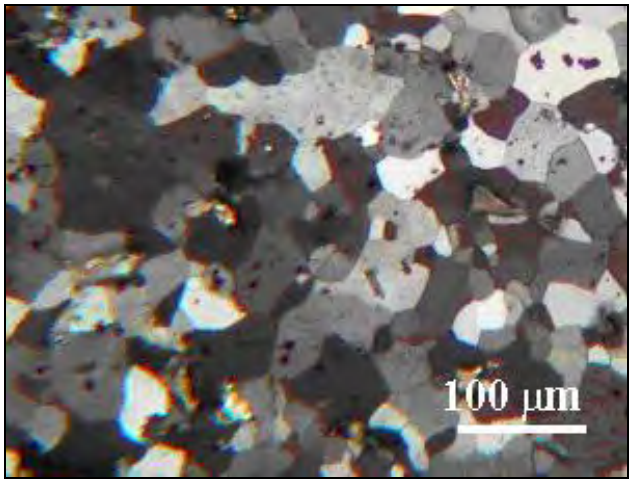
The grain size distribution of examined alloys after TMT II is shown in Figures 4a and 4b. It was shown that the range of the grain size in both alloys is large, larger than in small-grained specimens. Also, there was no single dominant grain size value. Cumulative curves show that approximately 75 % of grains are between 20 and 55 µm in AlMg4.5Mn alloy, i.e. 75 % between 15 and 55 µm in AlMg6Mn alloy.

Since the variation of the grain sizes in the microstructures obtained after TMT I is small, the average

grain size can represent these microstructures. Results of grain size quantification of Al-Mg-Mn alloys after different TMTs are shown in Table 2.



a)



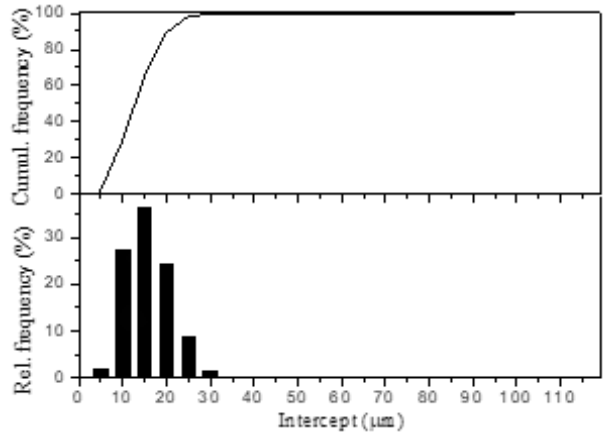
b)

Figure 2. Microstructure of AlMg6Mn alloy: a) after TMT I: 50 % CR+320°C/3h AC; b) after TMT II: (565°C/6h FC+450°C/4h FC) + 20 % CR +350°C/3h

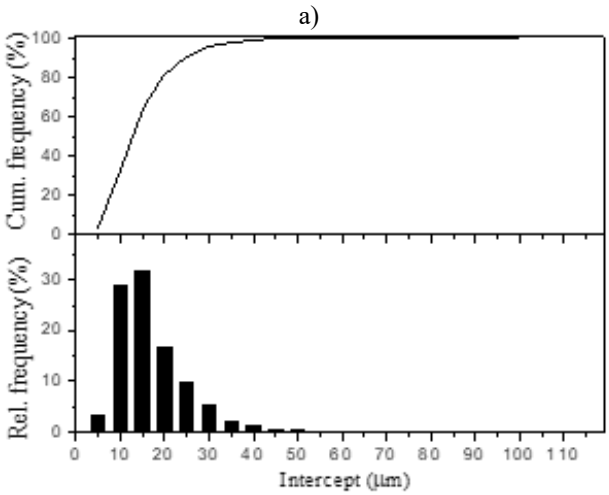
Table 2. Grain size in Al-Mg-Mn alloys after different TMTs.

Alloys	d_{av} (µm)	Range of the grain sizes, (µm)
	Small grained (TMT I)	Coarse grained (TMT II)
AlMg4,5Mn	13,3 ± 5.8	20-55
AlMg6Mn	13.7 ± 7.8	15-55

The results show that very close average grain size is obtained in both alloys after the same TMT. The average grain size of AlMg4.5Mn alloy is 13.3 ± 5.8 µm and AlMg6Mn alloy is 13.7 ± 7.8 µm. However, in the case of coarse grain alloys, the average grain size was not determined, because of wide range of the grain sizes. In this case, the average grain size does not represent the distribution of the grain size well. Therefore, the grain size in these microstructures is ranged from min to max value. The results shown that about 75 % of all grains in AlMg4.5Mn are in the range of 20-55 µm, i.e. in the range of 15-55 µm in AlMg6Mn alloy. It was shown earlier that microstructure development after cold rolling and annealing of Al-Mg alloys is closely related to both deformation and annealing temperature [11, 22-23]. The more homogenous microstructure in small grained specimens was obtained (Figures 1 and 2). The recrystallized grain size depends on the nucleation rate and growth rate. The effect of cold rolling reduction on recrystallized grain size is a direct result of an increase in the density of nucleation sites in the deformed microstructure. So, the final grain size in fully recrystallized small grain alloys is a result of an increase in the density of nucleation sites due to high reduction (50 %) before final annealing [14-16]. It also resulted in uniform grain growth, what was confirmed by grain size distribution results (Figure 3).



a)



b)

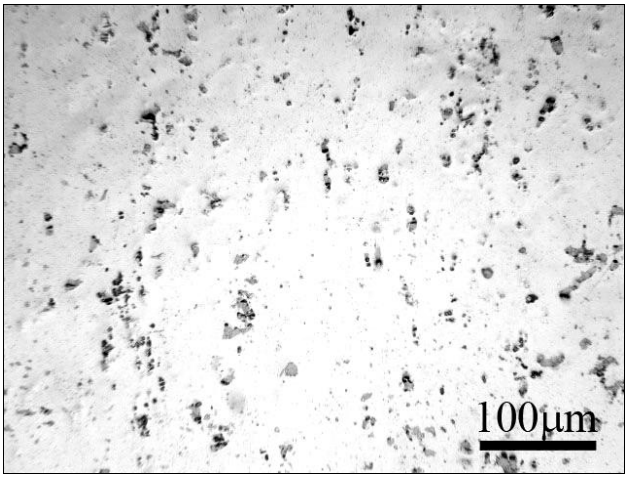
Figure 3. Grain size distribution in alloys with small grain (TMT I): a) AlMg4.5Mn, b) AlMg6Mn.

The grain growth after recrystallization in Al-Mg alloys is not significant, particularly with Mn addition [21, 27].

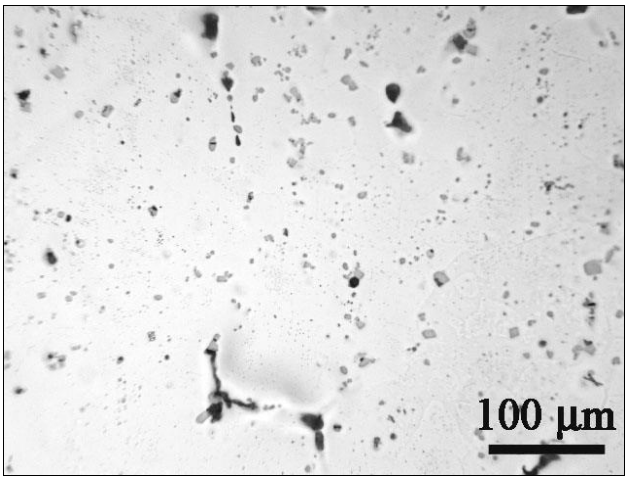
However, it was shown that in studied Al-Mg alloys with Mn addition, the grain growth during static recrystallization did not occur at critical strain (20 % and 25 % for AlMg4.5Mn and AlMg6Mn, respectively) and at 320°C [28]. Even more, the grain growth did not occur at increased temperature up to 500°C [29]. It was supposed that Mn bearing dispersoids (Al_6Mn) at grain boundaries

decreases the grain boundaries mobility during recrystallization and prevent the grain growth [1, 10, 18-19]. In order to alter the size and distribution of the second phase particles, two-stage annealing was applied. At first stage of annealing the fine, soluble second phase particles can be dissolved as much as possible, and then at second stage, during slow cooling rate and by keeping alloy at lower temperature, accelerate the growth of coarser particles [18]. It resulted in a decrease of the dispersoids density, interparticle distance increased, as published earlier for Al-Mg alloys [30]. It allowed the mobility grain boundary and grain growth.

Obviously, size and distribution of the second phase particles played a key role in grain size control and microstructure homogeneity. Increases of the particle size and interparticle space led to grain growth. The differences in size and particle distribution after TMT I and TMT II were observed in both alloys. Figure 4 shows particle distribution in AlMg6Mn alloy.



a)

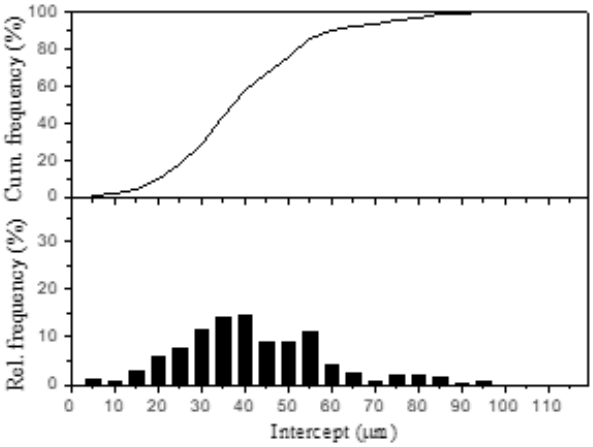


b)

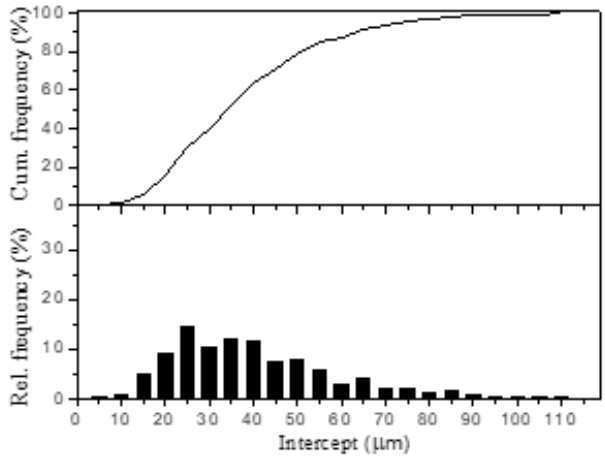
Figure 4. Particle distribution in AlMg6Mn alloy: a) TMT I): b) TMT II.

It was assumed that the inhomogeneous microstructure after recrystallization during TMT II is result of inhomogeneous distribution of the second phase particles and low reduction (e=20-40 %) before final annealing [18, 31]. In such microstructure the average grain size is not convenient for microstructure characterization, so the range of the grain sizes is given (Table 2).

The grain size distribution in both alloys after TMT II is shown in Figure 5.



a)



b)

Figure 5. Grain size distribution in alloys with coarse grained structure (TMT II): a) AlMg4.5Mn; b) AlMg6Mn.

The distribution of the grain size in coarse grain alloys shows the wide range of the grain size. It is supposed that such behavior can be result of inhomogeneous distribution of the second phase particles and small reduction (20 %) before final annealing.

4. CONCLUSION

After TMT which included 50 % CR+320°C/3h AC, homogenous microstructure in AlMg4.5Mn and AlMg6Mn alloys obtained. The distribution of the grain size is unimodal, and the average grain size was 13.3 µm and 13.7 µm in AlMg4.5Mn and AlMg6Mn alloy, respectively.

High temperature two-stage annealing (565°C/6h FC+450°C/4h FC) followed by 20 % reduction and final annealing at 280°C/3h for AlMg4.5Mn and 350°C/3h for AlMg6Mn, resulted in coarser grains in both alloys.

About 75 % of all grains are in the range of 20 µm to 55 µm in AlMg4.5Mn, i.e. 15 µm to 55 µm in AlMg6Mn alloy.

The less homogenous microstructure in coarse grain Al-Mg-Mn alloys is attributed to inhomogeneous distribution of the second phase particles after two-stage annealing and small reduction (20 %) before final annealing.

Abstract: *Highly toxic compounds such as chemical warfare agents (CWAs) are subject to strict international control, and their use is limited to protective and research purposes under national and international legislation, most notably the Chemical Weapons Convention. However, the potential use of these agents by terrorist groups, as well as their accidental release, continues to pose a serious threat to civilian populations. Ongoing efforts are focused on developing new strategies and technologies for the removal, decontamination, and detoxification of CWAs. One promising approach involves the use of metal oxide nanoparticles for the catalytic degradation of CWAs, such as magnesium oxide, titanium dioxide, and zirconium hydroxide being the most extensively studied materials. More recently, cerium dioxide (CeO_2) nanoparticles have demonstrated considerable potential for CWAs degradation, due to their ability to readily switch between +3 and +4 oxidation states. The degradation efficiency of CeO_2 nanoparticles strongly depends on their morphology, aggregation state, and surface area. In this study, we explored several synthetic routes for CeO_2 nanoparticles preparation, including homogeneous hydrolysis, the oxalate route, precipitation with ammonium-carbonate and the solution combustion synthesis. The morphology and structure of the obtained particles were characterized using scanning electron microscopy (SEM), Raman spectroscopy and N_2 adsorption experiments. Their degradation efficiency toward HD was evaluated by gas chromatography–mass spectrometry. In most cases, CeO_2 nanoparticles exhibited highly efficient removal of HD agent.*

Keywords: *cerium-dioxide, nanoparticles, catalytic degradation, chemical warfare agents*

1. INTRODUCTION

Chemical warfare agents (CWAs) belong to a group of exceptionally hazardous toxic chemicals whose production, possession and use are rigorously regulated by national legislation and international agreements, particularly the Chemical Weapons Convention. Although their legitimate handling is restricted to defensive, analytical and research activities, the risk associated with their intentional deployment in armed conflicts or terrorist attacks has not been eliminated. In addition, accidental releases during storage, transport or handling may also result in severe consequences for both human health and the environment. These concerns have stimulated continued research into advanced decontamination approaches, including more effective reactive formulations, improved detoxification technologies and the design of novel materials for individual and collective protection. In this sense, nanotechnologies, particularly the utilization of catalytically active metal-oxide nanoparticles as carriers of active chemistry represent a good starting point for the development of various decontamination formulations and novel protective materials. Stoichiometric nanocrystalline MgO was one of the first oxides proposed for the destruction of CWA [1], followed by other types of nanoparticles, including calcium-oxide (CaO) [2], titanium-dioxide (TiO_2) [3] and zirconium(IV)-hydroxide ($Zr(OH)_4$)[4]. While earth-alkaline oxides and $Zr(OH)_4$ decompose organophosphate agents *via* hydrolytic pathways, TiO_2 degrade organic substances by free-radical mechanism generated with water as an intermediate reagent in decomposition reactions. Here should be emphasized that not all CWAs are equally resistant toward degradation. For instance, G-class organophosphate agents namely soman (3,3-dimethylbutanyl methylphosphonofluoridate, GD) and sarin (2-propanyl methylphosphonofluoridate, GB) easily degrade by changing pH of the environment with the half-time of reaction being only 2 minutes in the pH above 8 and below 4. For detoxification of these agents, only hydrolytic cleavage of P-F bond is needed (Figure 1). On the contrary, some other types of agents are more resistant toward decontamination, and require both oxidative and hydrolytic degradation pathways. These are blister agent, sulfur mustard (1-chloro-2-[(2-chloroethyl)-sulfanyl]-ethane, HD) and VX (S-{2-[di(propan-2-yl)amino]ethyl} O-ethyl methylphosphonothioate). Degradation pathways of these two agents should be strictly controlled since there is a possibility of occurrence of byproducts which retain their toxic properties.

DOI: 10.5937/OTEH26129V

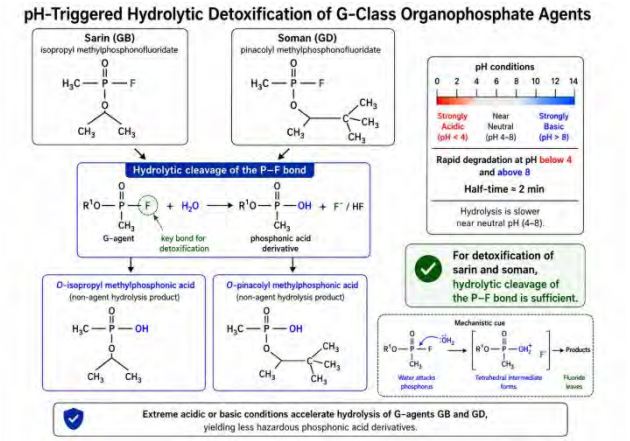

Figure 1. Hydrolytic detoxification of G-agents.

For instance, the partial oxidation pathway of sulfur mustard should be strictly controlled to yield sulfoxide product only, since further oxidation to sulfone gives product with blistering properties (Figure 2) [5].

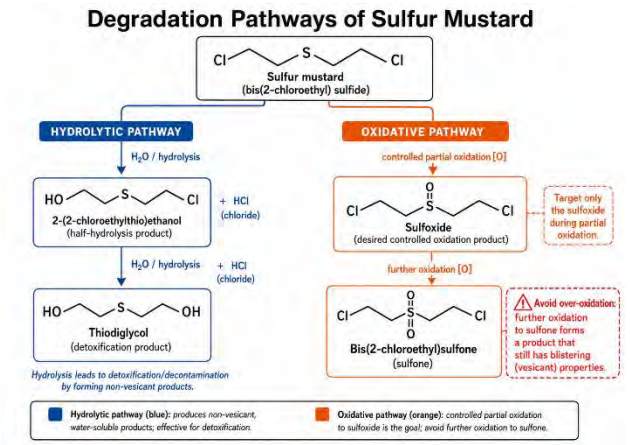

Figure 2. Degradation pathways of sulfur mustard.

The hydrolytic pathways of VX should be also strictly selective in a way that yield product of P-S bond cleavage only. If the P-O bond is cleaved, a very toxic EA2192 product, with potent anticholinesterase activity is obtained [6]. Moreover, further oxidation of diisopropylethylthio moiety is desirable (Figure 3).

Based on all of these stated above, there is a need for efficient decontamination agent which may provide both oxidative and hydrolytic pathways of CWA degradation. In this sense, nanoparticles of cerium-dioxide (CeO_2) seemed as a promising agent due to the several interesting properties. Cerium is the first element of lanthanide series. Its 4f orbitals are shielded by 5p and 4d orbitals, the electronic configuration of Ce+3 ion is $[Xe]4f^1$. By losing 3 electrons to achieve a +3 oxidation state, it gives up the two 6s and one 5d electron leaving only one 4f electron.

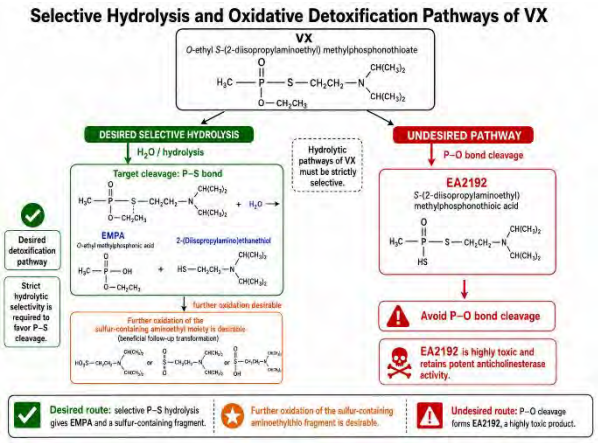

Figure 3. Degradation pathways of VX.

Due to an interesting electronic configuration, Ce exists easily in 3+ and 4+ oxidation states, meaning that $CeO_2 \rightarrow Ce_2O_3$ transition easily takes place, especially if the material is in its nano-form. Therefore, nanoceria has significant capacity to store and release oxygen and repeatedly pass through redox cycles rapidly. Due to these particular properties, CeO_2 nanoparticles are widely used as fuel oxidation catalyst [7], automotive exhaust treatment [8] and also these nanoparticles may exhibit enzyme mimicking activities including superoxide-dismutase, catalase, and phosphatase enzymes [9], [10].

The degradation efficacy of CeO_2 nanoparticles is strongly dependent upon their crystallite size, presence of oxygen vacancies and the presence of crystal lattice defects as well as their morphology. On the other hand, all these properties depend upon the synthetic routes used to obtain CeO_2 nanoparticles. In this study, we examined the influence of the synthetic routes for CeO_2 on their morphology and degradation efficacy using sulfur mustard. The aim of this work was to decipher whether degradation efficacy may be finely tuned by the synthetic routes used to obtain CeO_2 nanoparticles and how their morphology is related to their catalytic activity. For the synthetic routes we have chosen the most employed and the best described in the scientific literature, including: homogenous hydrolysis, precipitation with oxalic acid, precipitation with ammonium-bicarbonate and solution combustion synthesis, using urea as a fuel. Together with commercially available CeO_2 nanoparticles (25 nm in size, Sigma Aldrich) amorphous and the same that is annealed at 500 °C to induce crystallization. This yielded totally six different CeO_2 nanoparticles samples (Table 1).

The morphology and structure of the obtained particles were characterized using scanning electron microscopy (SEM), Raman spectroscopy and N_2 adsorption (BET isotherm analysis). Their degradation efficiency toward HD was evaluated by gas chromatography–mass spectrometry.

Table 1. CeO_2 nanoparticle samples investigated in this work.

Sample code	Synthetic route / origin	Key reagent or treatment	Brief description
CeO_2-1	Homogenous hydrolysis	Urea	CeO_2 nanoparticles obtained by homogeneous hydrolysis
CeO_2-2	Precipitation	Oxalic acid	CeO_2 nanoparticles obtained via oxalate precipitation route
CeO_2-3	Precipitation	Ammonium bicarbonate	CeO_2 nanoparticles obtained by carbonate/bicarbonate precipitation
CeO_2-4	Solution combustion synthesis	Urea as fuel	CeO_2 nanoparticles synthesized by solution combustion route
CeO_2-5	Annealed commercial CeO_2	Annealed at 500°C	Commercial CeO_2 nanoparticles, annealed at 500°C
CeO_2-6	Commercial CeO_2	Sigma-Aldrich, 25 nm	Commercial CeO_2 nanoparticles

2. MATERIALS AND METHODS

All chemicals used in this work were purchased from Merck or Sigma Aldrich and were used without further purification. The HD agent was synthesized at Military Technical Institute, Belgrade and its purity was checked by the GC/MS system, confirming at least 95% of purity.

Caution: *Chemical warfare agents are highly toxic and strictly regulated substances. All CWA-related experiments were conducted solely for the research purposes in an authorized facility by trained personnel, following approved safety, containment, decontamination, and waste-disposal procedures, in compliance with institutional, national, and Chemical Weapons Convention requirements. Unauthorized handling or use of these substances must not be attempted.*

2.1. CeO_2 nanoparticles preparation

Homogenous hydrolysis

The 3 g (6.91 mmol) of $Ce(NO_3)_3x6H_2O$ were placed in the 50 mL beaker and dissolved in 10 mL of hot deionised water with the addition of 1,5 mL of concentrated nitric acid. This solution was transferred into 1L round bottom 2- or 3-necked flask equipped with a magnetic stirrer and a reflux condenser. This solution was diluted with the 400 mL of deionised water, and 50 g of urea was added divided in ten smaller portions with stirring applied. After that, the mixture was heated at 90°C, to induce slow and steady decomposition of urea and consequent increase in pH of the solution, which causes white precipitate of $Ce(OH)_4$ to occur. After cooling the mixture to room temperature, the precipitate was separated by filtration and dried in the atmosphere at 105 °C. The $Ce(OH)_4$ obtained was further calcined at 500 °C for 2 hours to induce dehydration and crystallization of the CeO_2. This sample was designated as CeO_2_1.

Oxalate precipitation

The 8,6 g (19,8 mmol) $Ce(NO_3)_3x6H_2O$ were fully dissolved in 100 mL of deionized water, in 250 mL laboratory beaker that was placed on the magnetic stirrer. The 3 g of oxalic acid (23,88 mmol) was fully dissolved in the minimal amount of deionized water. This solution was transferred into dropping funnel and slowly, during 3h was added drop wise into solution of cerium-nitrate under vigorous stirring. The white precipitate of cerium(III)-oxalate is formed. The stirring of the mixture was continued for additional hour after the addition of oxalic acid. After that, the white precipitate was separated by filtration, and dried in the oven at 105 °C. The cerium-oxalate obtained was further calcined at 500 °C for 2 hours to induce combustion of the organic residue and crystallization of the CeO_2. This sample was designated as CeO_2_2.

Precipitation with ammonium-carbonate

The 8,6 g (19,8 mmol) $Ce(NO_3)_3x6H_2O$ were fully dissolved in 100 mL of deionized water, in 250 mL laboratory beaker that was placed on the magnetic stirrer. The 4,8 g of ammonium-carbonate (50,00 mmol) is fully dissolved in 100 mL of deionized water. This solution was transferred into dropping funnel and slowly, during 3h was added dropwise into the solution of cerium-nitrate under vigorous stirring. The white precipitate of cerium(III)-carbonate is formed. The stirring of the mixture was continued for additional hour after the addition of ammonium-carbonate. After that, the white precipitate was separated by filtration, and dried in the oven at 105 °C. The cerium-carbonate obtained was further calcined at 500 °C for 2 hours to induce combustion of the organic residue and crystallization of the CeO_2. This sample was designated as CeO_2_3.

The solution combustion synthesis

The stoichiometric fuel-to-oxidizer ratio was calculated according to the total oxidizing and reducing valences of the reactants, following the propellant chemistry approach. Considering urea as fuel with a reducing valence of +6 and cerium nitrate as an oxidizer with an effective oxidizing valence of −14 for CeO_2 formation, the stoichiometric molar ratio $Ce(NO_3)_3 \cdot 6H_2O$: urea was 1 : 7/3. Therefore, 4,3 g (9,9 mmol) of $Ce(NO_3)_3x6H_2O$ and 1,39 g (23.1 mmol) were dissolved in 30 mL of deionized water in a 250 mL beaker with vigorous stirring. After the full dissolution of the compounds, the mixture was heated slowly to evaporate a portion of water and to form a viscous gel. When the gel is being formed, the temperature of the heater was increased to 450 °C to induce combustion of the mixture. After combustion, the dry pale yellow CeO_2 is formed in the beaker. The cerium-dioxide obtained was further calcined at 500 °C for 2 hours to induce crystallization. This sample was designated as CeO_2_4.

Two other samples were: commercially available calcined at 500 °C was designated as CeO_2_5, and commercially available, amorphous without any thermal treatment was designated as CeO_2_6.

2.2. Morphological characterisation of the samples

The morphology and the size of the nanoparticles were investigated by scanning electron microscopy using JEOL

JSM-660 LV microscope. The surface of the samples was covered with layer of graphite to assure conductivity. The EDS analysis was done by energy dispersive spectrometer EDS OXFORDX-Max with Aztec software.

The Raman spectra of the samples CeO_2_2 and CeO_2_6 were recorded on Anton Paar Cora 5001 spectrometer. The BET surface areas for the samples CeO_2_3, CeO_2_5 and CeO_2_6 were determined by N_2 adsorption experiments using Anton Paar Nova 600 BET analyser.

2.3. HD degradation experiments

For the HD degradation experiments, the 30 mg of the each CeO_2 sample was placed in each of the eight eppendorf 2 mL microtubes. The solution of the HD of concentration 10 mg/mL was prepared in the *n*-hexane. The 50 μL of the HD solution was pipetted in shortest possible time interval in all test tubes. In the first tube, 950 μL of isopropanol was added immediately to terminate the degradation reaction (that is visibile almost as zero point time on the graph, while it is actually 20-30 seconds). After that, in the time intervals of 10, 20, 30, 40, 50, 60 and 70 min the isopropanol was added in test vials. The extraction of the remaining HD and possible degradation products was done by shaking the tubes for 15 minutes, and then the solid was separated by centrifugation at 12000 rpm. The 10 μL aliquot was drawn from the supernatant and placed in GC-MS vials filled with 980 μL of acetonitrile and 10 μL of the internal standard solution, naphthalene-d_8. The amount of HD was quantified and the resulted chromatogram inspected for the presence of degradation products. Calibration standards and the samples were analyzed on Shimadzu GC-MS QP2020 instrument, and the peak area in the chromatogram and the creation of the calibration curve (peak area vs. concentration) was done using Shimadzu LabSolution software. For the quantification of HD, the characteristic and the most intensive mass ion m/z 109 was used. The experimental conditions for the GC-MS instrument are given in the Table 2.

Table 2. GC-MS conditions

GC Conditions	
Parameter	**Value**
Starting column temperature	40 °C, 3 min
Temperature program	40-150°C, 10°C/min, 150-280 °C, 25°C/min, 280 °C, 10,8 min
Injector temperature	250 °C
Injection type	Grob type. Splitles t 0,75 min
Colum type	DB-5
Column dimensions	30 m x 0,25 mm ID x 0,25 μm
Carrier gas	Helium, 32 cm/sec
MS Conditions	
Parameter	**Value**
Temperature transfer line	280 °C
Temperature ion source	230 °C
Temperature detector	150 °C
Electron energy	70 eV
Mass range	35-500 *m/z*
Scanning rate	3,15 scan/sec
Library	NIST 05 Mass Spectral Data Base

3. RESULTS AND DISCUSSION

3.1. CeO_2 nanoparticles preparation

The all four synthetic procedures were easily reproduced, and the CeO_2 was obtained in relatively high yields. The differences between appearance of the crystallites for the different samples was obvious even with a naked eye. For instance, the samples obtained with precipitation by oxalic acid or ammonium-carbonate, CeO_2_2 and CeO_2_3 were very light and highly voluminous, while the sample obtained by solution combustion synthesis, CeO_2_4 was heavy, firm and appear more aggregated than the rest of the samples.

3.2. Morphology of the CeO_2 nanoparticles

The SEM images of all samples in two different magnifications are given in Figures 4 and 5.

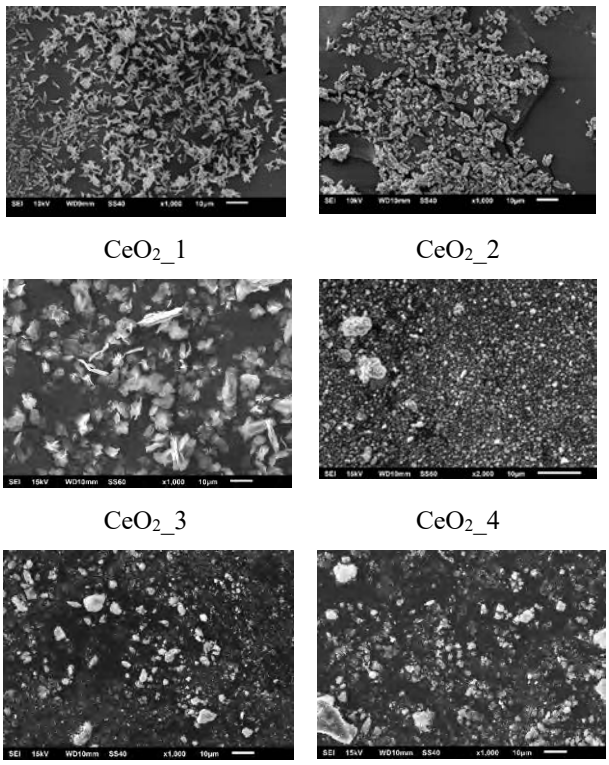

Figure 4. The SEM images of the CeO_2 samples under magnification of 1000x.

SEM analysis revealed pronounced morphology differences among the CeO_2 samples obtained by different synthetic routes. CeO_2_1, prepared by homogeneous hydrolysis, exhibited a highly anisotropic morphology composed of elongated rod-like and flower-like aggregates. CeO_2_2, obtained by oxalate precipitation, consisted mainly of irregularly shaped agglomerates with plate-like subunits. In contrast, CeO_2_3, synthesized by precipitation with ammonium carbonate, showed more open lamellar/flake-like morphology, with thin plate-like structures and exposed edges. CeO_2_4, prepared by solution combustion synthesis, displayed a finely dispersed granular morphology composed of small, quasi-spherical

particles forming porous aggregates. The annealed commercial sample, CeO_2_5, consisted of larger agglomerated particles, most likely due to thermally induced sintering, whereas the amorphous commercial CeO_2_6 showed strongly agglomerated, poorly defined particulate morphology.

The EDS analysis in all samples confirmed the presence of cerium and oxygen atoms only (results not shown).

The Raman spectra of CeO_2_2 sample (crystalline) and CeO_2_6 sample (amorphous) are given in Figure 6.

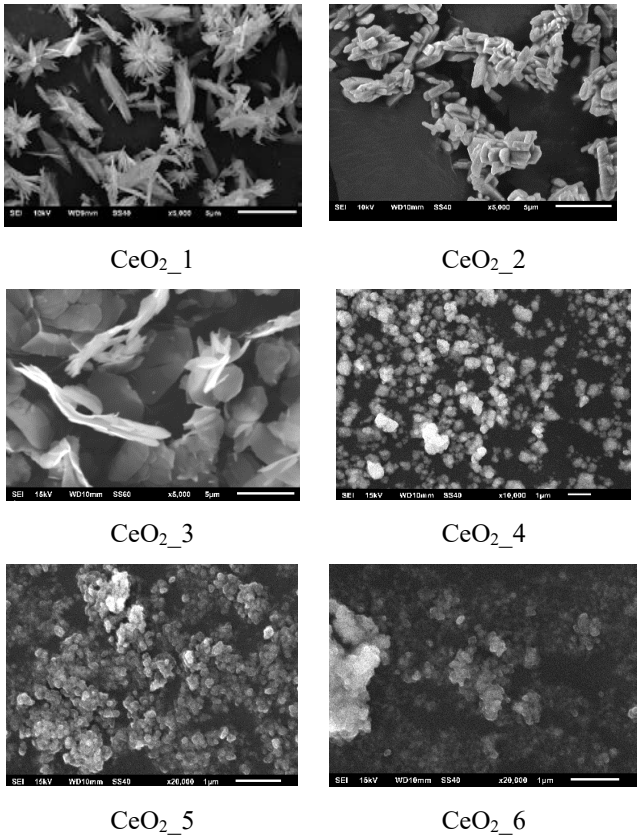

Figure 5. The SEM images of the CeO_2 samples under magnification of 5000x-20000x.

Figure 6. The Raman spectra of CeO_2_2 sample (crystalline) and CeO_2_6 sample (amorphous).

Raman spectroscopy was used to compare the structural ordering of selected CeO_2 samples. The crystalline CeO_2_2 sample exhibited a strong and sharp band at approximately 460–465 cm^{-1}, corresponding to the F2g mode of fluorite-type CeO_2, confirming the formation of a well-crystallized ceria phase. In contrast, the CeO_2_6 sample showed no dominant sharp F2g band, but rather a broadened and more complex spectral profile, indicating the absence of long-range crystalline order and confirming its amorphous or poorly crystalline character.

The pronounced spectral differences between these two samples demonstrate the strong influence of synthetic history and thermal treatment on the structural organization of CeO_2 nanoparticles.

Table 3. The specific surface area of the selected CeO_2 samples

	Sample		
	CeO2_3	**CeO2_5**	**CeO2_6**
Slope	30.8528	71.6628	69.0467
Intercept	0.274273	0.884697	1.12907
Correl. coeff.	0.999949	0.999857	0.999951
C constant	113.489	82.0026	62.1533
Surface area	111.881 m²/g	48.003 m²/g	49.626 m²/g

In the Table 3, the specific surface area obtained by N_2 adsorption isotherms fitted by BET method are given. Nitrogen adsorption measurements revealed pronounced differences in the specific surface area of the selected CeO_2 samples. The highest BET surface area was obtained for CeO_2_3, synthesized by precipitation with ammonium carbonate, reaching 111.9 $m^2\ g^{-1}$. This value is more than two times higher than those measured for CeO_2_5 and CeO_2_6, which exhibited specific surface areas of 48.0 $m^2\ g^{-1}$ and 49.6 $m^2\ g^{-1}$, respectively. The high correlation coefficients of the BET plots confirmed the reliability of the linear fitting in the selected pressure range. The markedly larger surface area of CeO_2_3 is consistent with its open flake-like morphology observed by SEM and may contribute to the higher availability of surface-active sites for HD degradation.

3.3. The HD Degradation experiments

The removal/degradation profiles of HD over the investigated CeO_2 samples are presented in Figure 7. They clearly demonstrate that the catalytic performance strongly depends on the synthetic route. Among all samples, CeO_2_3 showed the highest degradation efficiency, reducing the relative HD concentration to approximately 0.16 after 70 min. A pronounced decrease was already observed during the first 20 min, indicating rapid interaction of HD with the surface-active sites. This superior performance is in good agreement with the SEM observations, where CeO_2_3 exhibited open lamellar/flake-like morphology with exposed edges, and with BET analysis, which showed the highest specific surface area for this sample, 111.9 $m^2\ g^{-1}$. Such morphology and high surface area may provide a larger number of accessible adsorption and reaction sites for HD degradation. CeO_2_4, obtained by solution combustion synthesis, also exhibited relatively high degradation efficiency, reaching a final relative HD concentration of approximately 0.34. Its activity may be associated with the

fine granular morphology and porous agglomerate structure typically formed during combustion synthesis. These features may favor the formation of defect-rich surfaces and facilitate the accessibility of HD molecules to catalytically active sites.

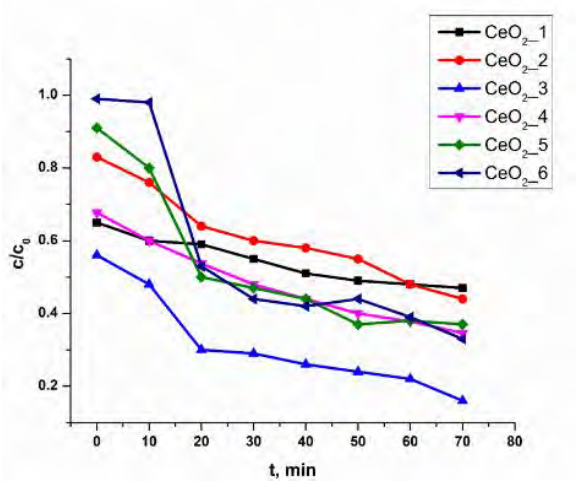

Figure 7. The HD removal over CeO_2 samples

In contrast, CeO_2_1 and CeO_2_2 showed lower degradation efficiency, despite their clearly developed morphologies. This suggests that anisotropic or crystalline morphology alone is not sufficient for high catalytic activity if the accessible surface area and density of reactive surface defects are not optimal. The comparison between CeO_2_2 and CeO_2_6 further indicates that crystallinity alone does not govern HD degradation. Raman spectroscopy confirmed that CeO_2_2 is crystalline, showing the characteristic fluorite CeO_2 band, while CeO_2_6 is amorphous or poorly crystalline. Nevertheless, CeO_2_6 showed considerable HD removal, especially after the first 20 min, despite its lower specific surface area of about 49.6 $m^2\ g^{-1}$ compared with CeO_2_3. This behavior may be related to the higher degree of structural disorder and defect concentration in amorphous CeO_2. However, its strongly agglomerated morphology probably limits the accessibility of these active sites, which may explain why it does not reach the performance of CeO_2_3. In order to obtain full degradation data with the posibility for the kinetic modelling and estimation which part of the HD removal includes adsorption and which is catalytic degradation, additional experiments should be performed with additional time points between 0 and 20 minutes.

4. CONCLUSONS

Overall, the results indicate that HD removal over CeO_2 nanoparticles is controlled by a combination of factors, including specific surface area, morphology, crystallinity, structural disorder, and probably the concentration of oxygen vacancies and Ce^{3+} surface sites. The high activity of CeO_2_3 appears to arise from the favorable combination of high surface area and open flake-like morphology, whereas the activity of CeO_2_4 may be related to its porous, combustion-derived, defect-rich structure. Therefore, the catalytic behavior cannot be explained solely by crystallinity or surface area, but rather by the accessibility and nature of surface-active sites.

Further research will encompass the incorporation of the most effective CeO_2 nanoparticles in the electrospun nanofibers of various polymers, as well as their application onto various substrates intended for CBRN protection, so the further work will consider the possibility of the scale-up of their application and use.

Abstract: *In recent years, an alternative CO CBRN ESC filter has been developed, differing from the standard military filter in the composition of its active bed by incorporating an additional hopcalite layer. Testing of its sorption characteristics revealed that the CO CBRN ESC filter did not achieve the required protection times against certain test gases. To improve the sorption performance, a new CO CBRN filter was developed. Compared with the previous CO CBRN ESC filter, the volumetric ratio of the active bed layers was modified by increasing the proportion of the hopcalite layer. The sorption characteristics of the new CO CBRN filter were evaluated, and the results confirmed the effectiveness of this approach. Significantly longer protection times were achieved for all tested gases compared with those obtained using the previous filter design. Although the increase in hopcalite content resulted in a higher filter mass and consequently reduced some aspects of its functionality, the new filter remains suitable for integration into military protective masks. It can be employed both for military applications and for protection in emergency and accidental hazardous situations.*

Keywords: *CO CBRN filter development, two-component active bed, increased hopcalite layer, sorption characteristics, functional characteristics.*

1. INTRODUCTION

Respiratory protection is a complex and multidisciplinary field that requires a systematic approach to the selection of suitable filters capable of ensuring adequate protection of the respiratory system under various hazardous conditions. The proper choice of a filter is of critical importance in emergency situations, industrial accidents, as well as in potential terrorist incidents involving toxic chemical agents. Current global safety and security challenges have emphasized the need for the development of alternative filter designs with broadened protective capabilities. Such filters should provide effective protection against a wide spectrum of toxic chemicals, while maintaining satisfactory performance characteristics.

In a previous study, TRAYAL Company, in collaboration with Military technical Institute, developed an alternative combined filter designated as CO CBRN ESC. This filter differs in the composition of its active bed compared to the standard military M7 filter and conventional CBRN filters. The active bed of the CO CBRN ESC filter consists of two distinct components: a layer of activated carbon impregnated with calcium chloride and a hopcalite layer, arranged in a volumetric ratio of 2:1 with a standard bed height.[1]

To simulate conditions representative of accidental exposure scenarios, the gas flow rate was varied during experimental testing, while parameters such as relative humidity of the gas mixture and inlet test gas concentration were kept constant throughout the experiments. The results obtained showed that the alternative filter did not meet the required 15-minute protection time at higher gas flow rates, in accordance with the NIOSH (National Institute for Occupational Safety and Health, USA) requirements for escape respirator filters. This was observed for the following test gases: phosgene, hydrogen cyanide, sulfur dioxide, and carbon monoxide. Therefore, the filter cannot be used as an escape-type respirator.

Corresponding author: T. Marković;
E-mail: tanjin.mejl@gmail.com

DOI: 10.5937/OTEH26130M

This raises several key questions regarding the required filter characteristics necessary to ensure extended protection time at a constant gas concentration under varying gas flow rates. In particular, it is important to determine which flow rates provide more realistic information on user protection during different exposure scenarios, such as normal walking or running conditions, as well as what filter mass can be considered acceptable in order to achieve improved protection without significantly compromising functional performance.[2]

Based on the results obtained in the previous study of the CO CBRN ESC filter, it was decided not to introduce major or costly modifications to the design of the new alternative combined filter, designated CO CBRN.[3]

Compared to the previous CO CBRN ESC filter, improvements in the sorption characteristics of the CO CBRN filter were achieved by modifying the volumetric ratio of the active bed layers. The volume of the activated carbon impregnated layer was kept unchanged, while the hopcalite layer was increased to its maximum packing height (approximately corresponding to the CBRN filter standard height). Consequently, the volume of the hopcalite layer in the new CO CBRN filter was doubled compared to that in the previous design.protection time at higher gas flow rates, in accordance with the NIOSH (National Institute for Occupational Safety and Health, USA) requirements for escape respirator filters. This was observed for the following test gases: phosgene, hydrogen cyanide, sulfur dioxide, and carbon monoxide. Therefore, the filter cannot be used as an escape-type respirator.

By increasing the hopcalite layer in the CO CBRN filter, as well as its total mass, an improvement in protection time across a broader range of test gases can be reasonably expected. However, such modifications are also associated with a reduction in certain functional characteristics during use. Despite the reduced operational functionality of the CO CBRN filter, it meets the mass requirement of up to 500 g for full-face masks according to the relevant standard SRPS EN 14387.

The testing of the new CO CBRN filter was conducted under the same defined and controlled experimental conditions as those applied to the previous filter. The experimental protocol included a constant inlet concentration, variation of test gas flow rates, as well as controlled humidity and temperature of the air–test gas mixture, which partially simulates conditions encountered in accidental exposure scenarios.

2. MATERIALS AND METHODS

The activated carbon is produced using TRAYAL Company technology, with a particle size distribution corresponding to the M3 filter and an iodine number not lower than 1250 mg/g. Hopcalite, as the second component, consists of a mixture of copper oxide (CuO) and manganese dioxide (MnO_2) and is defined by its physical and chemical characteristics, while its homologation is carried out within the manufacturing facility.[4]

The alternative CO CBRN combined filters used for sorption testing against selected test gases were filled with the described two-component active bed and manufactured using standard M3 filter production technology. In addition to the modification of the active bed layer (increased hopcalite volume), a modified anti-aerosol insert was introduced to enable more efficient utilization of the available space for the active filling. [5] The sorption performance of the newly developed co cbrn filter with respect to selected test gases was investigated in compliance with the methods specified by standards SORS 8748 and SRPS EN 14387.[6][7]

The testing methods involve monitoring and recording the protection time as an indicator of the sorption characteristics of the filter during exposure to test gases under defined experimental conditions and parameters. These methods include maintaining a constant inlet concentration of test gases and a controlled relative humidity of the gas–air mixture, while varying the flow rate of the inlet gas stream.

3. RESULTS AND DISCUSSION

The developed alternative combined CO CBRN filter contains a two-component active bed consisting of a layer of activated carbon impregnated with calcium salts ($CaCl_2$) and a hopcalite layer, arranged in a volumetric ratio of 1:1. Hopcalite is a mixture of copper and manganese oxides (Cu^{2+} and Mn^{4+}).

The activated carbon used in the filter is produced using a technology developed by TRAYAL Company, while the hopcalite of defined quality is supplied by a long-term external provider. As part of the standard quality control procedure for incoming materials, the hopcalite is tested in accordance with the relevant technical specification, and its physicochemical properties are verified immediately prior to filter filling.

3.1. Results of the Physical and Mechanical Characterization of Both Active Bed Components and the Filter

In order to obtain a clearer understanding of the potential broader application of the CO CBRN filter in different protection domains, as well as the possibility of improving its functional performance, it is necessary to evaluate the physical and mechanical properties of the materials of both active bed layers (activated carbon and hopcalite) prior to filter filling, in accordance with the SORS 8830/05 standard.[8][9] The results of the physical and mechanical characterization of the active bed materials used in the new CO CBRN filter are presented in Table 1.

Table 1. Physical and Mechanical Properties of CO CBRN Active Bed Materials

Physical and Mechanical Properties of Material	Impregnated activated carbon	Hopcalite
Moisture content (%)	1	0,04
Bulk density (g/L)	485	803

Mechanical strength (%)	84	63
Particle size distribution (%)		
>1.8 mm	0.00%	9,71%
1.6-1.8 mm	7,53%	20.19%
1.4-1.6 mm	20,86.%	24.04%
0.7-1.4 mm	71,50%	45.81%
0.5-0.7 mm	0.02%	014%
<0.5 mm	0.09%	0.11%

Considering that both activated carbon and hopcalite are granular materials in structure, and based on the results presented in Table 1, the physical and mechanical properties of the active bed materials of the new CO CBRN filter are comparable to those of the active bed materials used in the CO CBRN ESC filter. Compared to the previous CO CBRN ESC filter, the new CO CBRN filter retains the same volume of the impregnated activated carbon layer, while the volume of the hopcalite layer has been increased.

The decision to increase the proportion of the hopcalite layer in the new filter was based on the inferior protection time performance observed for the CO CBRN ESC filter against certain test gases. In the CO CBRN filter, the hopcalite layer was increased to achieve an approximately equal contribution of both active bed layers, while the total volume of the active bed was adjusted to match the existing filter housing design up to its maximum filling height. After the evaluation of the physical and mechanical properties of the active bed materials and assembly of the new CO CBRN filter, the filter was further tested for total mass, inhalation resistance, and filtration efficiency against paraffin oil mist.

Table 2. Functional Characteristics of the CO CBRN Filter

Filters COCBRN	Mass (g)	Inhalation resistance (Pa) 30 L/min i 95 L/min	Filtration efficiency (%)
Sample 1	385	188/720	$2x10^{-3}$
Sample 2	397	185/764	$1x10^{-3}$
Sample 3	404	190/850	$1.5x10^{-3}$

The results presented in Table 2 indicate the following characteristics of the newly developed combined CO CBRN filter:

• Compared to the previous CO CBRN ESC filter, the first observed change is an increase in the total filter mass of approximately 80 g, primarily due to the increased hopcalite layer. As a consequence, the CO CBRN filter is not suitable for use in half-mask respirators or children's masks.

• The changes in the height and composition of the active bed also lead to a significant change in the inhalation resistance of the filter.

• The obtained values of filtration efficiency against paraffin oil mist remained unchanged, since the anti-aerosol layer was retained from the previous CO CBRN ESC filter design.

The presented results indicate that the newly developed combined CO CBRN filter complies with the requirements of the SRPS EN 14387 standard in terms of total mass (up to 500 g for full-face masks) and inhalation resistance (2P3). Accordingly, further testing of the sorption characteristics of the filter against standard-defined test gases can be continued.

These findings confirm that the alternative active bed configuration can be applied in filter manufacturing, thereby providing a realistic potential for practical implementation, particularly in emergency situations where user response and operational conditions may vary.

3.2. Results of the Sorption Characteristics Testing of the CO CBRN Filter against NBC Test Gases (Phosgene, Chloropicrin, and Hydrogen Cyanide)

The testing of the sorption characteristics of the newly developed combined CO CBRN filter against NBC test gases (phosgene, hydrogen cyanide, and chloropicrin), expressed as protection time (in minutes), was conducted under the following conditions:

• inlet concentration of test gases (phosgene and hydrogen cyanide): 1000 ppm,
• inlet concentration of test gas (chloropicrin): 2200 ppm,
• relative humidity of the air–gas mixture (phosgene, hydrogen cyanide, and chloropicrin): 80%, and
• air–gas mixture flow rates: 30 L/min and 64 L/min.

The inlet concentrations of the test gases, as well as the relative humidity of the incoming air–gas mixture, were kept constant throughout all filter samples tested. In order to simulate conditions closer to accidental exposure scenarios, the sorption characteristics were evaluated at different gas flow rates of 30 L/min and 64 L/min.

The obtained results of the sorption performance of the CO CBRN filter against NBC test gases (phosgene, hydrogen cyanide, and chloropicrin), expressed as protection time (in minutes), are presented in Table 3 (relative humidity of the gas–air mixture: 80%).

Table 2. Functional Characteristics of the CO CBRN Filter

Test -gas	Inlet concentration of the gas mixture (ppm)	Protection time (min) 30 L/min	Protection time 64 L/min
Phosgene	1000	45 46 48	18 19 20
Chloropicrin	2200	38 38 39	29 29 30
Hydrogen cyanide	1000	>50 >53 >55	25 27 26

By comparing the protection times of the CO CBRN filter against the three test gases with those obtained for the previous CO CBRN ESC filter, it can be observed that the

increase in the hopcalite layer (by nearly twofold) leads to a significant improvement in the protection time of the CO CBRN filter, in some cases even resulting in a doubling of performance, particularly for phosgene and hydrogen cyanide.

For both the CO CBRN filter and the previous CO CBRN ESC filter, Figures 1 and 2 illustrate the difference in protection times against phosgene at different flow rates (30 L/min and 60 L/min).

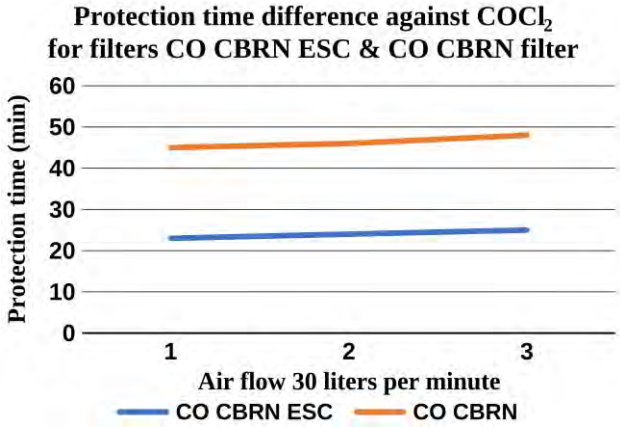

Figure 1. Difference in time protection against phosgene on air flow 30 L/min

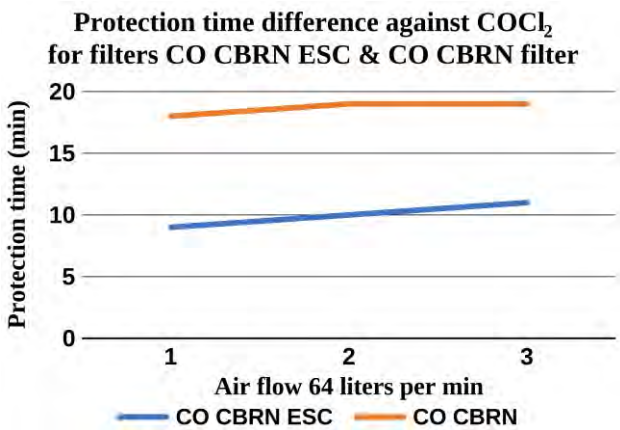

Figure 2. Difference in protection time against phosgene under an air flow rate of 64 L/min

3.3. Results of the Sorption Performance Evaluation of the CO CBRN Filter against Industrial Toxic Gases (Sulfur Dioxide, Cyclohexane, Ammonia, and Carbon Monoxide)

The sorption characteristics of the combined CO CBRN filter against industrial toxic gases (sulfur dioxide SO_2, cyclohexane C_6H_{12}, and ammonia NH_3), expressed in terms of protection time, were evaluated under the following test conditions:

- Inlet concentration of the test gases: 1000 ppm
- Relative humidity of the air-gas mixture: 70% (until breakthrough)
- Flow rate of the air–gas mixture: 30 L/min and 64 L/min

The sorption characteristics of the combined CO CBRN filter against industrial toxic gas carbon monoxide CO expressed in terms of protection time, were evaluated under the following test conditions:

- Inlet concentration of the test gas: 2500 ppm
- Relative humidity of the air-gas mixture: 80% (until breakthrough at 200 ppm and temperature 50 °C)
- Flow rate of the air–gas mixture: 30 L/min and 45 L/min

Due to the limitations of the test apparatus used for evaluating the sorption characteristics of the filter against carbon monoxide, a flow rate of 64 L/min could not be achieved. The system operates using an artificial lung at 20 cycles per minute and 1.5 L per cycle, while the maximum achievable setting is 30 cycles per minute, corresponding to 45 L/min. The obtained results of the sorption performance of the CO CBRN filter against industrial test gases, expressed as protection time, are presented in Table 4.

Comparison of the protection times of the CO CBRN filter against the four industrial test gases with those obtained for the previous CO CBRN ESC filter shows that the increase in the hopcalite layer leads to a significant improvement in protection performance, particularly for sulfur dioxide and carbon monoxide.

For both the new CO CBRN filter and the previous CO CBRN ESC filter, Figures 1 and 2 illustrate the difference in protection times against sulfur dioxide at different flow rates (30 L/min and 60 L/min). The observed difference in protection time for sulfur dioxide is approximately four times greater at the lower flow rate of 30 L/min, while at the higher flow rate the difference is less pronounced.

Table 4. Sorption Characteristics of the CO CBRN Filter against Industrial Test Gases

Test-gas	Relative humidity of the air-gas mixture (%)	Inlet concentration of the test gas (ppm)	Protection time (min) 30 L/min	Protection time (min) 64/ 45* l/min
SO_2	70	1000	126 128 126	25 26 26
NH_3	70	1000	95 100 97	48 50 46
C_6H_{12}	70	1000	78 75 85	34.3 29.1 33
CO	80	2500	50 54 48	60 59 59

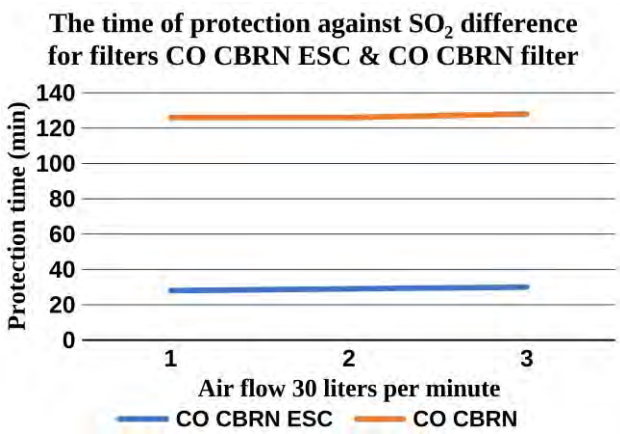

Figure 3. Difference in time protection against SO_2 on air flow 30 L/min

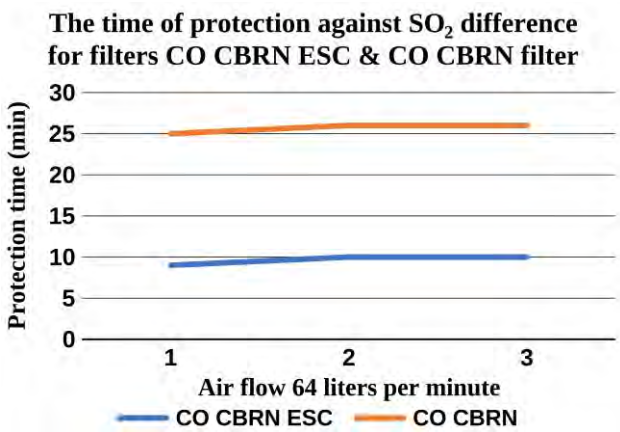

Figure 4. Difference in protection time against SO_2 under an air flow rate of 64 L/min

Given that the tests have shown that, in accordance with the American standard for escape respirator filters, the CO CBRN filter achieves the required 15-minute protection time at higher gas flow rates and under the specified inlet concentrations, it can be concluded that the filter, when integrated into a full-face respirator, has potential applications both in accidental scenarios and fire-related emergencies, as well as in military use.

Preliminary tests of the protection time of the CO CBRN filter against the above-mentioned test gases were also conducted under conditions of increased inlet gas mixture concentrations (5000 ppm) and a lower flow rate of 30 L/min. The obtained results are presented in Table 5. The protection time results indicate the potential applicability of the CO CBRN filter in environments where toxic gas concentrations are significantly higher than the initially defined test conditions (1000 ppm and 2500 ppm).

Table 5. Sorption Characteristics of the CO CBRN Filter against Industrial Test Gases at 5000 ppm

Test gas	Relative humidity [%]	Protection time [min] 30 L/min
SO_2	70	29 28
NH_3	70	26 22
C_6H_{12}	70	38 39
CO/	80	30 32

4. CONCLUSION

In a previous study, the results of the sorption characteristics testing of the CO CBRN ESC filter showed that it did not meet the required 15-minute protection time at higher gas flow rates for the following test gases: phosgene, hydrogen cyanide, sulfur dioxide, and carbon monoxide. Consequently, the filter cannot be used as part of a military respirator for emergency situations in which fire-related hazards may also occur.

In order to improve the protection time of the filter against the above-mentioned test gases, a new CO CBRN filter was developed. Compared to the previous CO CBRN ESC filter, the ratio of the active bed layers was modified in favor of the hopcalite layer, with the bed height adjusted to the maximum filling height corresponding to a standard CBRN filter design. The sorption characteristics of the CO CBRN filter were evaluated against NBC agents and toxic industrial gases under the same experimental conditions as those applied for the CO CBRN ESC filter.

In addition, the obtained results for the CO CBRN filter suggest that, due to the basic nature of hopcalite, an increase in protection time can also be expected for other acidic test gases such as chlorine (Cl_2) and hydrogen sulfide (H_2S).
The increased capacity and bed height of the new CO CBRN filter, resulting from the higher hopcalite content, also indicate the potential for adequate protection under exposure to higher gas concentrations (up to 5000 ppm).

However, the increase in the hopcalite layer in the CO CBRN filter also leads to an increase in its total mass, which results in reduced functional performance during use. Despite this limitation, the filter can still be used as an integral component of full-face respirators for both military applications and emergency situations in peacetime. Due to the increased total mass, the CO CBRN filter is not suitable for use in half-mask respirators, children's masks, or evacuation hoods.

Abstract: *This study examines the influence of Laser Powder Bed Fusion (LPBF) process parameters on the quality of AlSi10Mg alloy parts. Two sets of samples were fabricated using different combinations of laser power, scan speed, and hatch spacing, resulting in distinct energy densities. Visual examination revealed that lower energy density resulted in rough surfaces and delamination, indicating insufficient interlayer bonding. Chemical analysis confirmed that all samples met EN AC-Al10SiMg compositional requirements, while hardness measurements showed no significant variation between parameter sets or build orientations. Microstructural observations identified typical LPBF features, including fine cellular Al–Si eutectic and coarse dendritic like grains, with pores more frequent in low-energy samples. The results demonstrate that LPBF process parameters strongly affect surface morphology while having negligible impact on bulk hardness. Optimizing energy density is essential for achieving improved microstructural uniformity and overall part quality in AlSi10Mg components.*

Keywords: *LPBF, Al10SiMg, Process parameters*

1. INTRODUCTION

Additive Manufacturing (AM) enables the production of complex geometries directly from a digital model, without the need for traditional tools or molds. Among various AM techniques, Laser Powder Bed Fusion (LPBF) is most adopted method for manufacturing metal components. The LPBF process uses a high energy laser beam to selectively melt a layer of metal powder, forming parts layer by layer [1, 2] under extremely high cooling rates on the order of $10^6 - 10^8\ ^\circ C/s$. Such thermal conditions lead to the formation of a unique microstructure, characteristic of LPBF process, which differs significantly from the microstructures of alloys produced by conventional processes such as casting, rolling or forging [3]. Wide range of metal powders for use in LPBF process is developed such as 316L steel, maraging steel, titanium, nickel, aluminum alloys and others. Al alloys offer good compromise between strength and density, in addition to being inexpensive. Most common Al alloy used in LPBF is Al10SiMg, a hypoeutectic aluminum alloy containing approximately 10% Si with an addition of Mg. This alloy is recognized as highly suitable for AM due to its excellent processability, low density, good corrosion resistance, and favorable mechanical properties. Compared with other metal powders, aluminum alloys still present challenge in the LPBF process due to high reflectivity, high thermal conductivity and low melt viscosity [1, 2, 4]. In the LPBF process, AlSi10Mg forms a fine cellular Al–Si eutectic, with a silicon network distributed around primary aluminum cells, resulting in increased strength and hardness compared to cast alloy states. However, this microstructure simultaneously leads to reduced ductility and increased sensitivity to residual stresses [4]. Components produced from AlSi10Mg are widely used in automotive engineering, aerospace structures, robotics, energy systems, and lightweight mechanical assemblies, where the combination of low weight and high strength is essential [5]. Despite these advantages, the final quality of

DOI: 10.5937/OTEH26131C

LPBF-fabricated AlSi10Mg parts is sensitive to process parameters, which govern melt pool behavior, microstructural evolution, defect formation, and mechanical properties. Key LPBF parameters include laser power, scan speed, hatch spacing, layer thickness, preheating temperature, and scanning strategy. Together, these parameters determine the volumetric energy density delivered to the powder bed, influencing melt pool stability, track geometry, layer bonding, and porosity formation. Insufficient energy input typically leads to lack-of-fusion, while excessive energy can cause keyhole porosity, evaporation of alloying elements, and microstructural inhomogeneity [6]. Hatch spacing affects the overlap between adjacent melt tracks, while scanning strategy influences residual stress distribution and grain texture. Therefore, optimizing process parameters is essential for achieving high density, uniform microstructure, and reliable mechanical properties. In addition to process parameters, the quality of AlSi10Mg powder plays a crucial role. Powder used for LPBF must exhibit spherical morphology, narrow particle size distribution, low oxide content, and good flowability, as deviations can lead to segregation, non-uniform layer deposition, and increased porosity [7]. Recycled powder, although economically attractive, often shows increased oxygen content and altered particle size distribution, which may degrade the mechanical properties of printed parts [8]. Considering all the above, LPBF process parameters have a decisive influence on the quality of AlSi10Mg parts, including their density, microstructure, mechanical properties, defect formation, and long-term reliability. Understanding the interdependence of these parameters is fundamental for process optimization and improving the characteristics of final components.

2. EXPERIMENTAL PROCEDURE

2.1 Material and LPBF process

To produce additively manufactured samples, Eplus 3D EP-M450 machine was used. Two sets of samples made of Al10SiMg powder were produced with a different set of process parameters, (Table 1). The laser energy density (E) related to the LPBF process is calculated according to formula [1]:

$$E = \frac{P}{V \cdot H \cdot L_T} \qquad (1)$$

where P is laser power, V is the laser scan speed, H represents hatch distance and L_T is layer thickness. For both sets of sample's, layer thickness was held constant, while other parameters were changed, which gave energy density of 39.3 J/mm^3 for set I, and 50.3 J/mm^3 for set II parameters. For set I, nine identical cubes with dimensions (10x10x10) mm were produced (marked 1-9), and for set II, five identical cubes with dimensions (15x15x10) mm were produced (marked A-E). The morphology and particle size distribution of used powder is shown in Figure 1. Most of the observed powder particles are spherical, and the rest shows ellipsoidal or uneven shape. Particle size ranges from 3 µm to 70 µm, with mean size of 20.2 µm. 10 % of particles have size to 3,6 µm, 50 % of particles have size up to 20,3 µm while 90 % of particles are up to 38,9 µm. Mean value of particle circularity is 0,97. A JEOL JSM-6610LV scanning electron microscope was used to observe the morphology of used powder, while size and circularity were determined on Anton Paar Litesizer DIA 500 instrument

Table 1. Used process parameters

2.2 Characterization

Visual examination of the manufactured parts was performed after the samples were removed from the build plate, by naked eye and by Leica stereo microscope equipped with DFC 245 camera.

To determine if change in process parameters affected elements evaporation from the powder during melting, chemical composition of the produced samples was analyzed by Optical Energy Spectrometer (OES) Belec Compact Port.

Hardnes was determined by Brinell method (HB 2.5/62.5), according to SRPS EN ISO 6506 standard. Measurements were performed on XY plane (plane parallel to the build plate), and on XZ/YZ plane (plane parallel to the build direction).

For microstructure analysis samples were wet grounded on SiC paper, polished using diamond suspension and etched using Keller A reagent (1 ml HF, 1.5 ml HCL, 2.5 ml HNO_3 and 95 ml H_2O) for 8 s. Samples were observed in polished and etched state on Leitz Metaloplane optical microscope in bright field. Microstructure was analyzed in XY and XZ/YZ plane.

3. RESULTS

3.1. Visual examination

The surface morphology of produced samples is shown on Figure 2 for set I parameters and on Figure 3 for set II parameters. The surface of the samples produced using the parameter set I was visibly rougher than the surface of samples made with parameter set II. Observation under stereo microscope showed that the surface of parameter set I specimens was less uniform, with presence of coarse spherical particles (marked with red arrows) and fine powder particles (marked with yellow arrows), Figure 2a. Additionally, delamination of layers was observed on samples 7, 8, and 9, figure 2b-d.

Samples produced with Set II parameters showed smoother and more uniform surfaces. Although fine powder particles (marked with yellow arrows) were still present, Figure 3, no delamination was observed.

3.2 Chemical composition

The chemical composition of produced samples is given in Table 2.

Table 2. Chemical composition of produced samples, mass. %

Element	Set I parameter samples	Set II parameter samples	EN AC-Al10SiMg according to SRPS EN 1706
Si	10.40	10.81	9.0-11.0
Fe	0.21	0.24	max. 0.55
Cu	<0.001	0.002	max. 0.05
Mn	0.008	0.007	max. 0.45
Mg	0.33	0.34	0.20-0.45
Ni	0.03	0.03	max. 0.05
Zn	<0,001	0.01	max. 0.10
Al	Balance	Balance	Balance

Chemical composition of samples from both sets of parameters is in accordance with standard SRPS EN 1706 for aluminum alloy EN AC Al10SiMg. No significant difference in chemical composition between samples from both sets of parameters is observed.

3.3 Hardness measurements

Results of hardness measurements are shown in table 3.

Table 3. Obtained hardness values, HB

	Measurement plane	Hardness, HB	Mean value
Set I	XY	129; 131; 129; 129; 131	130
	XZ/YZ	128; 128; 126; 128, 125	127
Set II	XY	130; 129; 130; 129; 133	130
	XZ/YZ	119; 119; 120; 119	119

3.4 Microstructure

Figure 4 shows typical microstructure of specimens produced using set I parameters in as polished and etched state. Metallurgical defects such as gas pores (marked with black arrows) and lack of fusion (marked with blue arrows) were observed. Apart from the defects, clear melt pool boundaries were also observed in as polished state as well as after etching. On Figure 5 is shown microstructure of samples produced with set II parameters. Microstructure of set II samples also contained metallurgical defects such as pores and lack of fusion. Sporadically, coarse pores were observed. Size of coarse pores is approximately 100 µm in diameter. Comparing set I and set II samples, pores are more frequent in set I samples. Under higher magnification, difference in microstructure between center and edge of melt pool
At the edges microstructure is coarser, while moving away from edges, microstructure changes and becomes

finer (Figure 4b and d, Figure 5b and d) On XY plane microstructure is cell like, while on XZ/YZ plane microstructure is dendrite like (Figure 4f and h, Figure 5f and h).

4. DISCUSSION

Visual examination revealed clear differences in surface quality between samples produced with parameter Set I and Set II. Samples produced using Set I parameters exhibited rougher surface, with presence of coarse spherical particles as well as fine powder particles. Additionally, delamination of layers was observed on samples produced using set I parameters suggesting inadequate interlayer bonding and lack-of-fusion defects. Formation of coarse spherical particles and delamination of layers can be attributed to balling effect. High reflectivity and thermal conductivity of Al can lead to formation of molten droplets on the powder bed surface. After solidification, these droplets form spherical particles which are known as balling phenomena [9]. The balling effect leads to uneven scan tracks and weak bonding between layers leading to porosity and delamination. Lack of balling defects and delamination of layers in set II parameter samples is attributed to higher energy density which provides enough molten material to reduce the occurrence of balling effect [9].

During LPBF process, high energy laser selectively melts metal powder which solidifies instantly as laser moves. This rapid solidification creates unique microstructure characterized by Al matrix and cellular network of Al-Si eutecticum. During solidification, high cooling rates lead to supersaturation of melt pool with silicon. As a result, microstructure exhibits fine Al-Si eutecticum. On Figure 4 and 5, two types of microstructures were observed: coarse and fine cell like and dendrite like. Coarse dendrite like structure grains, during cooling, nucleate and grow at the interface between previously solidified layer and melted phase of new layer. Subsequently, dendrites grow in the direction of heat flux [5, 10].

Figure 5. Microstructure of samples produced with Set II parameters; a-d) as polished, e-h) etched.

Chemical analysis performed using OES showed that both sets of samples had chemical compositions within the limits specified for EN AC-Al10SiMg alloy. No significant differences were observed between Set I and Set II samples.

Since samples from both sets of parameters were manufactured using powder from the same batch, the absence of compositional deviations confirms that differences in microstructure and defects are attributed to process parameters rather than metal powder variability.

Hardness values measured on XY and XZ/YZ planes showed no significant differences between the two sets of parameters. Set I samples exhibited mean hardness values of 130 HB (XY) and 127 HB (XZ/YZ), while Set II samples showed 130 HB (XY) and 119 HB (XZ/YZ). The results indicate that the difference in LPBF process parameters did not significantly affect bulk hardness. This is expected for AlSi10Mg alloy, where hardness is primarily governed by the fine cellular Al–Si eutectic formed under rapid LPBF cooling conditions. Since both sets of parameters resulted in fine eutectic structure, hardness remained unchanged [10].

5. CONCLUSION

This study investigates the influence of Laser Powder Bed Fusion (LPBF) process parameters on the quality of AlSi10Mg alloy samples. Two sets of samples were produced using different combinations of laser power, scan speed, hatch spacing resulting in two energy densities, 39.3 J/mm^3 for set I, and 50.3 J/mm^3 for set II parameters.

Samples manufactured with lower energy density (Set I) exhibited rougher surfaces, unmelted powder particles, and delamination between layers, indicating insufficient interlayer bonding and lack-of-fusion defects. Samples produced with higher energy density (Set II) showed smoother surfaces and no delamination. Microstructural analysis revealed typical LPBF features in both sets, including fine cellular Al–Si eutectic and coarse dendrite like grains at melt pool boundaries, with pores and lack-of-fusion defects present in all samples but more frequently in Set I samples.

Hardness measurements showed no significant differences between parameter sets or measurement planes. Overall, the results demonstrate that LPBF process parameters strongly affect surface morphology and defect formation, while having negligible influence on bulk hardness. Optimizing energy density is therefore essential for achieving uniform microstructure, adequate layer bonding, and improved part quality in AlSi10Mg components.

Abstract: *This study investigates the development and characterization of thermal insulation composite liners (L) based on hydroxyl-terminated polybutadiene reinforced with carbon fibers of different lengths and modified with silicon dioxide nanoparticles (nano-SiO_2). The aim of this study was to examine the influence of nano-SiO_2 contents on the physicochemical and mechanical properties of the liners. The prepared composite liners were characterized by Fourier transform infrared (FTIR) spectroscopy, physicochemical analyses, and uniaxial tensile testing. The obtained results showed that the addition of nano-SiO_2 affects the dynamic viscosity of uncured composite liners, density and mechanical properties of the cured composite liners, indicating the importance of proper nano-filler dispersion and compatibility with the polymer matrix. This study provides a foundation for further optimization of liner formulations intended for rocket motor thermal protection systems. The results suggest that improved dispersion of nano-SiO_2 could further enhance the overall properties of the composites.*

Keywords: *composite liner, nano-SiO_2, dispersion, physical and mechanical properties*

1. INTRODUCTION

Thermal protection and structural integrity of solid rocket motors are highly dependent on the materials located between the propellant grain and the motor case. In composite solid rocket motors the propellant is bonded to the motor case through an elastomeric interfacial layer known as a liner. Positioned between the propellant and the motor case wall, the liner provides adhesion, transfers mechanical stresses and contributes to the overall integrity of the motor system [1].

Reliable bonding between the liner, propellant and motor case is essential for the proper operation of a solid rocket motor [2]. The liner acts as a structural interface responsible for stress transfer to the load-bearing components and prevents propellant grain movement. Loss of adhesion may lead to void formation, pressure fluctuations, unstable combustion, motor failure or explosion [3].

Therefore, the liner formulation must be chemically compatible with the propellant constituents while also being capable of establishing a stable chemical bond with them. To ensure such compatibility, the liner binder is typically based on the same polymeric system used as the binder in the propellant formulation [1]. In this study hydroxyl-terminated polybutadiene (HTPB) was used as the polymer matrix. HTPB is one of the most widely used binders in composite solid rocket propellants due to its favorable mechanical, thermal and chemical properties. It is characterized by a low glass transition temperature, pronounced hydrophobicity and a high concentration of terminal hydroxyl groups, which enable effective crosslinking with isocyanate curing agents forming a cross-linked polyurethane network.

Fibrous reinforcements, such as short Kevlar or carbon fibers, and flame retardants or intumescent additives, such as melamine or ammonium polyphosphate, improve the thermal properties of HTPB-based composite liners by forming a thermally protective char layer.

Moreover, liner composite formulations filled with micron-sized particles generally exhibit limited mechanical and functional properties. The development of nanocomposites, based on ultrafine fillers in the nanometer scale, enables significant improvements in mechanical, thermal and dynamic-mechanical performance compared to microfilled systems. The properties of these materials depend on the degree of cross-linking of the polymer matrix, the functional group

Corresponding author: S. Pepić
E-mail: spepic00@gmail.com
DOI: 10.5937/OTEH26132P

ratio (NCO/OH) and the type and content of fillers. Increased cross-linking density leads to higher stiffness and elastic modulus, while reducing elongation at break and swelling capacity. Therefore, functional fillers are used to optimize performance by simultaneously enhancing mechanical and barrier properties.

In this context, silicon dioxide nanoparticles (nano-SiO_2) is recognized as an effective filler due to its high specific surface area and excellent thermal stability. It contributes to improved mechanical properties and reduced migration of low-molecular-weight components [4]. However, its pronounced hydrophilicity may lead to particle agglomeration, making controlled dispersion within the polymer matrix essential [5].

The aim of this study was to investigate the effect of different nano-SiO_2 contents on the physicochemical and mechanical properties of HTPB-based thermal insulation liners containing carbon fiber reinforcement and flame-retardant additives for solid rocket motor applications. A four liner formulations containing various amounts of nano-SiO_2 were prepared and characterized. The influence of nano-SiO_2 concentration on thermal insulation liner performance was evaluated in order to identify the optimal filler content and to improve the overall material properties.

2. MATERIALS AND METHODS

2.1. Materials

For the preparation of thermally insulating liner formulations, several components were used. Hydroxy-terminated polybutadiene (HTPB) (average molecular weight, Mn: 2900 g·mol^{-1} and hydroxyl functionality: 2.4, glass transition temperature, T_g: -80 ºC) supplied by Evonik, Germany, was used as the polymer binder. Carbon fibers of different geometries were used as reinforcing fillers, including milled carbon fibers (0.2 mm) and chopped carbon fibers (3 mm), purchased from R&G Faserverbundwerkstoffe GmbH, Waldenbuch, Germany (Figure 1) and carbon nanofibers (CNFs) (purity ≥ 99.9%, 1-15 µm). Additional carbon fillers were used to improve the thermal stability and mechanical performance of the liner systems.

Ammonium polyphosphate (APP) and melamine (purity ≥ 99.8%) both procured by Thermo Scientific Chemicals, Germany, were incorporated as additives to enhance the thermal resistance and flame-retardant properties of the formulations.

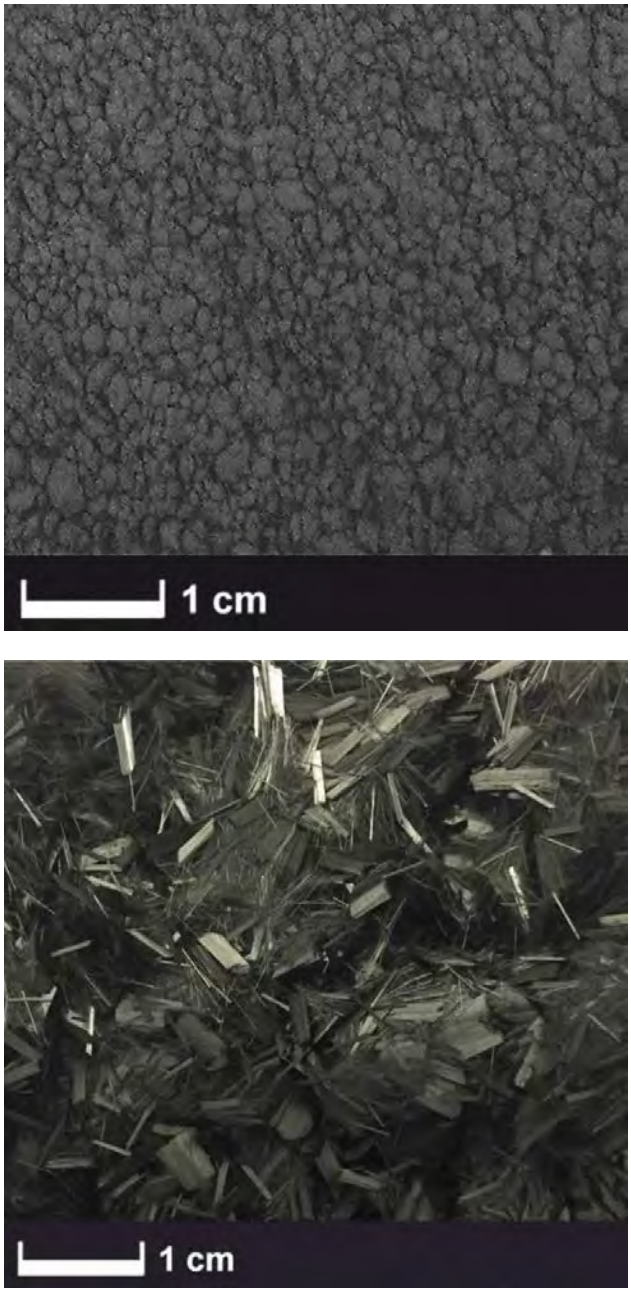

Figure 1. a) Milled carbon fiber 0.2 mm b) Chopped carbon fiber strands 3 mm (retaken from the R&G Faserverbundwerkstoffe GmbH)

Castor oil (*Ricinus communis seed oil,* functionality: 3, average molecular weight, Mn: 933 g·mol^{-1}) was used as a reactive plasticizer. The NCO/OH ratio in the formulations was adjusted to 0.33 to control the crosslinking density. The antioxidant AO 2246 (2,2'-bis(4-methyl-6-tertbutyl) phenol) supplied by Sigma Aldrich, Germany, was used to prevent oxidative degradation of the polymer matrix. Isophorone diisocyanate (IPDI) supplied by Evonik, Germany, while dibutyltin dilaurate (DBTDL) was used as a catalyst for the curing reaction. Nano-SiO_2 (purity ≥ 99.5%, particle size in the range of 20-30 mm), purchased by Speed UP (US Research), was used as a nano-filler to improve mechanical reinforcement and thermal stability of the liner systems.

2.2. Homogenization of the liners

Mixing and homogenization of the components (Table 1.) were carried out in a laboratory DRAIS mixer (1.5 L capacity) at room temperature and a stirring speed of 40 rpm. In the first stage, HTPB, RU and DBTDL were added into the mixing vessel. Subsequently, AO2246, APP, melamine, chopped and milled carbon fibers and nano-SiO_2 were gradually added in small portions under continuous mixing. Finally, the IPDI curing agent was added into the mixture and homogenization was continued at room temperature for an additional 15 minutes to ensure a uniform dispersion of all components. The liquid mixture was then cast into a PTFE mold (200 mm × 200 mm × 3 mm) and cured in an oven for four days at 60 ºC.

Table 1. Composition of liners

Component	Mass content (wt. %) of liner formulations			
	L1	**L2**	**L3**	**L4**
HTPB	36.57	36.77	36.89	36.97
Castor oil	5.85	5.88	5.90	5.91
AO 2246	0.18	0.18	0.18	0.18
Melamine	25.00	25.00	25.00	25.00
APP	25.00	25.00	25.00	25.00
CNFs	0.50	0.50	0.50	0.50
Carbon fibers; 0.2 mm	2.40	2.40	2.40	2.40
Carbon fibers; 3.0 mm	0.50	0.50	0.50	0.50
Nano-SiO_2	**0.50**	**0.25**	**0.10**	**-/-**
DBTDL	0.06	0.06	0.06	0.06
IPDI	3.44	3.45	3.47	3.47

2.3. Characterization of Materials

The remaining amount of the uncured liner was used for the determination of dynamic viscosity using Brookfield HBT viscometer at 25 ºC. Measurements were performed during the first 75 minutes after completion of the mixing procedure and incorporation of all components.

The Fourier transform infrared spectroscopy (FT-IR) spectrum of the cured liners was recorded in absorbance mode using a Nicolet™ iS™ 10 FT-IR spectrometer (Thermo Fisher Scientific, Waltham, MA, USA), within a range of 400-4000 cm^{-1} at a resolution of 4 cm^{-1}.

The density of the cured liner formulations was determined using a KERN YDB-03 analytical balance (Version 1.4; 2021-003) at 23 ºC.

For the evaluation of mechanical properties, test specimens were prepared with dimensions of 115 x 25 x (3 ±1) mm and a gauge length of 46.5 mm. Mechanical testing was performed on an Instron 1122 Universal Testing Instrument (Instron, Nortwood, MA, USA) at 20 ºC with a loading rate of 50 $mm \cdot min^{-1}$.

The following mechanical properties were determined:

- tensile strength (σ_m),
- elongation at maximum force (ε_m), and
- elongation at break (ε_p)

3. RESULTS AND DISCUSSION

3.1. FTIR Analysis

FTIR analysis was used to evaluate the chemical structure of the prepared liner formulations and to confirm the formation of the polyurethane network during the curing process. The FTIR spectra of samples L1 – L4 are shown in Figure 2. The absorption bands at 3463 and 3516 cm^{-1} are assigned to N-H stretching vibrations characteristic of polyurethane structures, while the weak band at 3322 cm^{-1} indicates the presence of residual hydroxyl groups that did not fully react during network formation. The absorption bands at 2916 and 2845 cm^{-1} correspond to aliphatic (-CH_2-) stretching vibrations of the HTPB backbone. The characteristic band at 1706 cm^{-1} corresponds to the stretching vibration of the urethane carbonyl group (C=O), confirming the formation of the polyurethane structure. The band at 1640 cm^{-1} is assigned to C=C stretching vibrations of residual unsaturated bonds within the polybutadiene chains.

Bands at 1516 and 1435 cm^{-1} are attributed to N-H bending and C-H bending vibrations, respectively, while the peak at 1238 cm^{-1} corresponds to C-N stretching vibrations within the urethane structure. In the lower wavenumber region, absorption bands at 964 cm^{-1} and 910 cm^{-1} confirm the presence of Si-O-Si and Si-O vibrations, confirming the presence of nano-SiO_2 particles within the polyurethane matrix.

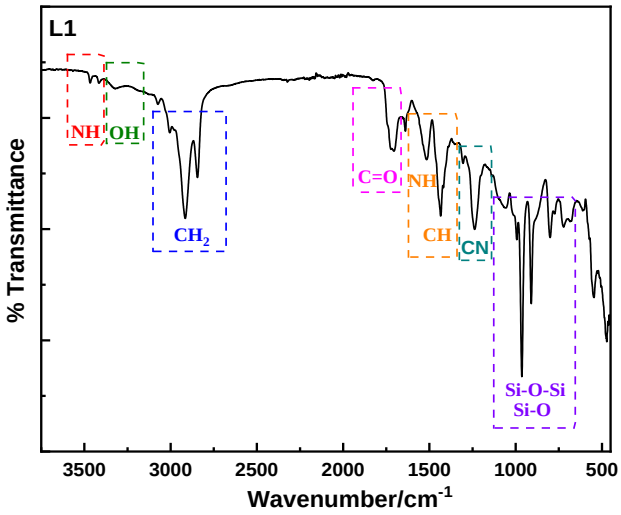

Figure 2. FTIR analysis of the liner L1

3.2. Viscosity measurements of uncured composite liners

After the homogenization process, the liner must exhibit an appropriate viscosity to ensure proper casting and application onto the inner wall of the rocket motor chamber. The time during which the material retains suitable rheological properties for processing is defined as the gelation time – *pot life*. This parameter depends on the resin-curing agent system, as well as on the type and content of fillers and other additives.

The viscosity of uncured liner formulations changes over

time and represents a key parameter for *pot life* determination. Therefore, dynamic viscosity was measured at 15-minute intervals after homogenization, over a total period of 75 minutes, which was considered sufficient for the planned application procedure.

The results are presented in Table 2, while the corresponding graphical representation is shown in Figure 3.

Table 2. Dynamic viscosity of uncured liner formulations.

Time (min)	Dynamic viscosity (Pa·s)			
	L1	L2	L3	L4
15	592	624	736	800
30	736	816	752	1072
45	/	/	800	1312
60	912	1088	896	/
75	/	1184	992	/

Note: L1-L4 represent different liner formulations with different contents of nano-SiO_2

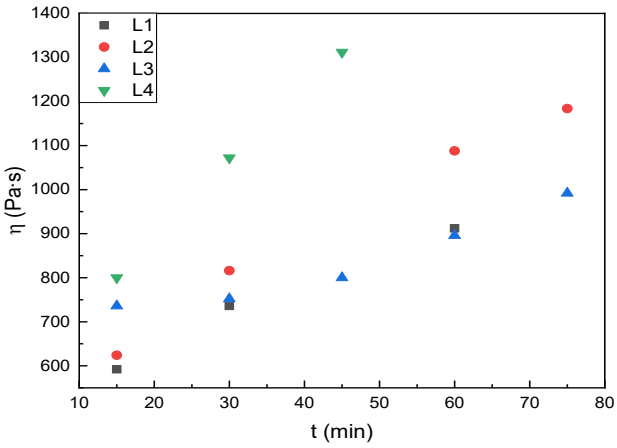

Figure 3. Comparison of the initial viscosity of experimental liner formulations

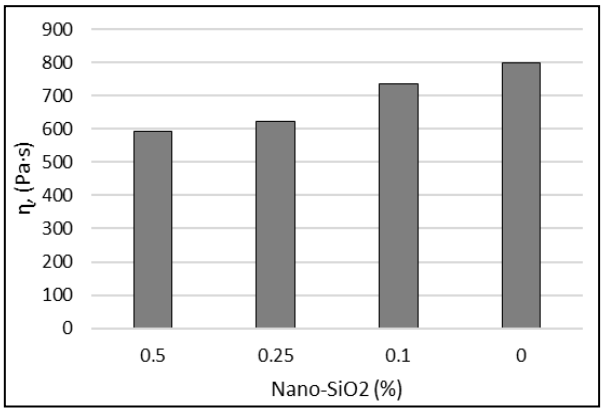

Figure 4. Dynamic viscosity 15 minutes after IPDI addition

Based in the time-dependent viscosity profiles, an increase in viscosity over time is observed, confirming the progress of crosslinking reactions. The results show that sample L4, without nano-SiO_2, exhibits the fastest and most pronounced viscosity increase (Figure 4). With increasing nano-SiO_2 content, the initial viscosity is partially reduced. However, sample L1, containing the highest nano-SiO_2 content (0.5 wt.%), shows the lowest viscosity after 15 minutes from the addition of the curing agent.

The decrease in viscosity with increasing nano-SiO_2 content is attributed to nano-particle dispersion within the HTPB/IPDI matrix. Such insertion of nano-SiO_2 between HTPB polymer chains and IPDI cross-linker partially interrupts the crosslinking reaction. The gradual viscosity decrease at higher nano-SiO_2 contents extends the gelation time and improves control of the liner application process.

3.3. Density determination

A key requirement for thermal insulation liners is low density (1.05-1.10 g·cm^{-3}) to reduce the overall mass of the propellant grain. The addition of fillers requires a balance between improved thermal stability and ablation resistance and the resulting increase in density. High-density fillers such as silicon dioxide contribute to the formation of a more stable char layer. However, their content must be optimized to maintain low liner density. The average density values of the prepared formulations are presented in Figure 5. A slight increase in density with increasing nano-SiO_2 content was also confirmed.

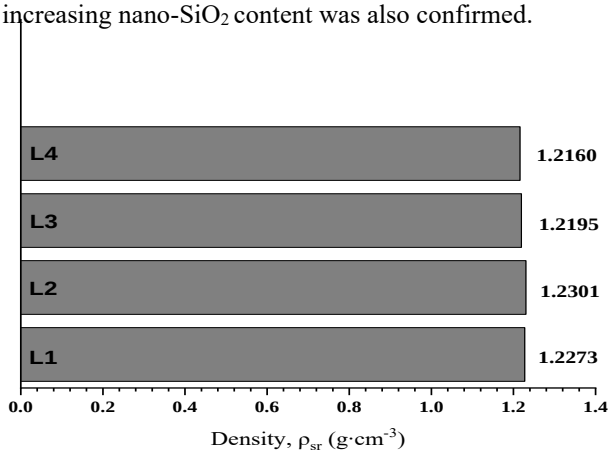

Figure 5. Density values of liner formulations L1-L4.

Note: The reported values are the average of four measurements.

3.4. Mechanical characterization

Mechanical testing was performed to evaluate the effect of nano-SiO_2 content on the tensile properties of the developed liner formulations (Figure 6). The obtained values of tensile strength, elongation at maximum force, elongation at break and Young's modulus (Table 3) indicate that the incorporation of different amounts of nano-SiO_2 significantly affects the mechanical behavior of the liners.

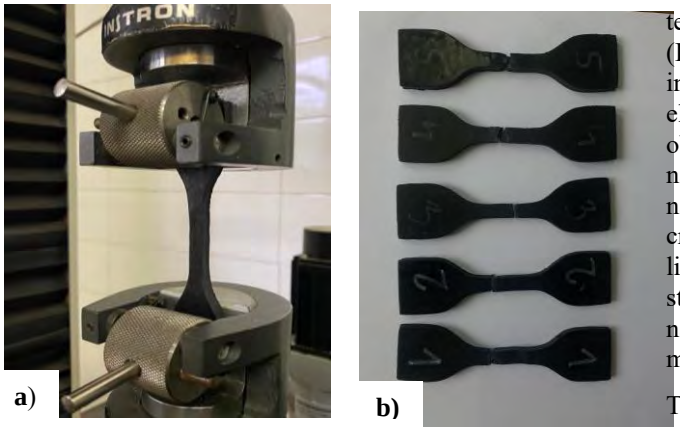

Figure 6. Appearance of L2 specimens before (a) and after (b) tensile strength testing

The polymer structure and mechanical performance of polyurethane-based liners are directly related to the degree of cross-linking achieved during the curing process. Highly cross-linked networks generally exhibit increased stiffness and tensile strength, while lower cross-linking densities promote greater flexibility and elongation. The tested formulations demonstrated typical elastomeric behavior characterized by large reversible deformations under tensile loading.

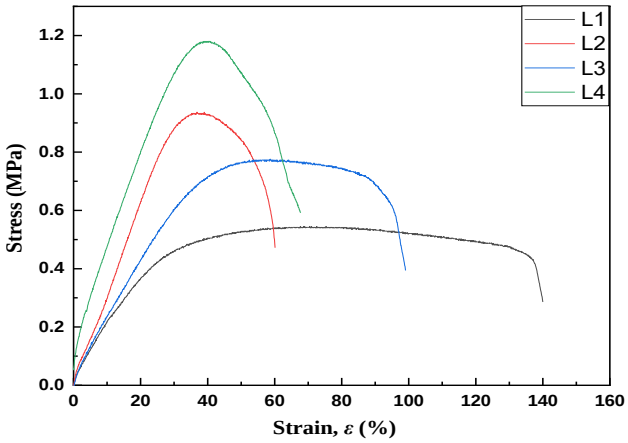

Figure 7. Stress-strain curves of the tested materials L1-L4

Table 3. Tensile strength, deformation at maximum force and at break and Young's modulus of the tested materials at T=20 ºC.

	σ_m, [daN/cm^2]	ε_m, [%]	ε_p, [%]	E [MPa]
L1	5.66 ± 1.30	51.97 ± 14.77	116.23 ± 23.68	1.08 ± 0.02
L2	9.34 ± 1.14	39.59 ± 8.25	66.85 ± 15.98	3.98 ± 0.02
L3	8.30 ± 1.34	52.54 ± 11.98	90.50 ± 29.54	3.98 ± 0.01
L4	10.75 ± 1.51	49.75 ± 10.78	79.22 ± 27.72	3.98 ± 0.01

Note: The reported values are the average of five measurements.

Among the investigated samples, L1 containing the highest nano-SiO_2 content (0.5 wt.%) exhibited the lowest tensile strength and the highest elongation at break (Figure 7). As the nano-SiO_2 content decreased, a gradual increase in tensile strength accompanied by a decrease in elongation at maximum force and elongation at break was observed. This behavior suggests that higher amounts of nano-SiO_2 contribute to the more pronounced insertion of nano-SiO_2 between HTPB polymer chains and IPDI cross-linker which significantly interrupts the cross-linking reaction. Moreover, the reduction in tensile strength may be attributed to the tendency of silica nanoparticles to form agglomerates within the HTPB matrix.

The observed decrease in tensile strength with increasing nano-SiO_2 content is consistent with literature data and can be primarily associated with nanoparticle agglomeration [7]. At lower concentrations, nano-SiO_2 particles are more uniformly distributed within the polymer matrix, whereas increasing particle content promotes particle-particle interactions and the formations of larger agglomerates. These agglomerates act as stress concentration sites and facilitate crack initiation during tensile loading, leading to a reduction in tensile strength Furthermore, the optimal values of tensile strength and elongation at break and maximal force were obtained for sample L3 indicating an optimal homogenization condition and nano-SiO_2 distribution.

Overall, the obtained results indicate that the mechanical performances of the developed liners are strongly dependent on the dispersion state of nano-SiO_2 and the resulting structure of the polyurethane network. Surface modification of nano-SiO_2 with reactive organosilane coupling agents, such as amino-, epoxy-, or isocyanate-functionalized silanes, represents a promising strategy for improving nanoparticle dispersion and overcoming compatibility limitations.

4. CONCLUSION

The influence of nano-SiO_2 and carbon nanofibers on the properties of HTPB-based thermal protection liners was investigated. FTIR analysis confirmed the formation of polyurethane bonds and successful curing of all developed formulations. Rheological measurements showed that the incorporation of nano-SiO_2 affected the viscosity evolution and *pot life* of the liner mixtures, indicating its influence on the curing process and network formation.

Mechanical testing revealed that increasing the nano-SiO_2 contend led to a decrease in tensile strength and an increase in elongation at break. The highest tensile strength was obtained for the formulation without nano-SiO_2 content exhibited the greatest elongation. These results were attributed to the tendency of nano-SiO_2 particles to agglomerate within the polymer matrix, affecting the degree of crosslinking and the homogeneity of the polyurethane network.

The obtained results demonstrate that the content and dispersion of nano-SiO_2 play a crucial role in determining the processing characteristics and mechanical performance of HTPB-based liners. Further optimization

of nanoparticle dispersion and surface modification of nano-SiO_2 may provide additional improvements in liner properties and contribute to the development of advanced thermal protections materials for rocket motor applications.

Abstract: *The paper deals with the numerical simulation of the hot forging process on a hammer. Today, it is hard to think of reliability in automotive, mechanical, or defense engineering without using forged parts. Their toughness and field safety are just too critical. But to get a high-quality component, you have to know exactly how the metal behaves and flows inside the die during heavy deformation. This is why numerical process simulations have become our go-to tool for updating or creating new forging technologies.*

Instead of burning budget on slow and expensive shop-floor trials, we built a finite volume model to map out deformation, shifting stresses, and forging forces while the steel is compressed under the hammer. We focused heavily on pinning down those weak spots in the tooling that can mess up the final geometry or trigger unexpected downtime.

The data from Simufact Forming basically gave us a clear window into the material's core during the hits. It let us judge whether the planned workflow actually works, showing us exactly how the die fills and how efficient the whole setup is. This CAE-driven method makes perfect sense for modern manufacturing because it cuts down product development time drastically.

Keywords: *hot forging, Simufact Forming, material flow, defense indsutry, numerical simulation*

1. INTRODUCTION

Hot forging is one of the most important technologies for metal forming. Modern technologies such as 3D metal printing have been developed, but hot forging plays a very important role in the manufacturing process of parts under high loads. Hot forging has an important role in military and automotive industries due to good mechanical properties of manufactured parts. The lower values of the yield stress are obtained when the workpiece is heated up. However, it is very difficult to lubricate because of the high temperatures. In hot forging process, the tools are loaded by high temperature, friction due to sliding of material on tool surface and in case of hammer forging, impact load.

Numerical simulations of processes using software based on the finite volumes method are successfully applied to eliminate material flow defects, determine and optimize process parameters, determine tool stresses to prevent tool breakage, and predict workpiece properties through stress-strain analysis. In addition, it is very easy to make changes to the tool design and monitor the impact of these changes on process parameters, thus achieving optimal tool geometry at all stages of the process.

Die life acts as an important factor on the productivity. In warm forging process, wear is the predominant factor affecting the die life since it sustains higher temperature and working pressure. Lee and Jou [1] reported that die life in warm forging is affected by wear in over 70%. This kind of failure affects not only the cost but also the tolerances of the forging. Developing methods which allow prediction of wear and which are suited to be used in the design stage is the most effective way in order to optimize the process.

In accordance with the methodological approach of Lee and Jou [1], the lifetime estimation of hot forging tools requires the application of Archard's wear law integrated within a finite volume numerical simulation. This

DOI: 10.5937/OTEH26133K

approach enables a precise correlation between the local conditions at the interface (pressure, sliding speed, temperature) and the predicted wear in the most stressed zones of the engraving.

According to Hartley and Pillinger [2], the degradation of finite elements is one of the primary challenges in the simulation of the forging process, which is why the implementation of reliable re-meshing strategies is necessary to maintain the stability of the calculation. Accordingly, in this paper, a nonlinear refresh criterion based on an increase in effective plastic deformation of 0.4 was adopted.

The phenomena at the interface between the forging tool and the workpiece are extremely complex and involve the combined influence of high friction, heat generation and material flow. When defining the numerical model in this paper, the influence of imperfect lubrication was simulated using a friction factor of 0.65, which required additional optimization of the size of the final mesh size to 1.5 mm in order to avoid numerical anomalies.

For the numerical analysis of the hot forging process, the Simufact Forming software was used, which in recent research (Delić et al) [3] has been successfully applied for the prediction of tool wear and the analysis of deformation forces. The numerical model in this paper was additionally validated through the optimization of flow parameters under highly loaded friction conditions [3].

As pointed out by Hawryluk et al. [4], tribological conditions in the hot forging process are extremely dynamic and subject to changes due to lubricant degradation. In accordance with these findings, the friction factor μ=0.65 was applied in this paper, which covers realistic conditions of limited lubrication at the tool-workpiece interface.

Following the methodology applied by Davoudi et al. [5], numerical analysis of forging tools requires precise definition of local contact stresses. The application of fine discretization (mesh size 1.5 mm) in this work enabled the detection of critical zones of stress concentration on the engraving radii, which ensures high reliability of the prediction of tool behavior under the influence of large deformation forces.

Yin et al. [6], emphasize that incorrect positioning of the ingot (billet) in relation to the center of the die leads to eccentric loading and premature breakage of the central punch, which can be successfully corrected by optimizing the guides and the forging positioning process itself.

As Řiháček et al. [7] proved in their comparative analysis of numerical methods in the Simufact.forming software, the finite volume method (FVM) shows superior numerical stability compared to the classical finite element method (FEM) when modeling processes with large deformations and intensive material flow.

The network refresh strategy implemented in this paper, based on the plastic strain increment of 0.4, is fully aligned with the findings of Řiháček et al. [7], who point out that optimal accuracy and stability of calculations are achieved by a combination of a suitable numerical solver and controlled adaptation of the network model.

As pointed out by Chenot et al [8], numerical simulation is increasingly replacing expensive and time-consuming trial and error methods on real machines, allowing engineers to find optimal solutions faster. The integration of optimization modules with simulation software allows not only to reduce production costs, but also to improve the mechanical properties of the final part through controlled preform geometry.

2. SIMULATION CONDITIONS

A three-dimensional thermo-mechanical finite volumes model was developed using Simufact Forming software in order to analysis the upset forging process of an industrial component manufactured from 42CrMo4 steel.

Steel 42CrMo4 (according to the standard EN 10083) is a low alloy improvement steel, which is very appreciated in the forging industry because of its high strength, excellent toughness and good hardenability. The material contains a precise balance of chromium and molybdenum, resulting in superior resistance to material fatigue and impact loads and is the ideal choice for the manufacture of components that are highly stressed in the defense and automotive industries. 42CrMo4 presents a stable behavior at high temperatures during the hot forging process, which allows to obtain complex geometries without the risk of internal defects, and after a proper thermal treatment it presents superior mechanical properties necessary to work in the most difficult operating conditions.

The simulation model consisted of three main geometrical entities: the workpiece, the upper die and the lower die. The workpiece geometry was imported as a CAD model and discretized using an adaptive size of mesh.

The workpiece material was defined as $42CrMo_4$ steel using the material data available in the Simufact material database. The material behavior was considered temperature-dependent in order to accurately represent the hot forging conditions.

First case: The forging operation was simulated on a Hammer MPM-1000 machine. The initial workpiece temperature was set to 1200°C, while the initial die temperature was 250°C. The ambient temperature was defined as 20°C. Contact interactions between the workpiece and the dies were modelled using friction conditions 0.5.

Second case: The forging operation was simulated on a Hammer MPM-1000 machine. The initial workpiece temperature was set to 1100°C, while the initial die temperature was 250°C. The ambient temperature was defined as 20°C. Contact interactions between the workpiece and the dies were modelled using friction conditions 0.65.

The simulation was performed for the given thermo-mechanical conditions, considering the heat transfer between the workpiece and the tools, the temperature increase due to plastic deformation and the influence of temperature on the material flow behavior.

The aim of the numerical model was to analyze the material flow, distribution of the effective strain, stress state and development of the forging force during forming operation. The obtained results were used to evaluate the suitability of the selected technological solution and to indicate potential critical regions that could influence the quality of the final forging.

3. RESULTS AND DISCUSSION

The numerical simulation provided a detailed insight into the thermo-mechanical behavior of the workpiece during the hot die forging process. The obtained results enabled the evaluation of material flow, effective strain distribution, stress state, temperature field and forging force development throughout the forming operation.

Two numerical simulations of the hot die forging process were performed in order to investigate the influence of friction conditions on the material behavior during forming.

The first simulation was carried out using a shear friction factor of 0.50, while the second simulation considered an increased friction factor of 0.65. In addition, a finer mesh size was applied in the second case.

The obtained results showed that the increase in friction reduced the maximum effective strain from approximately 6.25 to 4.52, indicating a more restricted material flow. At the same time, local material compression increased, which was reflected in higher local density values and a greater number of remeshing operations during the simulation.

The maximum workpiece temperature remained within the expected range for both cases, although a slight reduction was observed for the higher friction condition.

The numerical results confirm that friction conditions significantly affect material flow behavior, deformation distribution and overall process stability during hot die forging.

The analysis confirmed that the material successfully filled the die cavity under the selected technological conditions. The distribution of effective plastic strain and stresses indicated the regions subjected to the highest deformation intensity, while the temperature field showed the thermal conditions during the forming process.

Special attention was paid to the influence of friction conditions on the material behavior. Comparative analysis of the investigated cases demonstrated that the change in friction coefficient affected the material flow pattern, deformation distribution and contact conditions between the workpiece and the dies.

In addition to the standard process parameters, the numerical model enabled the evaluation of potential critical regions by means of the Cockroft-Latham damage criterion and die wear prediction. These results provide useful information for assessing process stability and the quality of the final forging.

Increase in wear: When moving from μ =0.5 to μ =0.65, the maximum die wear (Max die wear) increased from 1.3E-11 to 8.54E-11. This is almost 6.5 times the higher value, confirming that even small changes in the tribological conditions at the tool-workpiece interface drastically shorten tool life.

Drastic jump in pressure: The Max pressure value jumps from 4691.77 MPa to an incredible 22829.8 MPa Such high pressure values indicate that with greater friction, the material moves much harder through the forging engraving, which creates an extreme load on the surface of the tool.

Deformation parameters: It is interesting that the Max effective plastic strain decreases from 6.25 to 4.52 at higher friction. This is the expected behavior because higher friction restricts the free flow of the material which directly confirms the theoretical proposition that friction dictates the deformation mechanism in hot forging.

Table 1. Comparation of results

Parameter	*μ=0.5*	*μ=0.65*
Max effective plastic strain	6.25	4.52
Max pressure	4691.77 MPa	22829.8 MPa
Max plastic strain rate	29235.5	194846
Max die wear	1.3E-11	8.54E-11
Max temperature	1286.11°C	1263.25°C

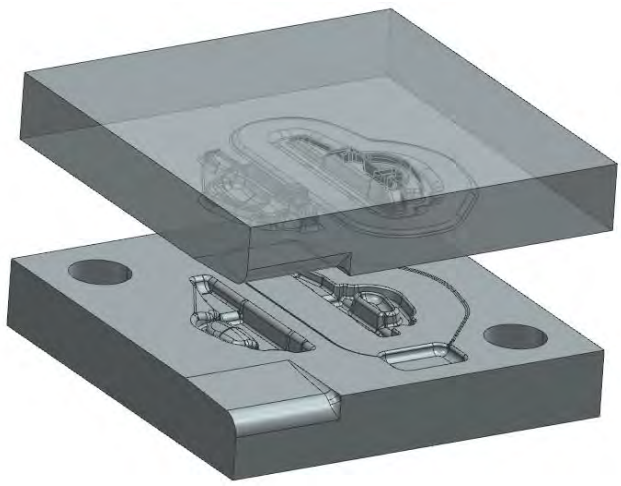

Figure 1. Upper and lower die for forging

Figure 1 shows a 3D model of the tool assembly, which includes the upper and lower dies imported in the Simufact Forming software environment. The geometry of the tool is imported from the CAD system with the application of precise discretization, which ensures a reliable mapping of contact surfaces and interactions with the workpiece during the forging process.

The forging process of the analyzed industrial component consists of operations: the preforming operation and the finishing operation, which are necessary to achieve the required geometric characteristics and precision of the

part. The initial step includes the operation of compressing (upsetting) the preform, which prepares the raw material for the deformation process, followed by the final stage, in which the material is completely pressed into the engraving of the tool under the influence of high pressures and temperatures. This sequential division into preparatory and final operations enables a more even material flow, reducing the risk of internal defects and optimizing the use of energy during hammer forging.

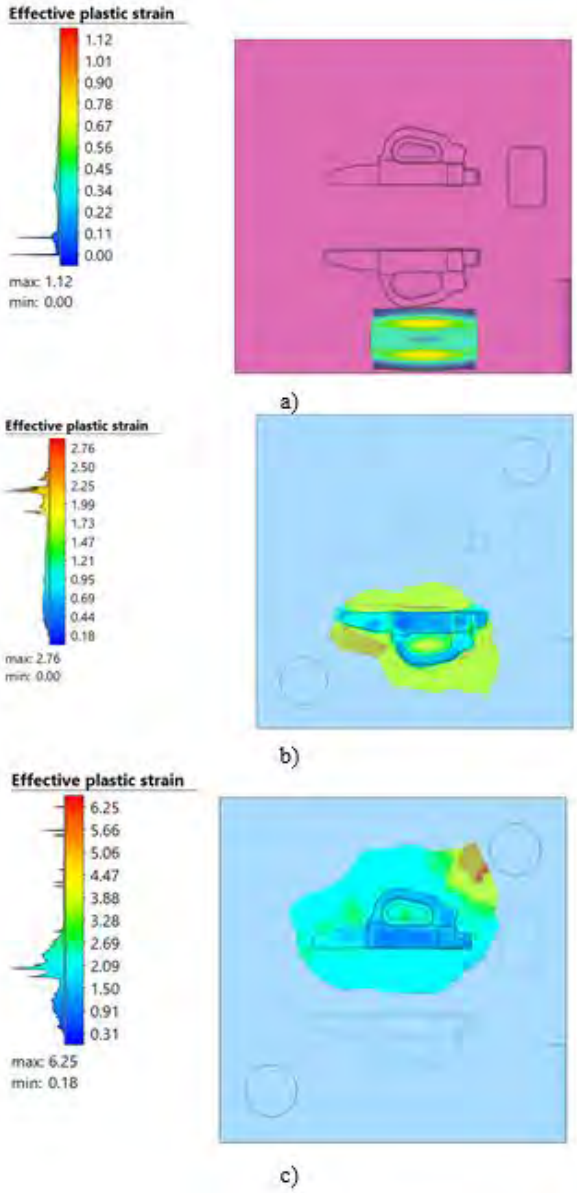

Figure 2. Value of Plastic Strain for first case: a) Upsetting; b) Pre-forging; c) Final forging

Figure 2 shows the distribution of the effective plastic deformation in the final phase of the forging hammer stroke (at 65 mm stroke) for the initial numerical model with a defined friction factor μ = 0.5. The contour display indicates a characteristic inhomogeneous deformation field, typical for hot forging processes of asymmetric parts in open molds. The maximum value of the effective plastic deformation reaches a value of 6.25 and is strictly localized on the periphery of the forging, in the zone of crown formation (upper right segment figure 3c). This high value is a direct consequence of the intense shearing of the material that leaves the central engraving under pressure and enters the narrow rim channel. This peripheral ring of highly deformed material creates the necessary hydrostatic resistance, which forces the remaining volume of 42CrMo4 steel to fill the deepest segments of the tool, such as the trigger guard zone.

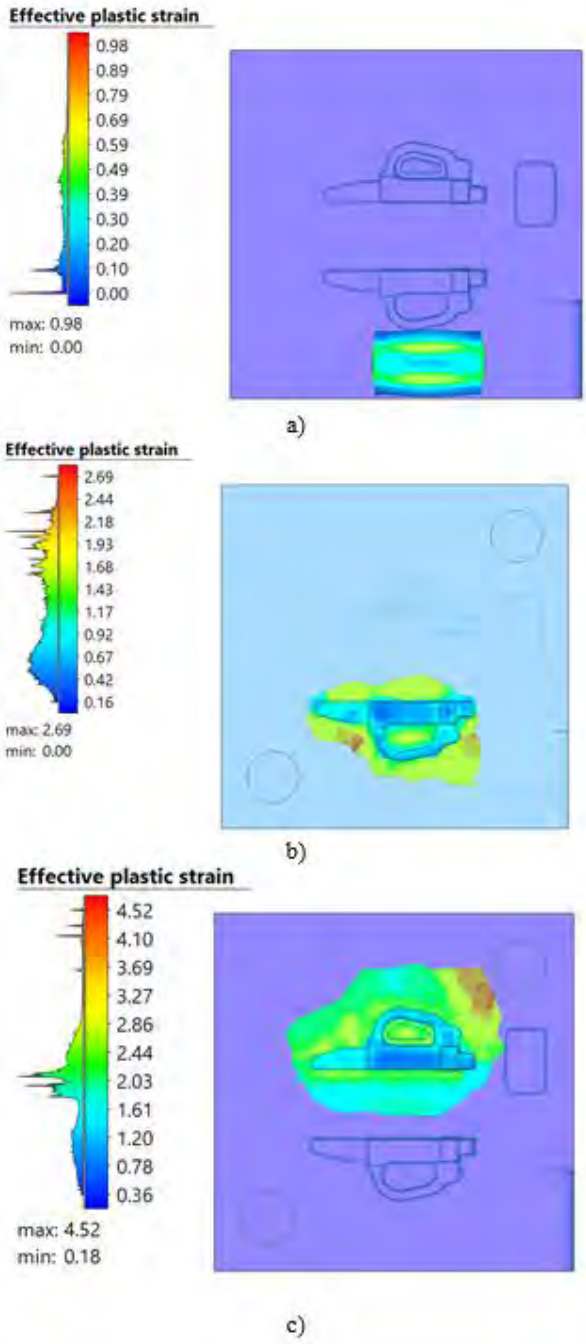

Figure 3. Value of Plastic Strain for second case: a) Upsetting; b) Pre-forging; c) Final forging

In contrast to the rim zone, the working part of the forging (central zone) shows a significantly lower and more homogeneous deformation profile. This uniform distribution in the core of the component indicates a stable material flow without the appearance of critical zones that could lead to internal defects, such as folds or cracks. However, although the deformation field in the central part is stable, this basic network model showed signs of numerical instability at the very end of the stroke

(Increment 2143). This served as the basis for further optimization of the remeshing conditions and the size of the final elements in subsequent iterations, especially in analyzes with more realistic, higher friction factors.

In order to achieve more realistic forging conditions, which include imperfect lubrication and high flow resistance in contact with the tool, an optimized numerical model with a friction factor of μ = 0.65 was created. Figure 4 shows the distribution of effective plastic deformation at the very end of the process (at 65 mm stroke). In order to preserve the stability of the calculation under such rigorous conditions, a fine spatial discretization was applied (mesh size of 1.5 mm) with a stricter nonlinear criterion of mesh refresh (remesh) at a plsatic strain increment of 0.4.

Unlike the base model, the maximum recorded effective plastic strain value is now 4.52. This drop in the maximum value is an indicator of the exceptional stability of the solver; namely, the finer mesh and stricter remesh criterion successfully eliminated local numerical anomalies and "lock-in" effects at sharp radii, enabling smooth mathematical tracking of material flow.

As expected, the zone of maximum deformation (red spectrum) is still localized in the peripheral ring of the forging part. The main progress of this model is, however, presented in the centre, working zone of forging. The deformation field in the region of the rifle body and trigger guard is significantly more homogeneous.

This stable and visually continuous material flow under high friction conditions proves the robustness of the applied meshing strategy. The obtained results confirm that the optimized model is free from non-physical peaks, thus providing highly reliable initial data for any further thermo-mechanical analysis of forging tools and the assessment of their service life.

The obtained simulation results confirm that numerical analysis represents an efficient tool for the investigation and optimization of industrial forging processes. The developed model made it possible to evaluate the influence of selected technological parameters without the need for costly experimental trials.

The comparison of the analyzed cases indicates that friction conditions have a significant influence on the material flow and deformation behavior during the forging process. Variations in friction affect the contact conditions between the dies and the workpiece, which consequently influence the stress distribution, effective strain and overall process performance.

The application of damage and die wear criteria contributes to a better understanding of potential critical zones and provides additional information for improving tool design and technological parameters.

The presented approach demonstrates that CAE methods can support the development of industrial forging technologies by reducing development time, improving process reliability and contributing to higher product quality.

For a more detailed analysis (Figure 4 and 5) of the state of deformation, mapping of the effective plastic deformation was carried out using measuring points placed at characteristic places inside the working part of the forging. This approach made it possible to precisely monitor the intensity of deformation in the zones of interest, which eliminates the influence of numerical extremes localized on the rim and gives a more realistic insight into the distribution of deformation within the piece itself.

Case 1 ($\mu=0.5$), Figure 4: Application of a higher friction coefficient resulted in a more homogeneous deformation profile in the same zones, with values ranging from min 0.38 to max 2.98. The reduction of the maximum deformation values in the working part of the forging confirms that the decreased friction limits the free flow of the material, which achieves a more stable filling of the engraving and reduces the risk of internal defects due to uneven flow.

Case 2 ($\mu=0.65$), Figure 5: In the central zones of the forging, recorded values of effective plastic deformation range from min 0.36 to max 3.37. This distribution indicates a more intensive penetration of the material into the engraving of the tool, but also potentially greater variations in the deformation field due to bigger frictional resistance.

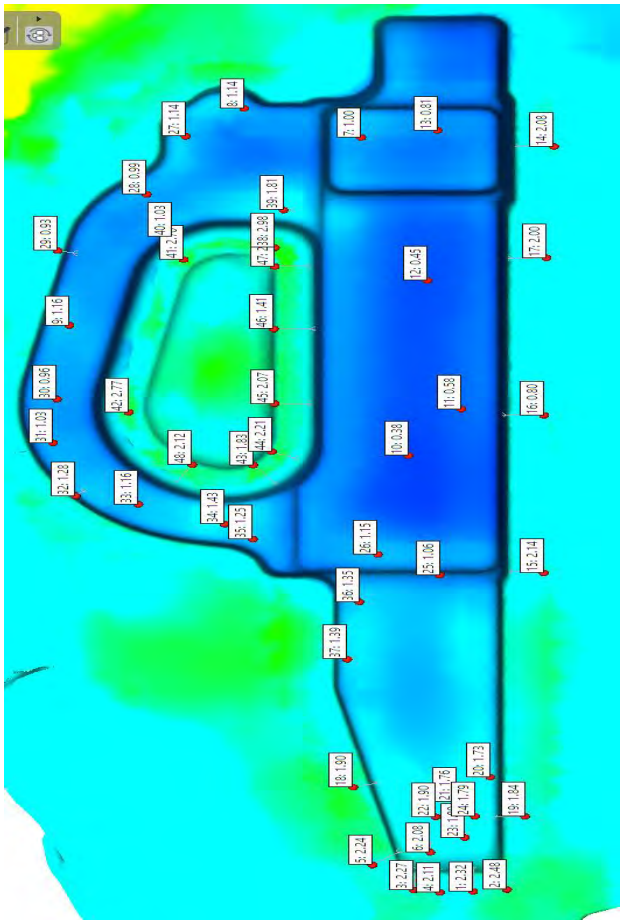

Figure 4. Plastic Strain point on forging part first case

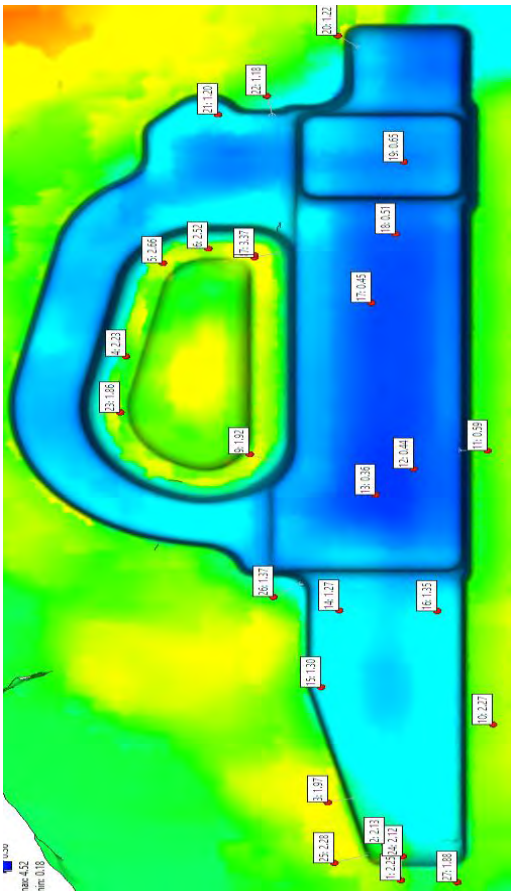

Figure 5. Plastic Strain point on forging part second case

5. CONCLUSION

In this paper, a numerical analysis of the forging process was carried out, where the finite volume method (FVM) was applied and showed exceptional stability and reliability in the simulation of large plastic deformations. The comparative analysis indicates that the results obtained by the FVM solver are fully comparable with the experimental data, thus confirming their applicability in industrial tool design. The key contributions of the research are reflected in the following: It has been confirmed that the precise definition of friction conditions, using the shear model with the factor μ =0.65, is the basis for a reliable simulation of wear. The application of the Simufact wear model enables the early detection of critical zones on the tool, which directly affects the increase of the service life of the dies. The analysis showed that the independent control of the movement of the punch significantly reduces the risk of material defects, such as "cold joints" (cold shut), which significantly improves the quality of the final product. Based on the above, it can be concluded that the integration of modern numerical simulations and experimental verification provides a comprehensive tool for forging process optimization. This approach enables the reduction of development costs, faster production and guaranteed high-quality production of parts with complex geometry.

The results of this study show that the conditions of friction have a major influence on the hot forging process. A higher friction factor results in a more restricted material flow, which increases the contact pressures at the interface between the tool and the workpiece, and in turn results in higher tool wear. Simultaneously the maximum effective plastic strain is reduced due to the reduced ability of the material to flow freely in the die cavity. The findings confirm that friction is one of the most important technological parameters affecting the stability, efficiency and the general quality of the hot forging process.

Future research may include a more extensive parametric analysis involving different process conditions, as well as the validation of numerical results by comparison with experimental and industrial production data. Such an approach would further improve the accuracy of the simulation model and contribute to the development of more efficient forging technologies.

Abstract: *Today, it is impossible to imagine mechanical parts in the automotive, mechanical or military industry without forgings, primarily because of their durability and safety in operation. However, in order to obtain a quality part, one must know exactly how the material flows through the tool and what happens during the deformation itself. That's why numerical simulations have become our main tool when developing or changing forging technology.*

Instead of expensive tests in the plant, we used a computer model to follow in detail the propagation of deformations, the change of stress and the movement of the forging force during the compression of the steel. We mainly focused on identifying critical regions in the tool that can adversely affect the geometry of the forging or cause unexpected production downtime.

The results from Simufact gave us in practice a "window" into the interior of the material during compaction. Based on that, we precisely assessed whether the proposed technological solution is good, monitoring how the mold is filled and how efficient the whole process actually is.
This engineering approach through CAE methods clearly proves its value in the industry, because it directly saves us time for new product development.

Keywords: *forging, Simufact Forming, material flow, military vehicle, CAE*

1. INTRODUCTION

The hot forging is one of the most important technologies for metal forming. New technologies like 3D metal printing have been developed, but hot forging is still very important in the production process of parts under high loads. Due to good mechanical properties of manufactured parts, hot forging has an important role on military and automotive industries. Lower values of the yield stress are obtained when the workpiece is heated up. But it is very difficult to lubricate because of the high temperature. In hot forging process, the tools are subjected to high temperature, friction due to sliding of material on tool surface and in case of hammer forging, impact load.

The ever-increasing costs of material, energy and especially manpower demand that forging processes and tooling be designed and developed with minimum amount of trial and error with shortest possible lead times. Hence, to keep up with the competition the cost-effective application of computer aided techniques i.e. CAD, CAM, CAE and especially Finite Element Analysis (FEA) and Finite Volume Analysis (FVA) based computer simulation are an absolute necessity. The practical use of these techniques requires knowledge of the principal variables of the forging process and their interaction.

CAE simulations of processes using software based on the finite element method are successfully applied to eliminate material flow defects, determine and optimize process parameters, determine tool stresses to prevent tool breakage, and predict workpiece properties through stress-strain analysis. In addition, it is very easy to make changes to the tool design and monitor the impact of these changes on process parameters, thus achieving optimal tool geometry at all stages of the process.

In hot forging processes, the lifetime of forging tools

(upper and lower dies) is largely limited by the occurrence of abrasive wear, thermal fatigue and plastic deformation. Research shows that wear is the dominant failure mechanism, responsible for as much as 70% of all damage to tools. Validation of numerical tool wear models is performed by comparing simulation results with experimental measurements on three-dimensional measuring machines (CMM) [1].

Lee and Jou [2] applied Archard's wear law within a finite volume framework to estimate the service life of hot forging tools. Their approach enabled the prediction of wear development based on local contact conditions such as pressure, sliding velocity and temperature.

Hartley and Pillinger [3] highlighted the importance of remeshing techniques in forging simulations due to severe element distortion caused by large plastic deformations. Their findings demonstrated that adaptive mesh refinement is essential for maintaining numerical stability.

Hawryluk et al. [4] investigated tribological conditions in hot forging processes and showed that friction conditions continuously evolve as a consequence of lubricant degradation and elevated temperatures.

Davoudi et al. [5] emphasized the importance of accurate contact stress prediction in forging tool analysis. Their work demonstrated that fine mesh discretization improves the identification of stress concentration zones and increases prediction accuracy.

Yin et al. [6] reported that improper billet positioning may result in eccentric loading and premature tool failure, highlighting the importance of accurate billet alignment during forging operations.

Řiháček et al. [7] compared different numerical approaches implemented in Simufact Forming and concluded that the finite volume method provides superior numerical stability in simulations involving severe plastic deformation and intensive material flow.

Chenot et al. [8] demonstrated that numerical simulation can significantly reduce the need for costly experimental trials by enabling process optimization in a virtual environment before industrial implementation.

Studies on hot deformation behavior of Cr-alloyed steels have shown that dynamic recrystallization is the dominant softening mechanism at elevated temperatures. The flow stress response is strongly dependent on temperature and strain rate, making accurate material modelling essential for reliable numerical simulations [9].

2. SIMULATION CONDITIONS

A three-dimensional thermo-mechanical finite element model was developed using Simufact Forming software in order to analysis the upset forging process of an industrial component manufactured from 38HS steel.

Steel 38HS (according to the standard GOST 4543) is an improved steel which is highly valued in the forging industry due to its high strength, excellent toughness and good hardenability. The material has a precise balance of chromium and molybdenum, which gives a superior resistance to material fatigue and impact loads and is the ideal choice for the manufacture of components that are highly stressed in the defense and automotive industries. 38HS exhibits a stable behavior at high temperatures during the hot forging process, enabling the production of complex geometries without the risk of internal defects. After a suitable thermal treatment, 38HS shows superior mechanical properties required to operate in the most challenging working conditions.

The simulation model consisted of three main geometrical entities: the workpiece, the upper die and the lower die. The workpiece geometry was imported as a CAD model and discretized using an adaptive finite element mesh.

The workpiece material was defined as 38HS. The material behavior was considered temperature-dependent in order to accurately represent the hot forging conditions.

The forging process was simulated through three consecutive stages: upsetting, pre-forging and final forging. The upsetting and pre-forging operations were analyzed using a single mesh configuration, since their primary purpose was to generate the intermediate billet geometry required for the final forging stage.

A mesh sensitivity analysis was performed exclusively for the final forging operation, which represents the most critical stage of the process due to the complex die geometry and intensive material flow. Three mesh sizes were investigated: 3.0 mm, 2.2 mm and 1.5 mm. All other process parameters, including billet temperature, die temperature, friction factor and press characteristics, were kept constant throughout the analysis.

This approach enabled the influence of mesh density on numerical stability, computational time and predicted process parameters to be evaluated while maintaining identical initial conditions obtained from the upsetting and pre-forging simulations.

The simulations were performed using the finite volume (FV) solver in Simufact Forming. The initial billet temperature was set to 1250 °C, while the die temperature was maintained at 250 °C. A shear friction model with a friction factor of m = 0.5 was applied at the workpiece–die interface. The forging operation was simulated using a Forging hammer with an impact energy of 35 kJ and an efficiency factor of 0.7. The total forging stroke was 70 mm and each simulation was divided into 100 equal increments.

Therefore, the only variable parameter among the analyzed cases was the mesh density, allowing the determination of the influence of element size on numerical stability, computational time and predicted process parameters to be evaluated.

3. RESULTS AND DISCUSSION

The numerical simulation of the hot forging process was carried out using the finite volume solver implemented in Simufact Forming. The objective of the analysis was to evaluate material flow, strain distribution, contact conditions and the influence of mesh density on the numerical stability of the obtained results.

The simulation results confirmed complete filling of the die cavity and successful material flow throughout the forging operation. The highest values of effective plastic strain were recorded in the flash region and in areas characterized by intensive material redistribution. Such behavior is expected in hot forging processes due to the constrained flow conditions near the die parting line.

The computational cost increased significantly with mesh refinement. The simulation time increased from approximately 34 minutes for the 3.0 mm mesh to 90 minutes for the 2.2 mm mesh and 111 minutes for the 1.5 mm mesh. In addition, the number of remeshing operations increased from four to six, indicating a higher degree of mesh distortion during the forming process.

Because similar anomalies appeared in both refined meshes, it can be concluded that the observed behavior is related to local numerical effects rather than to the actual physical response of the material. Consequently, the 3.0 mm mesh provided the most stable and physically meaningful solution while maintaining acceptable computational efficiency.

Table 1 presents the influence of mesh density on the maximum effective plastic strain and maximum contact pressure obtained during the final forging simulation. The results indicate that mesh refinement leads to a gradual increase in both parameters. The maximum effective plastic strain increased from 1.92 for the 3.0 mm mesh to 2.07 and 2.09 for the 2.2 mm and 1.5 mm meshes, respectively. The relatively small difference between the 2.2 mm and 1.5 mm meshes suggests that the solution approaches numerical convergence with respect to plastic strain.

A similar trend was observed for the maximum contact pressure, which increased from 1215 MPa for the 3.0 mm mesh to 1499 MPa and 1790 MPa for the 2.2 mm and 1.5 mm meshes, respectively. This behavior is expected because finer meshes provide a more accurate representation of local contact conditions and stress concentrations, particularly in regions with complex die geometry.

The obtained results demonstrate that CAE-based process simulation is an effective tool for evaluating forging technology before industrial implementation. The performed analyses enabled detailed insight into material flow, strain development and die filling conditions, reducing the need for costly experimental trials and shortening the development cycle of forged components intended for military vehicle applications.

Figure 1 shows a 3D model of the tool assembly, which includes the upper and lower dies imported in the Simufact Forming software environment. The geometry of the tool is imported from the CAD system with the application of precise discretization, which ensures a reliable mapping of contact surfaces and interactions with the workpiece during the forging process. Figure 1 also show forged part.

Table 1. Comparation of results

Parameter	Mesh 3.0 mm	Mesh 2.2 mm	Mesh 1.5 mm
Max effective plastic strain	1.92	2.07	2.09
Max pressure (MPa)	1215	1499	1790
Max strain rate (s^{-1})	173982	402216	364102
Max die wear (mm)	1.67E-11	2.53E-11	2.06E-11
Max temperature (°C)	1351.52	1372.61	1537.31

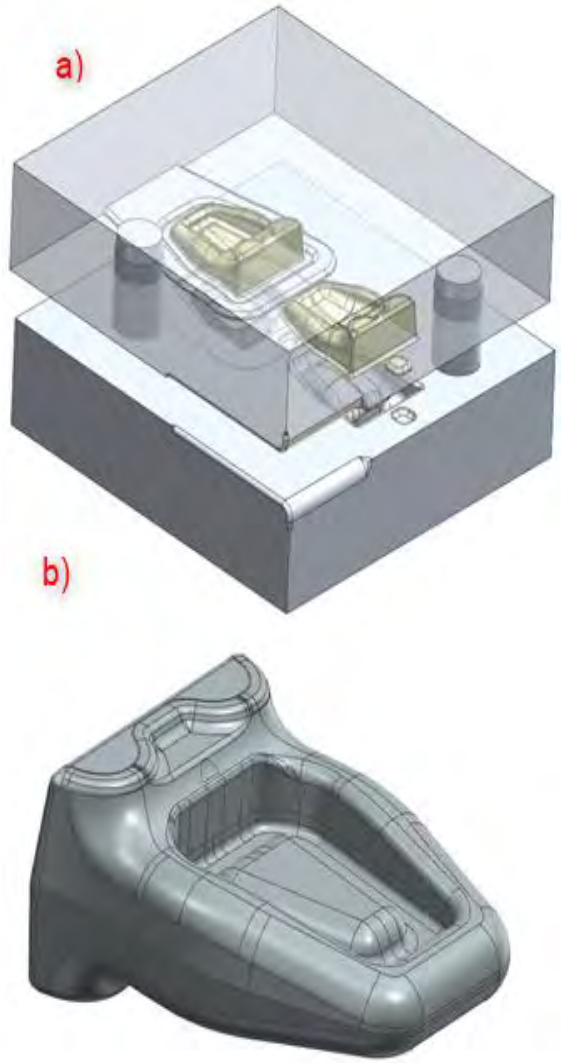

Figure 1. 3D model: a) Upper and lower die for forging; b) Forged part

Figure 2 presents the upsetting and pre-forging stages used to obtain the intermediate billet geometry for the final forging operation. These stages were identical for all analyzed cases and were simulated using the same process parameters and mesh configuration.

Figures 3, 4 and 5 illustrate the final forging stage

performed with different mesh densities in order to evaluate the influence of element size on the numerical results. Figure 3 shows the results obtained using a 3.0 mm mesh, Figure 4 presents the simulation performed with a 2.2 mm mesh, while Figure 5 corresponds to the finest analyzed mesh of 1.5 mm.

All simulations were carried out under identical technological conditions, including the initial billet temperature of 1250 °C, die temperature of 250 °C, friction factor of μ = 0.5 and hammer energy of 35 kJ. Therefore, the only varying parameter among the analyzed cases was the mesh density used in the final forging stage.

The comparison of the obtained results enabled the evaluation of mesh sensitivity, computational efficiency and numerical stability, while maintaining identical initial conditions generated during the upsetting and pre-forging operations.

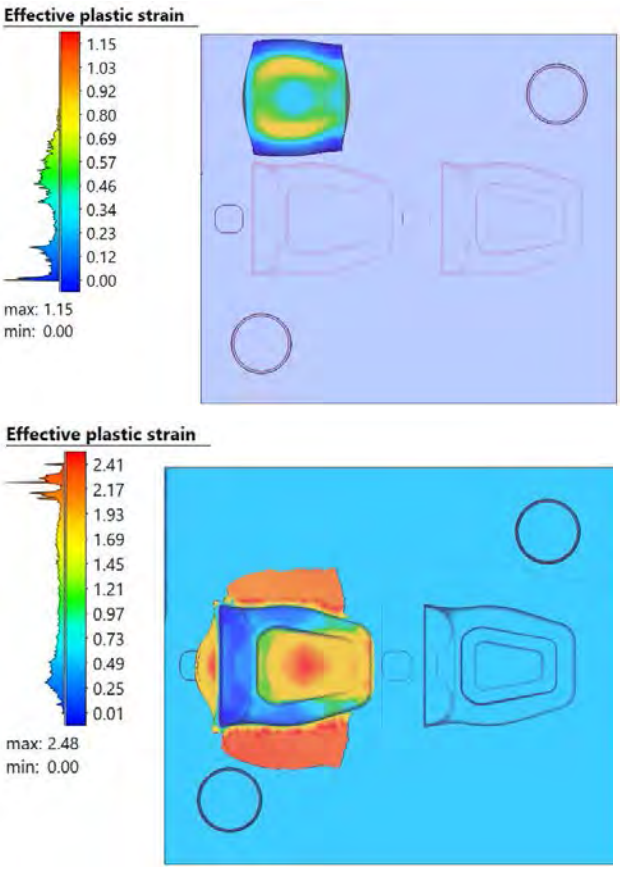

Figure 2. Upsetting and pre-forging

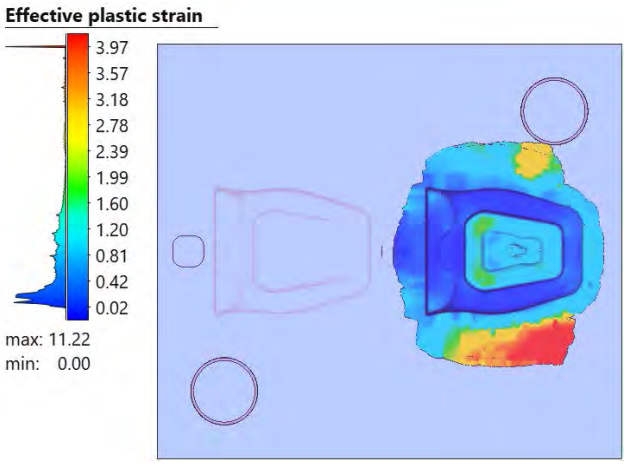

Figure 3. Value of effective plastic strain mesh 3 mm

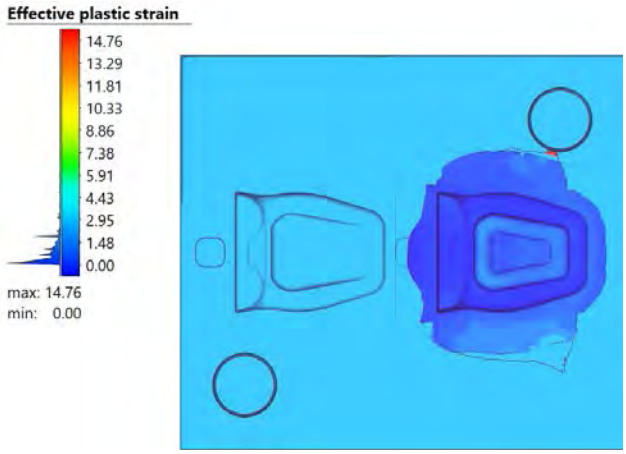

Figure 4. Value of effective plastic strain mesh 2.2 mm

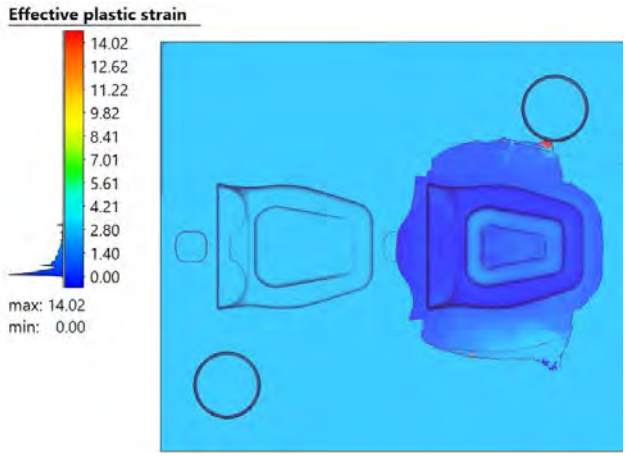

Figure 5. Value of effective plastic strain mesh 1.5 mm

Figure 6 shows the distribution of effective plastic strain for the three mesh configurations investigated. In all cases, the highest values are observed in the forgings wreath region, where the material is subjected to severe compression as it flows into the narrow flash gap. These localized maxima are expected and represent the most intensive plastic deformation occurring during the forging process rather than the deformation of the forged component itself. Therefore, the effective plastic strain values reported in Table 1 were measured directly on the forged part, excluding the forgings wreath region, in order

to provide a representative comparison of the deformation state within the final product. The results indicate only minor differences between the investigated mesh sizes, confirming that mesh refinement has a limited influence on the predicted deformation of the forged component, while mainly affecting the resolution of localized deformation in the forgings wreath region.

5. CONCLUSION

In this paper, a numerical analysis of the forging process was carried out, where the finite volume method (FVM) was applied and showed exceptional stability and reliability in the simulation of large plastic deformations.

This study presented a numerical simulation of the hot forging process of a 38HS steel component intended for military vehicle applications using Simufact Forming software. The conducted CAE analysis enabled a detailed investigation of material flow, strain distribution, temperature evolution and die filling behavior throughout the forging operation.

The simulation results confirmed complete die cavity filling and demonstrated that the proposed forging technology is capable of producing the required component geometry without critical defects that could compromise the manufacturing process. The highest deformation values were observed in the flash region, which is consistent with the expected material flow characteristics of hot forging processes.

A mesh sensitivity analysis was performed using element sizes of 3.0 mm, 2.2 mm and 1.5 mm. Although finer meshes provided a more detailed representation of local deformation phenomena, they significantly increased computational time and introduced numerical instabilities manifested through nonphysical pressure, density and temperature peaks. Among the analyzed models, the 3.0 mm mesh provided the most stable and computationally efficient solution while maintaining physically meaningful results.

The obtained findings demonstrate that CAE-based simulation represents a valuable engineering tool for the design and optimization of forging technologies. By enabling virtual process verification prior to industrial implementation, numerical simulation reduces development costs, minimizes experimental trials and shortens product development time.

The methodology applied in this study can be successfully extended to other forged components manufactured from 38HS steel and may serve as a basis for future research focused on process optimization, tool design improvement and advanced thermo-mechanical analysis of hot forging operations.

Future work may involve the investigation of additional process parameters and their impact on forging performance. The incorporation of experimental validation and industrial production data would allow for further calibration of the numerical model, leading to improved prediction accuracy and enhanced process optimization in industrial forging applications.

Abstract: *The design of rocket motors with case-bonded propellant grains requires reliable thermal protection systems capable of protecting the motor case from high thermal and mechanical loads during operation. Due to that, it is important to apply thermally stable insulating material using a suitable technology and achieve good adhesion between thermal insulation and rocket motor case. This paper presents the development of the system of adhesive layer and cement for optimal interfacial bonding of EPDM based thermal insulation and steel rocket motor case. An EPDM thermal insulation compound reinforced with chopped and milled carbon fibers was selected for application to the rocket motor case and further evaluated through thermal analysis and adhesion testing. The gluing of EPDM-based thermal insulation to the interior of the rocket motor case was performed by vulcanization in an autoclave using the adhesive layer and cement as adhesion promoters. Thermal stability of the insulation material was evaluated by simultaneous thermal analysis (STA), while adhesion between rubber-rubber and rubber-steel was determined according to ASTM D1876 and ASTM D6862 standards. The results confirmed satisfactory adhesion properties of the selected adhesive system and adequate thermal stability of the insulation compound. The rocket motor case was successfully lined with the developed EPDM-based thermal insulation in a thickness range of 1.8–2.2 mm and vulcanized under industrial processing conditions.*

Keywords: *EPDM rubber, thermal insulation rocket motor case, adhesion, thermal protection*

1. INTRODUCTION

Rocket motors with case-bonded propellant grains require thermal protection systems capable of protecting the motor case from the extreme thermal and mechanical loads generated during motor operation . Thermal insulation is applied directly to the inner wall of the motor case to reduce heat transfer from combustion gases and prevent overheating of the metallic structure. In addition to thermal protection, the insulation layer may also serve as an inhibitor, protecting selected propellant surfaces during combustion [1, 2, 3].

Elastomer-based thermal insulation materials are widely used in rocket motor applications due to their processability, elasticity and thermal stability. Among them, EPDM rubber is of particular interest because of its resistance to thermal ageing and oxidation. In the investigated thermal insulation compound, chopped and milled carbon fibers, ammonium polyphosphate and melamine were used to improve thermal protection performance [4, 5, 6].

A critical requirement for the reliable operation of case-bonded rocket motor systems is the interfacial adhesion between the thermal insulation material and the metal motor case. Insufficient adhesion may lead to delamination, local heat accumulation and degradation of structural integrity during service [7]. For this reason, the development of the system of adhesive layer and cement and the suitable vulcanization technology must ensure an optimal interfacial bonding between thermal insulation and the metal rocket motor case.

The aim of this work was to optimize the interfacial bonding of EPDM-based thermal insulation through the development of a system of adhesive layer and cement and the development of suitable vulcanization technology for applying an EPDM-based thermal insulation to the inner wall of a steel rocket motor case.

2. EXPERIMENTAL

An EPDM-based thermal was used for application to the inner wall of a steel rocket motor case. The thermal

insulation was designated TG-H-727/3. The composition of the investigated thermal insulation compound is presented in Table 1. A sulfur-based curing system consisting of mercaptobenzothiazole (MBT), tetramethylthiuram disulfide (TMTD), and sulfur was used for vulcanization of the experimental compounds. Commercially available processing additives were also incorporated at optimum levels to improve processability. The thermal insulation was designated TG-H-727/3. Homogenization of the compounds was performed on a two-roll mill. After mixing, test specimens were prepared and curing conditions were determined from rheological measurements, while thermal stability was evaluated by STA.

The rocket motor case made of Č.4734 steel (according to the YUS) was prepared by abrasive blasting of the inner surface, followed by application of the system of adhesive layer and cement. The thermal insulation lining consisted of an adhesive layer with a thickness of 0.6 mm and a thermal insulation layer with a thickness from 1.4 mm to 1.6 mm, resulting in a total lining thickness between 1.8 and 2.2 mm.

After application, the lined rocket motor cases were vulcanized in an autoclave using direct steam at 150 °C and a pressure of 0.5 MPa for 40 min.

3. RESULTS AND DISCUSSION

3.1. Thermal Stability of the EPDM-based Thermal Insulation

The thermal stability of the investigated EPDM-based thermal insulation was evaluated by STA. The TG curve (Figure 1) showed a negligible mass loss below 250 °C, which can be attributed to the evaporation of residual low-molecular-weight components and moisture. The main degradation stage occurred between approximately 250 °C and 480 °C and corresponded to the thermal decomposition of the EPDM matrix and the release of volatile pyrolysis products. The compound exhibited a final mass loss of 71.87 %, while maintaining sufficient thermal stability throughout the temperature range relevant for the investigated application.

The DTG curve (Figure 2) revealed three characteristic degradation peaks located at approximately 298 °C, 384 °C and 464 °C. The first peak was associated with the decomposition of melamine and ammonium polyphosphate, the second with the formation of a protective carbonized layer, and the third with the primary degradation of the EPDM matrix. The obtained results confirmed the thermal behavior of the selected insulation compound and supported its use in the thermal protection system of the rocket motor case [8].

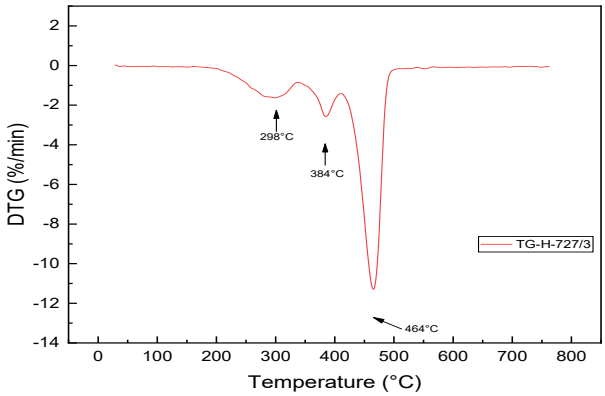

Figure 2. DTG curve of the TG-H-727/3 formulations

3.2. Adhesion Properties and Verification of the Application Technology

The sample codes used in the adhesion tests are defined as follows: T denotes the EPDM-based thermal insulation compound TG-H-727/3; P denotes the adhesive layer based on TG-HD-727/C3; C3 denotes TG-HD-727/C3 when used as a cement; C6 denotes the TG-D-727/C6 cement. For comparative rubber-rubber and rubber-metal adhesion testing, an adhesive based on natural rubber (NR), designated MC, was also used. The number in the sample code identifies the individual specimen [8].

The rubber-rubber peel test results (Table 5) revealed a strong influence of both the adhesive layer and the selected cement on the bond strength. The highest average peel strength (10.63 N/cm) was obtained for specimen T/P-C3-C3-T/P-C3, which contained the TG-HD-727/C3 adhesive layer and the C3 cement on both bonded surfaces. Failure occurred within the adhesive layer, indicating good compatibility between the thermal insulation, the adhesive layer and the cement system.
Specimens prepared without the additional adhesive-layer application exhibited significantly lower peel strength values. The average peel strength of specimen T-C3-T was 4.01 N/cm, while specimen T-C6-T showed the lowest value of 2.82 N/cm. These results demonstrate that the incorporation of the TG-HD-727/C3 adhesive layer considerably improves adhesion between thermal insulation layers. The intermediate value obtained for

specimen T/P-C6-C6-T/P-C6 (5.30 N/cm) suggests that the adhesive layer alone is not sufficient to achieve maximum bond strength and that the choice of cement also plays an important role.

Table 5. Rubber-rubber peel strength of the EPDM-based thermal insulation system

sample code	L (mm)	F_{max} (N)	F_{min} (N)	F_{avg} (N)	$F_{avg/L}$ (N/cm)	mean value (N/cm)
1-1 (T/P-C3-C6-T/P-C3)	31.65	27.00	24.00	25.32	8.0	6.70
1-2 (T/P-C3-C6-T/P-C3)	30.96	17.60	15.50	16.64	5.39	
2-1 (T-C6-T)	32.45	13.70	11.20	12.50	3.85	2.82
2-2 (T-C6-T)	31.28	7.10	4.00	5.63	1.80	
3-1 (T/P-C3-C3-T/P-C3)	30.83	27.88	26.60	27.70	9.04	10.63
3-2 (T/P-C3-C3-T/P-C3)	31.40	38.70	36.60	38.38	12.22	
4-1 (T-C3-T)	31.13	9.00	5.70	7.90	2.54	4.01
4-2 (T-C3-T)	32.04	18.70	16.80	17.56	5.48	
5-1 (T/P-C6-C6-T/P-C6)	31.67	21.00	14.50	16.79	5.30	5.30

The rubber–metal peel test results (Table 6) showed significant differences in adhesion performance among the investigated bonding systems. Specimens T-C6 (1-1), T-C6 (1-2), T-C3 (2-1) and T-C3 (2-2) represent the bonding systems based on C6 and C3, while T-MC represents the comparative MC adhesive. The highest peel strength was obtained for specimen T-MC, with an average value of 15.99 N/cm. Among the investigated C3 and C6 systems, specimen T-C6 (1-1) exhibited the highest peel strength of 5.03 N/cm. The results demonstrate differences in the adhesion performance of the investigated bonding systems for joining the EPDM-based thermal insulation to the metal substrate.

Table 6. Rubber-metal peel strength of the EPDM-based thermal insulation system

sample code	L (mm)	F_{max} (N)	F_{avg} (N)	$F_{avg/L}$ (N/cm)
1-1 T-C6	32.55	18.40	16.37	5.03
1-2 T-C6	32.29	5.40	4.10	1.27
2-1 T-C3	32.68	12.90	12.43	3.80
2-2 T-C3	32.38	11.10	9.07	2.80
T-MC	31.84	49.90	9.64	15.99

The results of the rubber-rubber shear test (Table 7) showed that specimens T-C3-T (2-1) and T-C3-T (2-2) exhibited the highest shear stresses, reaching 0.232 N/mm² and 0.207 N/mm², respectively. During testing, elongation and tearing of the rubber were observed, indicating good adhesion and high mechanical resistance of the bonded joint. In contrast, specimens T-MC-T (3-1) and T-MC-T (3-2) exhibited lower shear stresses, accompanied by interfacial debonding, which indicates weaker adhesion compared with the systems based on C3 and C6 cements.

Table 7. Rubber-rubber shear strength of the EPDM-based thermal insulation system

sample code	L (mm)	b (mm)	A (mm^2)	F_{max} (N)	F_{avg} (N)	F_{max}/A (N/mm^2)
1-1 T-C6-T	21.35	21	448.35	53.25	53.1	0.119
1-2 T-C6-T	21.71	21	455.91	84.9	80.94	0.185
2-1 T-C3-T	22.30	21	468.3	108.8	108.01	0.232
2-2 T-C3-T	22.35	21	469.35	97.10	95.70	0.207
3-1 T-MC-T	21.41	21	449.61	76.8	72.61	0.171
3-2 T-MC-T	21.43	21	450.03	68.89	68.41	0.153

The rubber-metal shear test results (Table 8) showed similar shear stress values for specimens T-C6 and T-C3, amounting to 0.287 N/mm² and 0.240 N/mm², respectively. These results indicate good adhesion between the EPDM-based thermal insulation system and the steel substrate. For specimen T-C6, failure occurred through rubber tearing rather than debonding at the interface, suggesting that the adhesive bond strength exceeded the cohesive strength of the rubber.

Table 8. Rubber-metal shear strength of the EPDM-based thermal insulation system

sample code	L (mm)	b (mm)	A (mm^2)	F_{max} (N)	F_{avg} (N)	$F_{max/A}$ (N/mm^2)
T-C6	21.83	21	458.43	131.5	103.47	0.287
T-C3	21.31	21	447.51	107.3	105.18	0.240

Both specimens, T-MC-T (1-1) and T-MC-T (1-2), exhibited high shear stress values (Table 9). The slightly higher value obtained for specimen T-MC-T (1-1) indicates good homogeneity of the bonded region and efficient crosslinking between the two rubber layers. The obtained results confirm the ability of the MC adhesive to produce mechanically stable joints between the rubber layers.

Table 9. Shear strength of bonded rubber layers in the EPDM-based thermal insulation system

sample code	L (mm)	b (mm)	A (mm^2)	F_{max} (N)	F_{sr} (N)	F_{max}/A (N/mm^2)	
1-1 T-MC-T	27.12	3.35	90.85	75.30	75.30	0.829	0.793
1-2 T-MC-T	25.83	3.35	86.53	65.60	65.50	0.758	

3.3. Application and Dimensional Verification of the Thermal Insulation Lining

The developed EPDM-based thermal insulation system was successfully applied to the inner surface of the steel motor case using the selected adhesive layer TG-HD-727/C3, TG-D-727/C6 cement and thermal insulation compound TG-H-727/3. The application process included surface preparation by sandblasting, adhesive treatment of the chamber wall, positioning of the insulation layer (Figure 3a), air-assisted blowing (Figure 3b), and subsequent vulcanization in an autoclave at 150 °C and 0.5 MPa for 40 min [8].

Particular attention was paid to achieving a uniform insulation thickness and reliable bonding between the insulation layer and the metallic substrate. The use of a duplicated insulation structure consisting of a 0.6 mm adhesive layer and a 1.4 mm to 1.6 mm thermal insulation layer enabled stable positioning of the material and prevented displacement during processing. The selected joining procedure, including a 45° scarf joint and pressure-assisted consolidation, ensured continuous contact between adjacent insulation segments and minimized the possibility of local defects or air entrapment.

Figure 3a.

Figure 3b.

Figures 3 (a and b) Application process of the EPDM-based thermal insulation lining to the rocket motor case

Dimensional verification performed after application of the adhesive layer and thermal insulation confirmed that the final coating thickness was within the target range of 1.8–2.2 mm throughout the chamber length. The measured inner diameter values demonstrated good process repeatability and indicated that the insulation layer was distributed uniformly over the entire internal surface, as shown in Figure 4. Maintaining dimensional tolerances is particularly important in solid rocket motors because local thickness variations may affect thermal protection efficiency, combustion chamber geometry, and subsequent bonding of the liner and propellant.

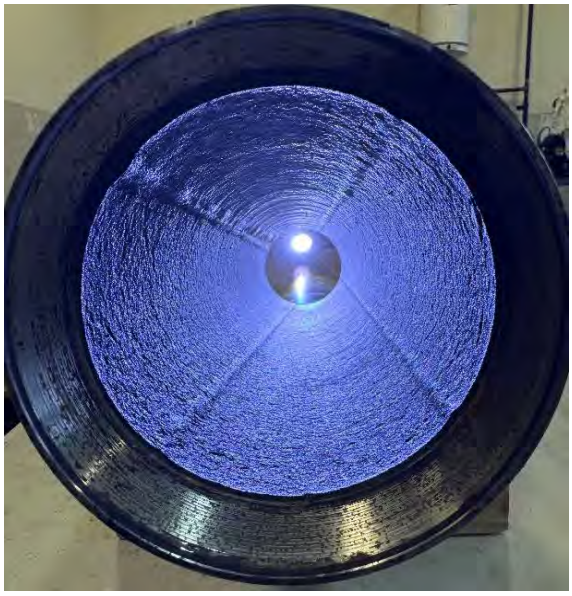

Figure 4. Interior view of the rocket motor case after application of the EPDM-based thermal insulation lining

4. CONCLUSION

An EPDM-based thermal insulation system for application to the inner wall of a steel rocket motor case was successfully developed and verified. The selected thermal insulation compound TG-H-727/3 exhibited satisfactory thermal stability, as confirmed by STA, and was therefore considered suitable for further application studies.

Adhesion testing demonstrated the effectiveness of the developed bonding system. The incorporation of the TG-HD-727/C3 adhesive layer and TG-D-727/C6 cement improved the adhesion between rubber layers and metal case. Satisfactory adhesion between the insulation system and the metal substrate was confirmed through peel and shear testing.

A technological procedure for surface preparation, application of the adhesive system, installation of the thermal insulation lining and autoclave vulcanization was successfully established. The developed procedure enabled the production of a continuous insulation lining with a thickness of 1.8–2.2 mm on the inner wall of the rocket motor case.

The successful lining and vulcanization of steel rocket motor case confirmed the applicability of the developed manufacturing technology under industrial processing conditions. The obtained results demonstrate that the proposed EPDM-based insulation system and the associated application technology are suitable for implementation in rocket motor thermal protection systems.

Abstract: *Biochemical methods for the detection of nerve agents are highly sensitive, rapid, and based on the ability of organophosphorus compounds to irreversibly inhibit enzymes from the cholinesterase family. The decrease in enzyme activity after exposure to a sample is directly proportional to the concentration of the nerve agent, making these methods powerful analytical tools, both for field detection and quantitative analysis. Nerve agents undergo various degradation pathways during long-term storage, and the complex mixture of potentially interfering compounds that accumulate over the years can affect the accuracy of enzymatic assays. In this work, a comparative analysis of the two VX samples with significantly different degradation profiles was performed using inhibition assays with electric eel acetylcholinesterase (AChE) and equine serum butyrylcholinesterase (BChE). The resulting linear regression analysis, alongside the independent GC-MS benchmark, were used to evaluate the overall inhibitory potency of the samples, screen for matrix interferences and assess the applicability of this biochemical method for quantifying residual VX in long-term stored stockpiles.*

Keywords: *cholinesterases, nerve agent VX, enzymatic method, quantitative analysis.*

1. INTRODUCTION

The interactions of highly toxic organophosphates (OPs) with enzymes from the cholinesterase family (ChEs) have been the subject of scientific research for almost a century. In this area, numerous scientific studies are focused on the development of methods for the detection and quantitative analysis of these toxic compounds. Biochemical quantification of OPs relies on the irreversible nature of ChE inhibition by OPs and is based on measuring the residual enzyme activity after a certain time of reaction with the inhibitor. Under defined experimental conditions, the reduction in enzyme activity directly correlates with both the concentration of the inhibitor and the duration of its interaction with enzyme. In certain regimes, when the inhibitor is in large excess, the inhibition reaction follows pseudo-first-order kinetics and this correlation corresponds to equation:

$$\ln (v_t/v_0) = - k_i \cdot [I] \cdot t \qquad (1)$$

where k_i is the bimolecular inhibition constant, $[I]$ is the inhibitor concentration, v_0 is the initial velocity of the enzymatic reaction and v_t is the velocity after the inhibition period t. The bimolecular inhibition constant k_i is a characteristic property of a specific irreversible inhibitor and its efficacy against a target enzyme, which serves as a key metric for comparing the inhibitory potency of different compounds [1].

Different OPs show significant differences in inhibitory potency towards ChEs from different sources. The most potent OPs known are the lethal nerve agents, which are considered to be among the deadliest chemical warfare agents to date [2]. Although their development and stockpiling as weapons are strictly prohibited by the Chemical Weapons Convention (CWC), the use of nerve agents in research, testing and development within the field of chemical defense is permitted under strict compliance with the CWC's obligations, as it remains vital for advancing protective and medical countermeasures. Consequently, possessing reliable methods for their quantitative determination is essential to maintain safety and monitor these processes effectively. While various methods for the quantification of nerve agents have been described, they often require laborious sample preparation and expensive, high-resolution analytical devices. Compared to these sophisticated techniques, biochemical methods based on ChE inhibition are rapid, simple and cost-effective [3], offering a convenient and advantageous supplementary analytical tool for many laboratory applications.

Although there are few compounds with an inhibitory potency comparable to that of nerve agents, the results of enzymatic analysis can be affected by various chemical and environmental factors. Sampling and analysis of nerve agents from different storage containers led to the identification of a large number of impurities, the type

DOI: 10.5937/OTEH26136B

and quantity of which depended on various factors, such as the quality and type of precursors used in production, the stabilizers applied, the manufacturing process and the numerous reaction pathways driving various degradation processes during storage [4][5]. Any potential biological activity that these compounds might exhibit towards the enzyme could affect the accuracy of enzyme inhibition-based methods. This is particularly important when the analysis is performed under conditions where the concentration of potentially interfering compounds is many times higher than the concentration of the target analyte, which is the case with highly degraded inhibitors.

Nerve agent VX (O-ethyl S-(2-diisopropylamino)ethyl methylphosphonothiolate) is one of the deadliest chemicals known. For chemical forensics, the researchers analyzed three unstabilized VX samples using NMR, LC-HRMS, and GC-MS (CI and EI) and detected over 40 compounds, including synthesis by-products, degradation products, unreacted precursors, and contaminants such as phosphonic acids, phosphonates, phosphonothioates, alkyl sulfides, aminothioalkanes, and unidentified species [4]. Consequently, enzymatic tests must take these impurities into account, especially the possibility that the samples contain a compound known as EA 2192 (diisopropylaminoethyl methylthiophosphonic acid), which is potent ChE inhibitor and almost as toxic as VX itself.

In this work, a comparative analysis of the two VX samples with significantly different purity was performed using inhibition assays with acetylcholinesterase (AChE) from electric eel and butyrylcholinesterase (BChE) from equine serum. Additionally, GC-MS analysis was performed to obtain approximate data on the quantitative ratio of the remaining VX content in the tested samples. The aim was to investigate the impact of the impurities present on the quantitative comparison of VX stocks with different degradation profile by ChE inhibition assays and to consider the application of this biochemical method for the assessment of residual VX content in long-term stored samples.

2. MATERIALS AND METHODS

Lyophilized equine serum BChE and electric eel AChE (type V-S), as well as butyrylthiocholine iodide (BTCh), acetylthiocholine iodide (ATCh) and 5,5'-dithiobis (2-nitrobenzoic acid) (DTNB) were purchased from Sigma-Aldrich. All other reagents were of analytical grade, purchased from Sigma, Fluka or Riedel de Haën. VX samples were made available by the Military Technical Institute (Belgrade, Republic of Serbia).

Stock solutions of AChE and BChE were prepared by dissolving lyophilized enzymes in 50 mM phosphate buffer pH 7.2 (PB) and stored at 4 °C. Dilutions were made daily to obtain enzyme solutions with an approximate activity of 1 U/mL. A solution of DTNB (4.8 mM) was prepared in PB. Substrate solutions, ATCh (30 mM) and BTCh (60 mM), were prepared in distilled water. Stock solutions of VX samples (10 % v/v) were prepared in 2-propanol weekly and stored at 4 °C. On the day of the experiment, stock solutions were kept at room temperature for 1 h and than appropriately diluted in 2-propanol to obtain VX sample solutions for use in the inhibition assays.

2.1. Inhibition assays

The AChE and BChE activity measurements were performed essentially according to the method of Ellman [6], using ATCh or BTCh as the substrate, respectively, and DTNB (Ellman's reagent) as the indicator. In brief, the enzyme solution (75 µL) was added to a cuvette containing PB (2.6 mL) pre-incubated at 25 °C, followed by addition of the tested VX sample solution (25 µL). After mixing, the content was incubated for 20 min at 25 °C. The enzymatic reaction was then started by the addition of DTNB (200 µL) and corresponding substrate (100 µL). The formation of the yellow anion obtained from the reaction between Ellman's reagent and the thiocholine generated by enzymatic hydrolysis of the substrate was monitored on a Cary 60 UV/VIS spectrophotometer (Agilent Technologies) by measuring the increase in absorbance at 412 nm for 2 min at 12 s intervals. One unit of enzyme activity was defined as the amount of enzyme that catalyzes the hydrolysis of 1 μmol of substrate per minute under the described conditions.

For each enzyme, a range of dilutions of both VX samples was used to cover a broad spectrum of different inhibition levels, and results that included residual enzyme activity between 10 % and 80 % were considered for data processing. To determine the initial enzyme activity (100 %), measurements were carried out as described above, except that 2-propanol was used as the sample instead of VX solution.

Considering that the VX concentrations in the tested samples were unknown, a more convenient way to process the experimental data was to present the dependence described by equation (1) as a function of the mass concentration of the VX sample instead of the concentration of VX in the incubation mixture, which after corresponding transformation and rearrangements gives the following relationship:

$$\log(100 \cdot \frac{A_r}{A_0}) = -\frac{k_i \cdot Q \cdot t \cdot 10^{-6}}{2{,}303 \cdot R \cdot M_{VX}} \cdot C_m + 2 \qquad (2)$$

where A_r and A_0 are the residual and initial enzyme activities, k_i is the bimolecular inhibition constant ($M^{-1}min^{-1}$), Q is the purity coefficient of VX in the tested samples, t is the inhibition time (20 min), R is the dilution factor of the VX sample solutions in the incubation mixture (108), M_{VX} is the molar mass of VX (267.38 $gmol^{-1}$), and C_m is the mass concentration of the VX sample solutions (ng/mL).

Because the VX samples were a complex mixture rather than a pure compound, the obtained data points were fitted via linear regression in MS Excel using the empirical equation:

$$\log(A_r\%) = \boldsymbol{B} \cdot C_m + \boldsymbol{A} \qquad (3)$$

where A_r% is the percentage of residual enzyme activity.

The resulting regression outputs were used to evaluate and compare the overall inhibitory potency among the tested samples and to screen for potential matrix interferences caused by impurities.

2.2. GC-MS analysis

Each of the two VX samples was prepared at two nominal concentration levels, approximately 4.7 and 9.0 μg/mL, using acetonitrile as the solvent. The lower- and higher-concentration preparations were designated **S1** and **S1h** for **VX1** sample, and **S2** and **S2h** for **VX2** sample, respectively. Semiquantitative estimation of the VX content was performed using naphthalene-d8 as an internal standard at a final concentration of 2 μg/mL. The samples were analyzed using a Shimadzu GCMS-QP2020 instrument, and the chromatograms and peak heights were evaluated using LabSolutions software. To screen the chromatograms for VX and VX-related degradation products, the extracted-ion chromatogram (EIC) at m/z 114 was examined. This ion is a characteristic, high-abundance fragment of VX and related compounds containing the 2-(diisopropylamino)ethyl moiety. The instrumental conditions are summarized in **Table 1**. Splitless injection was used to improve the detection of minor sample components and to facilitate comparison of their chromatographic responses.

Table 1. GC-MS operating conditions

GC conditions	
Parameter	**Value**
Initial oven temperature	40 °C (3 min)
Oven temperature program	40-150 °C at 10 °C/min; 150-280 °C at 25 °C/min; hold at 280 °C for 10.8 min
Injector temperature	250 °C
Injection mode	Grob-type splitless injection; splitless time 0.75 min
Column	DB-5
Column dimensions	30 m × 0.25 mm i.d. × 0.25 µm
Carrier gas	Helium; linear velocity 32 cm/s
MS conditions	
Parameter	**Value**
Transfer-line temperature	280 °C
Ion-source temperature	230 °C
Detector temperature	150 °C
Electron energy	70 eV
Scan range	m/z 35-500
Scan rate	3.15 scans/s
Library	NIST 05 Mass Spectral Database

3. RESULTS AND DISCUSSION

3.1. Inhibition assays

The enzyme inhibition assays were used for comparative analysis of two VX samples from different long-term stored stocks with distinct storage-induced degradation profiles. Sample **VX1** was taken from a frequently pipetted stock stored in a glass bottle with screw cap that was opened and closed periodically, while the sample **VX2** was from the flame-sealed glass ampoule. The residual AChE and BChE activities within the range of 20–80 % after 20 min inhibition were determined using 8 different mass concentrations of each VX sample for each enzyme. The obtained data points and their linear fits according to equation (3) are shown in **Figure 1** and **Figure 2**. The resulting semi-logarithmic plots confirmed a monotonically decreasing trend in concentration-dependent residual activity for both enzymes and both tested samples. Visually, a superior inhibitory potency was observed for the **VX2** sample, while more pronounced data scattering was evident for the **VX1** sample in both enzymatic assays. This pronounced scattering is likely attributed to the presence of interfering impurities, which may dynamically interact with the enzyme or the inhibitor, destabilizing the inhibition kinetics.

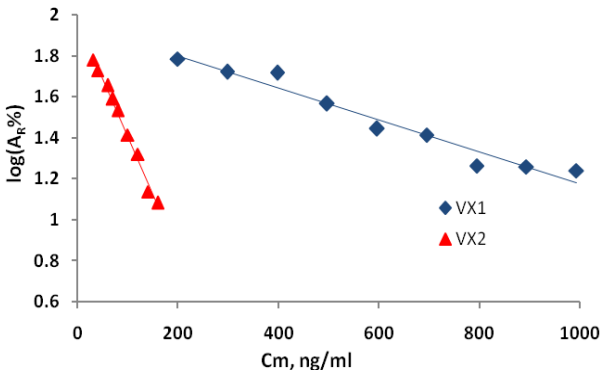

Figure 1. Semi-logarithmic plot of AChE inibition by **VX1** and **VX2** samples

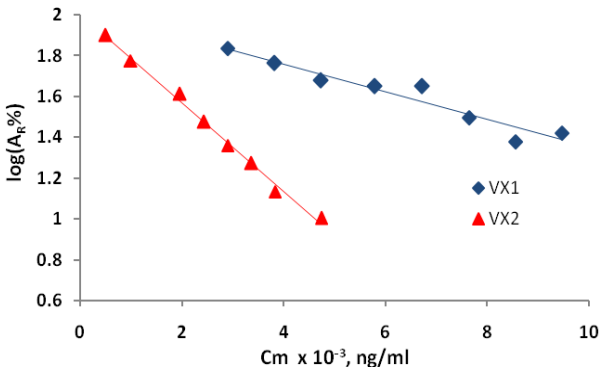

Figure 2. Semi-logarithmic plot of BChE inibition by **VX1** and **VX2** samples

The visual observations are in agreement with the expected quality of the tested samples, since the **VX1** sample originated from a source whose contents were more susceptible to handling-induced degradation and chemical alteration. In addition, AChE was more susceptible to inhibition by both tested samples, requiring much lower inhibitor concentrations to achieve the same reduction in activity as in BChE. This reveals that the AChE-based system provides a significantly higher sensitivity for the analysis of different VX samples compared to the BChE-based inhibition assay.

To further evaluate these effects quantitatively, we focused on the linear regression outputs for model presented by equation (3), which are shown in **Table 2**. The parameter ***B*** corresponds to the slope of the regression line and accounts for both the inhibitory potency and the purity factor of the tested samples, while the parameter ***A*** denotes the intercept on the ordinate and corresponds to the initial enzyme activity in the absence of the inhibitor, with theoretical value of 2. The calculated values for both parameters highly supported the visual findings and reflected the distinct inhibition profiles influenced by the purity-induced factors of the each sample. The obtained intercepts (***A***) for both enzymatic systems showed minor deviations from the theoretical value, confirming that the model closely reflects the initial enzyme activity before the inhibition. The slope values (***B***) corresponded to a higher sensitivity of AChE compared to BChE and a superior potency of **VX2** sample over **VX1**, the latter implying a higher purity of the **VX2** sample. The lower coefficients of determination (R^2) and higher standard errors (***SE***) associated with **VX1** sample successfully quantified the higher degree of experimental noise and data scattering observed visually, likely driven by the presence of interfering impurities. Conversely, the high R^2 values and lower ***SE*** values observed for **VX2** across both enzymes pointed towards less interference caused by impurities compared to **VX1**.

Table 2. The linear regression outputs: the slope (***B***), the intercept (***A***), standard errors of ***B*** and ***A*** (SE_B, SE_A) and the coefficient of determination (R^2)

ChE/sample	$B \pm SE_B$	$A \pm SE_A$	R^2
BChE/VX1	$(-6.77\pm0.77)\times10^{-5}$	2.029±0.050	0.93
BChE/VX2	$(-21.68\pm0.67)\times10^{-5}$	2.003±0.020	0.99
AChE/VX1	$(-7.76\pm0.62)\times10^{-4}$	1.953±0.040	0.96
AChE/VX2	$(-56.26\pm2.03)\times10^{-4}$	1.969±0.019	0.99

Linearization of the data for concentration-dependent inhibition was based on the model represented by equation (2), which was derived assuming pseudo-first order conditions, the presence of only one active inhibitory species (VX), and the absence of any interference caused by impurities in VX samples. If all of the above assumptions were satisfied, the slope ratio of samples **VX2** and **VX1** (B_{VX2}/B_{VX1}) would be the same for both ChE assays, as would the slope ratio determined by AChE and BChE assays (B_{AChE}/B_{BChE}) for each tested sample. This follows from the variables that define the slope in ideal conditions according to equations (2) and (3), since the expression for the slope ratio would reduce to the purity ratio (Q_{VX2}/Q_{VX1}) in the first case and to the bimolecular inhibition constant ratio ($k_{i(AChE)}/k_{i(BChE)}$) in the second.

To evaluate whether these enzyme inhibition assays can be used to quantitatively compare the VX content in tested samples, the ratio of the regression slopes B_{VX2}/B_{VX1} was calculated for each enzyme. Under ideal pseudo-first-order kinetics with a single active inhibitory component and no matrix interference, this ratio should directly reflect the relative purity of the two samples and remain constant regardless of the enzyme used. However, the experimental data (**Table 3**) contradict this ideal model, as they revealed a significant discrepancy between the values obtained by AChE and BChE assays. The facts that AChE-based test yielded a slope ratio that was more than twice the value obtained by BChE (7.25 vs. 3.20) and that the slope ratios were enzyme-dependent, strongly indicate that the ideal kinetic assumptions are not met. This discrepancy provides definitive evidence that the VX sample impurities do not behave as inert diluents, but actively engage in enzyme-specific interactions or interfere with the primary inhibitors bioavailability. These findings demonstrate that ChE inhibition assays cannot be universally and reliably applied for the direct quantitative cross-comparison of VX content across the samples of different and unknown purity, as the unpurified samples matrices actively interferes with the inhibition kinetics in an enzyme-specific manner.

Table 3. Comparative presentation of regression-derived slope ratios and the resulting calculated values: relative purity of **VX1** sample versus **VX2** sample (Q_{VX1}), and the relative k_i of BChE versus AChE ($k_{i(BChE)}$).

Enzyme	B_{VX2}/B_{VX1}	Q_{VX1} (%)
AChE	7.25	13.79
BChE	3.20	31.21
Sample	B_{AChE}/B_{BChE}	$k_{i(BChE)}$ (%)
VX1	11.46	8.72
VX2	25.95	3.85

Since the bimolecular inhibition constant is a characteristic property of each individual enzyme-inhibitor system, a biochemical fingerprint for the identification of an unknown irreversible inhibitor can be obtained by assessing its inhibitory potency against a group of structurally different or related enzymes. The inhibition spectrum (or relative inhibitory response profile), obtained by normalizing all k_i values for the enzymes in the group as a percentage of the highest value within that set, serves as a unique multi-enzyme barcode for identifying inhibitors.

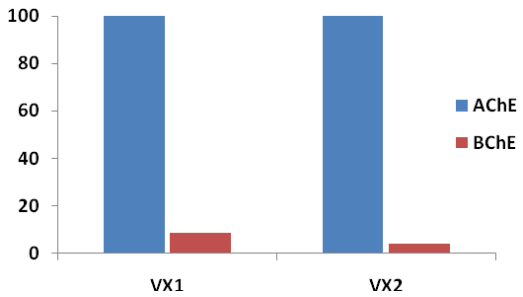

Figure 3. Inhibition spectrum of **VX1** and **VX2** samples

The two-enzyme inhibitory spectrum was established for each VX sample using relative k_i values derived from the ratio of the regression slopes between AChE and BChE. Although this approach mathematically does not provide new independent information, the graphical comparison

of these spectra **(Figure 3)** allows for visual observation of asymmetry between the two tested samples.

3.2. GC-MS analysis

The chromatogram of the **S1h** sample is shown in **Figure 4**. The total ion chromatogram (TIC) is shown in black, whereas the extracted-ion chromatogram at m/z 114 is shown in pink. Only a very small VX peak was observed at a retention time of approximately 17.350 min. Two additional relevant compounds were tentatively identified by comparison with the NIST library: *bis*[2-(diisopropylamino)ethyl] sulfide at 18.832 min, with an 81% library match, and *bis*[2-(diisopropylamino)ethyl] disulfide (DES) at 21.175 min, with an 88 % library match. The markedly lower VX response relative to the DES response qualitatively indicates extensive degradation of the **S1h** sample, only a small residual amount of the parent compound remaining.

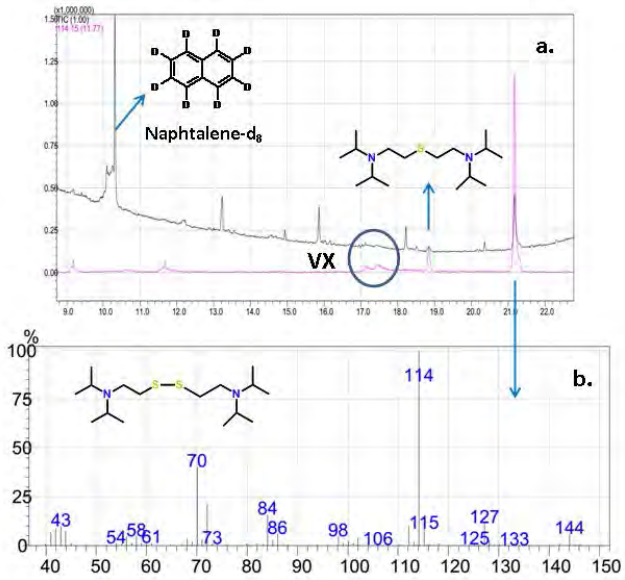

Figure 4. (a) Chromatogram of the **S1h** sample: TIC (black) and EIC at m/z 114 (pink); **(b)** mass spectrum of *bis*[2-(diisopropylamino)ethyl] disulfide (DES).

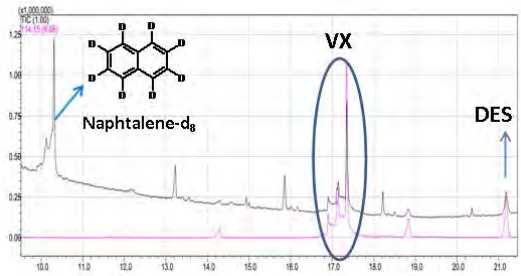

Figure 5. Chromatogram of the **S2h** sample: TIC (black) and EIC at m/z 114 (pink).

In the **S2h** chromatogram (**Figure 5**), VX was the dominant component, accompanied by smaller peaks tentatively assigned to DES and the corresponding sulfide. Pronounced tailing of the VX peak was observed, likely reflecting non-optimized chromatographic conditions. To assess whether the relative VX contents could be compared semi-quantitatively, the VX-to-internal-standard peak-height ratios were calculated for the **S2** and **S2h** samples. The ratio between these responses was consistent with the ratio of the nominal sample concentrations, supporting the use of this approach for a rough relative comparison under the applied conditions. On this basis, the residual VX contents in **S1** and **S1h** samples were estimated to be approximately one-fifth of those in the corresponding **S2** and **S2h** samples, indicating a relative purity of 20 % for the **VX1** sample compared to the **VX2** sample (Q_{VX1}). Several additional peaks observed in both chromatograms at retention times of approximately 13.2, 15.9, and 18.2 min did not contain the m/z 114 ion and were tentatively attributed to long-chain hydrocarbon contaminants originating from the GC column or inlet septum.

3.3. The practical relevance of ChE inhibition assays and future perspectives

The quantitative ratio of the remaining VX content in the tested samples determined by the slope-ratio method using AChE, BChE and by GC-MS analysis was found to be 7.25, 3.20 and 5, respectively, corresponding to a relative purity of the **VX1** sample of 14 %, 31 % and 20 %.

Despite the observed discrepancies between enzymatic assays and reference GC-MS analysis, the obtained results have significant practical and predictive value for analytical applications. This significance is manifested trough two key aspects, the first of which relates to the validity of the method as a screening tool, and the second to the dependence of the assay accuracy on the VX content ratio in the samples and their absolute purity.

Regarding the former, both applied enzymatic assays consistently identified the **VX1** sample as unusable for R&D applications. The results show that VX content in the **VX1** sample is below 31 % relative to the sample of **VX2**, so its absolute purity cannot exceed 31 %, the maximum value that can be reached if the **VX2** sample were 100 % pure. From an analytical perspective, whenever the determined quantitative ratio between samples exceeds 3, unambiguous information regarding the unsuitability of at least one sample is generated. In this context, the numerical discrepancies between the methods lose relevance, as the primary objective of rapid screening of inappropriate samples is successfully achieved. Therefore, these enzymatic assays provide a clear, rapid diagnostic signal to disqualify low-purity samples without immediately relying on cost-intensive chromatographic techniques.

Considering the second aspect, it is reasonable to expect that the convergence of results among different methods will increase as the difference in the quantitative inhibitor ratio decreases. However, this trend is a direct function of the absolute purity of the tested samples, which dictates the profile and variance of the interfering matrix impurities. Assuming that the ratio of residual VX content in the tested samples was exactly 5, the feasibility of using these enzyme assays to obtain analytically acceptable results can be evaluated through two extreme hypothetical scenarios, which are presented below.

In the high-purity scenario (e.g., samples of **VX2** and **VX1** had purity of 95 % and 19 %), the difference in the impurity matrix was extreme (5 % vs. 81 %), explaining the pronounced deviations in the enzymatic assays. In this case, samples with a lower quantitative ratio (< 5), regardless of their absolute purity, may only have a reduced difference in impurity levels. Therefore, it can be predicted that their testing would inherently lead to analytically acceptable agreement between the two enzyme assays, at the point when their quantitative ratio falls below a certain limit.

In the low-purity scenario (e.g., samples of **VX2** and **VX1** had purity of 5 % and 1 %), the impurity fractions were inherently similar (95 % vs. 99 %). Reducing the quantitative ratio would reduce the difference in impurity levels, but only if the absolute purity of the tested samples remain at the level of the low purity scenario. However, samples with higher absolute purity and the same quantitative ratio of 5 may only have an increased difference in impurity levels and consequently a greater difference in enzyme assay results. In this case, the performance of assays at ratios below 5 for a highly purified sample remains an open question.

Given that GC-MS analysis confirmed a significantly higher abundance of degradation products in **VX1** sample, the low-purity scenario can be rejected. This finding, supported by the results of ChE inhibition tests which pointed at high impurity loads in **VX1** sample, implies that the test conditions were closer to the high-purity scenario. Accordingly, the assumption that lower quantitative ratios of the tested VX samples will yield improved correlation in the enzymatic assays is well-founded. To fully define the accuracy windows and practical boundaries of enzymatic inhibition assays in VX sample analysis, further systematic investigations and development of matrix-matching calibration strategy are required. The focus of future work should be on establishing a robust calibration framework and selecting the most resilient and suitable single enzyme for high-throughput, rough quantitative profiling of partly-degraded VX samples.

5. CONCLUSION

The aim of this work was to examine the influence of impurities, present in two VX samples with different degradation profiles, on the results of ChE inhibition assays and their application in the quantitative comparison of residual VX content in stocks that have undergone distinct storage-induced decomposition.

The experimental results strongly supported the initial assumption regarding the varying degrees of purity between the two tested samples. The linear regression analysis for the inhibition of AChE and BChE yielded distinct profiles regarding both inhibitory potency and data consistency, driven by purity-related matrix interferences in each sample. The calculated relative purity values for **VX1** sample determined by AChE and BChE inhibition assays correctly classified the sample as heavily contaminated and unsuitable for application, a finding fully supported by preliminary GC-MS data. The dual-enzyme screening approach demonstrated excellent feasibility for ensuring the accuracy and reliability of enzyme-based assays during the quantitative determination of target inhibitors in non-homogeneous samples. The combination of regression metrics and slope ratio divergence across two distinct enzymes served as an effective tool to detect the presence of interfering impurities, assess relative sample heterogeneity and evaluate the susceptibility of different target enzymes to matrix effects.

The proposed methodology provides a robust and effective analytical framework for sample triage, preliminary quality assessment and semi-quantitative estimation of relative inhibitor content prior to definitive chromatographic analysis. While GC-MS remains indispensable for the final, precise quantification of highly heterogeneous matrices, the enzymatic approach serves as an excellent first-line screening method. Definitive mapping of the applicability threshold, which includes working with a broader sample library with varying purity gradients, a wider panel of alternative enzymes, and systematic cross-referencing with GC-MS data, will optimize this inhibition assay into a standardized screening protocol, fully capable of achieving a high degree of accuracy within analytically acceptable results.

Abstract: *The paper presents the results of an experimental investigation of the magnetoimpedance (MI) response of an $Fe_{72}Al_5Ga_2P_{11}C_6B_4$ amorphous ribbon, prepared by the melt-spinning rapid quenching technique on a rotating copper wheel. Characterization revealed that the internal configuration and the profile of the MI curves exhibit a strong frequency dependence, reaching a maximum MI ratio value of 31.3% at an operating frequency of 36.11 MHz without an external magnetic field. With an increase in the magnetic field intensity, a continuous decrease in the MI ratio values is observed. At frequencies above 75 MHz, slight distortions in the profile of the experimental curves are noticed at a field strength of approximately 8 kA/m, which hints at the presence of an internal magnetic anisotropy field. Considering the completely amorphous structure of the sample in the as-cast state, this aspect cannot be analyzed in more detail at this stage; however, its clear expression and dominant influence on the soft magnetic properties are expected after the thermo-activated transformation of the amorphous matrix into a nanocrystalline state via controlled isothermal annealing.*

Keywords: *Magnetoimpedance effect, Amorphous alloys, Melt-spinning, Magnetic anisotropy.*

1. INTRODUCTION

The phenomenon of magnetoimpedance (MI) represents a specific electromagnetic response observed in a narrow group of soft magnetic alloys with an amorphous or nanocrystalline structure. This effect is manifested through an intensive variation in the complex impedance of a ferromagnetic sample under the influence of an external direct current (DC) magnetic field. Since its discovery at the end of the last century, this phenomenon has become a fundamental platform for the development of high-sensitivity magnetic field sensors used in automotive, military, and aerospace industries [1-8].

It has been experimentally proven that the impedance module of a ferromagnetic material decreases with an increase in the external field intensity, while simultaneously increasing with the frequency of the excitation current flowing through the sample. Quantification of this effect is most commonly performed by defining the MI ratio according to the following equation:

$$\Delta Z/Z(\%)=100\% \cdot (Z(H)-Z(H_{max}))/Z(H_{max}), \quad (1)$$

where $Z(H_{max})$ represents the reference impedance value measured at the maximum intensity of the applied external magnetic field. Depending on the internal magnetic configuration and processing technology, under zero-field conditions (H = 0), the influence of remanent magnetization may come into play, the disappearance of which with an increasing field causes a characteristic asymmetry in the MI diagrams for opposite directions of the applied field (for the -H and +H directions).

The frequency dependence of the magnetoimpedance is directly induced by the skin effect, which is described by the equivalent penetration depth of the current through the conductor. This value increases due to the drop in the total magnetic permeability in a strong magnetic field, while it decreases with increasing frequency. The action of a high-frequency alternating current induces strong eddy currents in the sample, causing the displacement of charge carriers and the concentration of electrical energy towards the peripheral regions of the conductor. The penetration depth is defined by the following relation:

$$\delta_m=(\rho/(\pi\cdot\mu\cdot f))^{0.5}, \quad (2)$$

where σ is the electrical conductivity, μ is the magnetic permeability, and f is the frequency of the alternating current. In addition to pure electromagnetic parameters, the MI response is crucially influenced by the domain structure of the magnetic material, which is a direct function of the internal structural arrangement and the applied sample geometry. Therefore, the maximum values of the MI ratio

DOI: 10.5937/OTEH26137S

represent a compromise between the frequency and the strength of the magnetic field, which is precisely defined by experimental measurements.

2. EXPERIMENTAL PROCEDURE

The subject of experimental investigations in this study is a multi-component alloy with the composition $Fe_{72}Al_5Ga_2P_{11}C_6B_4$. Samples were synthesized in the form of thin ribbons (geometric dimensions: width about 2 mm, thickness about 40 μm) by applying the technology of ultra-rapid quenching of the liquid alloy melt on a rotating copper wheel (melt-spinning method) in a protected atmosphere.

The characterization of the magnetoimpedance (MI) effect was performed in a homogeneous external magnetic field with a maximum intensity up to 15 kA/m, which was generated using a custom-designed and controlled system with two pairs of Helmholtz coils providing field homogeneity above 99% [5, 9]. The measurement of the complex impedance of the investigated ribbon samples was realized in a wide frequency range using a vector network analyzer (instrument: Vector Network Analyzer Agilent 8753ES).

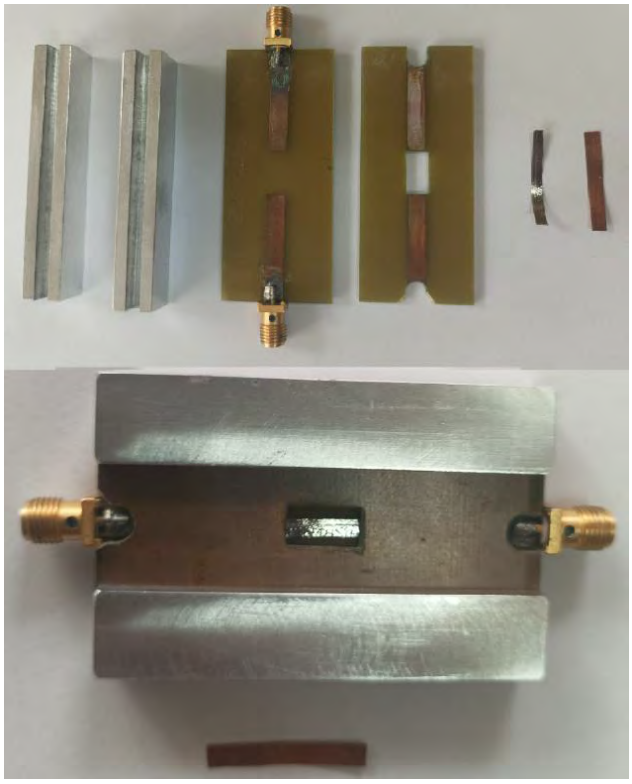

Figure 1. Sample holder configuration: (top) components of the microstrip holder, (bottom) amorphous ribbon sample positioned within the holder, showing the short-circuit element used for network analyzer calibration.

The sample holder was specifically designed in the form of a microstrip to accommodate the specific geometry of the investigated ribbon (Figure 1). The ends of the electrical contacts were placed at a fixed distance of 1 cm, while the total length of the measured ribbon was at least 2 cm to eliminate the influence of contact resistances at the connection points. The measurement is realized by connecting to a single port of the instrument, which automatically converts the reflection S_{11} parameters into the impedance of a 1 cm long sample. The systematic error introduced by the cables and the holder itself was eliminated by precise calibration of the measurement setup using a copper short-circuit jumper of similar dimensions.

The structural properties of the obtained ribbons in the initial state were investigated by X-ray diffraction (XRD) on a Rigaku SmartLab apparatus using a Cu Kα radiation source. The identification of the amorphous nature of the material was performed based on the shape and geometry of the diffraction lines recorded at room temperature. The surface morphology and topography of the free side of the amorphous ribbon were analyzed using scanning electron microscopy (SEM JEOL JSM-6610-LV), while the chemical homogeneity and quantitative composition of the constituent elements of the alloy were verified by energy-dispersive X-ray spectroscopy (EDS).

3. RESULTS AND DISCUSSION

3.1 XRD Analysis

X-ray structural analysis (XRD) confirmed the amorphous character of the synthesized ribbon in the initial as-cast state. In the obtained diffractogram (Figure 2), only a characteristic broad diffraction maximum (the so-called amorphous halo) is observed in the 2θ angle range between 40° and 50°. The complete absence of any sharp and intense Bragg reflections clearly indicates the absence of long-range crystalline order within the investigated material. This appearance of the diffraction profile unequivocally confirms that the applied ultra-rapid melt quenching technology successfully suppressed premature crystallization processes and effectively froze the structural disorder in the sample.

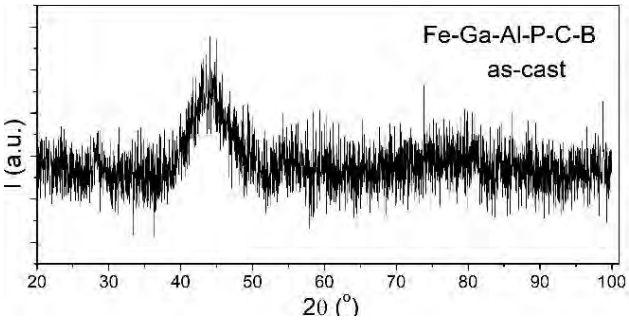

Figure 2. XRD pattern of the $Fe_{72}Al_5Ga_2P_{11}C_6B_4$ amorphous ribbon in the as-cast state.

3.2 SEM and EDS Analysis

Scanning electron microscopy (SEM) was applied for direct investigation of the surface morphology of the free (shiny) side of the cast ribbon. The micrograph shown in Figure 3 demonstrates high structural homogeneity and surface smoothness, without the presence of microporosity, cracks, or early crystal nuclei that could degrade the magnetic softness of the ribbons.

Concurrently, EDS analysis (Figure 4) was used for detailed chemical characterization of the sample. The results of quantification in atomic and weight fractions,

summarized in Table 1, confirm that the experimentally determined composition completely corresponds to the nominal stoichiometry of the $Fe_{72}Al_5Ga_2P_{11}C_6B_4$ alloy, testifying to the high chemical uniformity of the material along the entire ribbon sample.

Total:	100.00	100.00

3.3 Magnetoimpedance Measurements

The diagram in Figure 5 shows the MI ratio as a function of the excitation current frequency for different values of the external magnetic field. Experimental characterization established that the MI effect is highly pronounced in the frequency interval from 17 MHz to 40 MHz. The MI ratio reaches its maximum value at a frequency of 36.11 MHz under zero external field conditions (H = 0 A/m) and amounts to 31.3%.

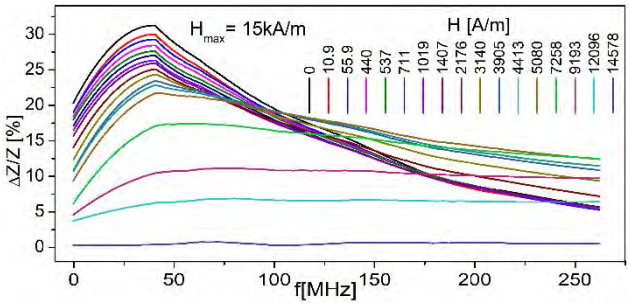

Figure 5. Frequency dependence of the MI ratio for different external magnetic field strengths up to H_{max} = 15 kA/m.

Analysis of the diagrams in Figures 5 to 8 reveals a constant, monotonic decreasing trend of the MI ratio with an increase in the magnetic field intensity acting longitudinally on the measured sample. This decrease in impedance is a consequence of the rotation of the magnetization vector in the direction of the external magnetic field. Also, the profile of the MI curves shows constant growth with increasing frequency up to 36.11 MHz (Figure 6), while with a further increase in frequency above this value, the curves are in a noticeable decline (Figure 8).

At frequencies higher than 75 MHz, specific deformations and distortions of the experimental curve profiles are observed at an external magnetic field strength of around 8 kA/m. Considering that the investigated alloy is completely amorphous in the initial state, this phenomenon cannot be analyzed or quantified in detail at this stage of the research; instead, the mentioned distortions serve as an early indication that only hints at the presence of an internal magnetic anisotropy field. This anisotropy is currently overshadowed by internal stresses generated during the rapid cooling of the liquid alloy melt [10 - 12].

Further insight into the frequency range from 18 to 36 MHz shows that the curves are almost completely overlapped (Figure 7). Therefore, it is expected that a controlled thermo-activated treatment (annealing) will lead to structural relaxation and transformation of the amorphous matrix into a two-phase nanocrystalline structure (with a dominant α-Fe(Si) phase), which will enable a clear expression of the magnetic anisotropy field and a drastic improvement in the MI performance, which will be the subject of our future work.

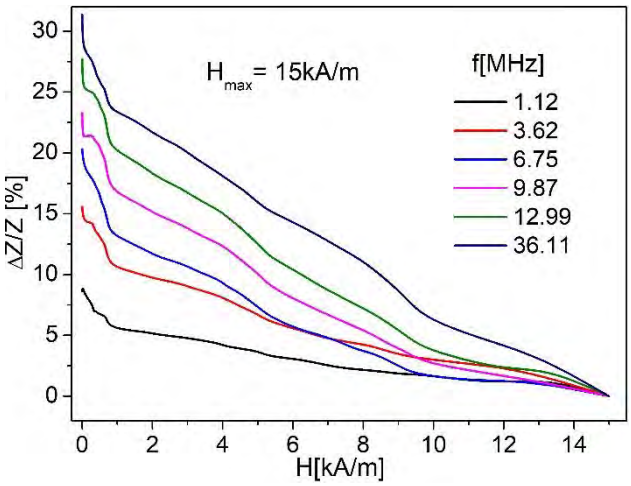

Figure 6. Magnetic field dependence of the MI ratio profiles at low excitation current frequencies ranging from 1.12 MHz to 36.11 MHz.

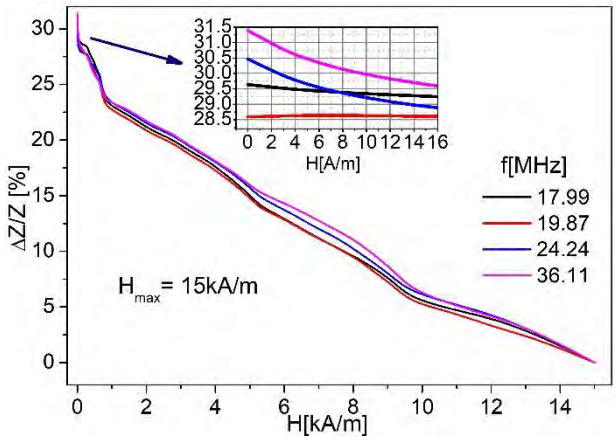

Figure 7. Superposition and convergence of the MI ratio curves in the optimal frequency range from 17.99 MHz to 36.11 MHz.

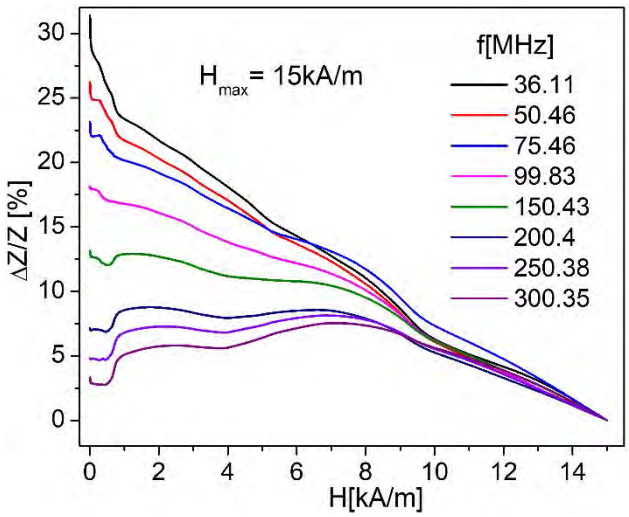

Figure 8. Magnetic field dependence of the MI ratio profiles at high frequencies from 36.11 MHz to 300.35 MHz, showing profile distortions near 8 kA/m that hint at the internal magnetic anisotropy.

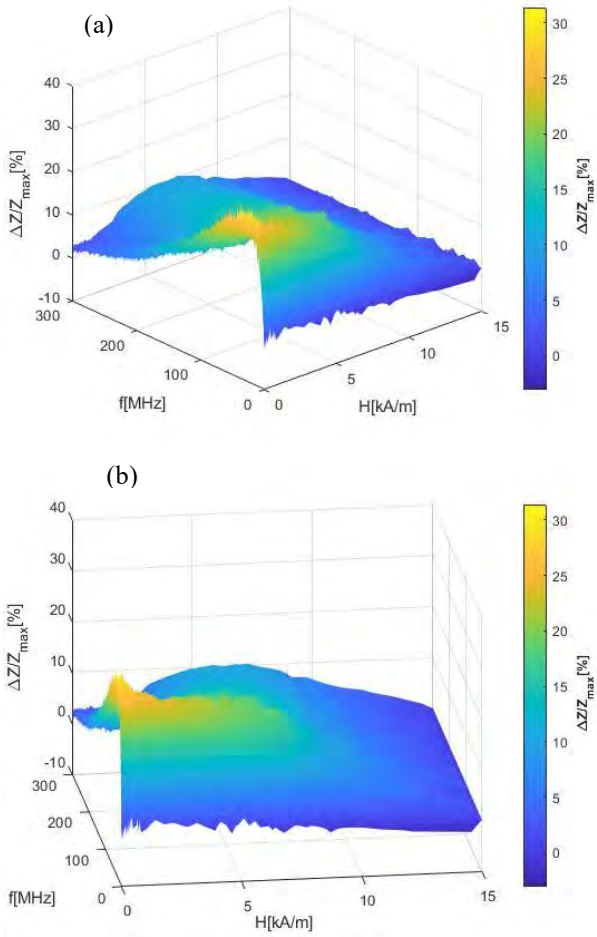
In order to comprehensively evaluate the simultaneous influence of the excitation current frequency and the external magnetic field strength on the magnetoimpedance properties of the investigated alloy, three-dimensional dependence diagrams along with a corresponding two-dimensional projection map were constructed, as presented in Figure 9. On the three-dimensional surface plots (Figures 9a and 9b), the spatial profile of the MI response is clearly and explicitly observed across the entire measured frequency range up to 300 MHz. This representation allows an unequivocal insight into the curve evolution, where a dominant peak of the MI ratio stands out at 36.11 MHz under low external field conditions, followed by a symmetrical drop in impedance with increasing field strength due to the magnetic saturation of the sample. On the other hand, the 2D projection color map from the top view (Figure 9c) provides a precise topographic overview of the impedance contours, where the optimal frequency zone for the stabilization of the effect is distinctly demarcated colorimetrically. These visualizations confirm the high linearity and sensitivity of the MI response in the characteristic domain, establishing a crucial experimental foundation for the precise engineering of future magnetic sensors based on this amorphous ribbon.



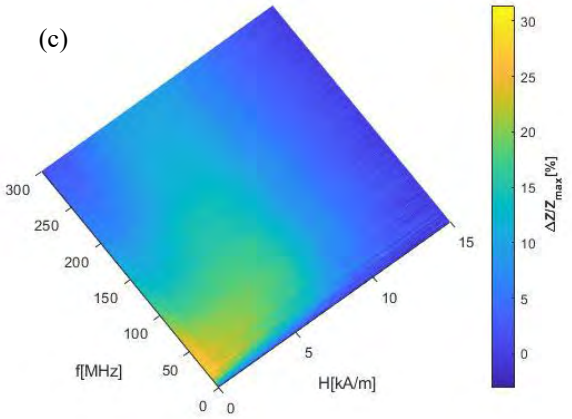


Figure 9. Magnetoimpedance (MI) ratio profiles as a multi-variable function of the excitation current frequency ,f and external magnetic field strength**: (a)** 3D surface plot from the front view emphasizing low-frequency peaks, **(b)** 3D surface plot from the rear view illustrating the high-frequency drop and profile distortions, and **(c)** 2D projection color map (top view) highlighting the optimal operational frequency window and convergence zones.

5. CONCLUSION

In this work, the magnetoimpedance response of an amorphous ribbon of a multi-component $Fe_{72}Al_5Ga_2P_{11}C_6B_4$ alloy obtained by the melt-spinning method was successfully evaluated. It was experimentally confirmed that the investigated material achieves its optimal MI profile at a characteristic frequency of 36.11 MHz, where the value of the MI ratio is 31.3% in the absence of a field. The shape and trend of the obtained curves show a high sensitivity to changes in the frequency of the excitation signal.

At high frequencies above 75 MHz and at a field strength of 8 kA/m, specific curvatures of the experimental curves were observed, representing an early indication and a hint of the existence of a magnetic anisotropy field. Since this phenomenon is overshadowed by structural disorder and residual casting stresses in the initial state, a complete analytical picture of the anisotropy field, as well as the projected increase in magnetic softness and sensitivity of the sensor element, are planned in the next phase through controlled isothermal annealing and the generation of a stable nanocrystalline matrix.

Abstract: *The aim of this work was to establish the correlation between thickness and impact energy. The steel tested in this work was 42CrMo4 steel in quenched and quench and tempered condition. Impact energy was measured on impact Charpy tester for specimens with width of 10 mm and thickness of 5,0mm, 7,5 mm and 10,0 mm. After austenitization of 850˚C/15minutes and quenching in oil, one group of samples were tested, while other after subsequent tempering of 560˚C/90minutes. For quenched samples are characterized with brittle fracture and impact toughness of 6,8 J, 9,1 J and 14.2 J for 5,0mm, 7,5 mm and 10,0 mm samples respectively. For tempered samples are characterized with mixed ductile and brittle fracture and impact toughness of 34,4 J, 56,2 J and 69,1 J for 5,0mm, 7,5 mm and 10,0 mm samples respectively. In both groups, cross section of samples was increased linearly, but impact energies did not follow the same trend. This behavior was attributed to permanent presence of plastic deformation, no matter the microstructure, i.e. absence of proportionality between cross-section surface and plastically deformed areas. Also, this feature is more pronounced in quenched samples, due to very low toughness of martensite.*

Keywords: *Charpy notch toughness, thickness, fracture.*

1. INTRODUCTION

Steel is the most dominant structural material with annual production of more than 1.85 milions of tonnes [1]. At the same time, continuos development of new grades of steels takes place. Improvement of strength and toughness is the only approach to decrease cross sections of steel structures, enhancing decrease in weight of construction itself [2]. These trends lead to design of steel sections, pipes etc. with smaller thickness. Today, structural steels are produced in hot rolling with thickness of as low as 1.5 mm [2-4].

Strength of new steels is very well controlled by strengthening mechanisms, through roles of microalloying elements and hot rolling parameters [5]. On the other hand, toughness is parameter related to energy release and is much more statistically described. During Charpy notch impact testing, samples are designed to localize crack initiation on the tip of machined groove [5-8]. Therefore, start of crack initiation depends both on quality of the notch (machining) and microstructure and impurities in steel at the tip. This is the reason why all these details are clearly described in Standards [9].

The aim of this paper is to test the same steel in two conditions with different sample thickness and compare obtained impact energies.

2. EXPERIMENTAL PART

Chemical composition of steel 42CrMo4 tested in this work is given in table 1. Steel was forged, and machined. Two groups of samples were tested, one after quenching (austenitization at 850˚C/15minutes and quenching in oil) and another after quenching and tempering (austenitization at 850˚C/15minutes followed by oil quenching and tempering at 560˚C/90minutes).

min	0,39	0,65	0,75	0,15			0,15
max	0,46	1,10	1,20	0,25	0,035	0,040	0,30

Charpy impact testing. The testing was performed using the SCHENCK TREBELL 150/300 J instrumented Charpy pendulum (Instron GmbH, Germany).

In order to evaluate the influence of different thickness on Charpy impact toughness samples had standardized [9] thickness of t=5,0mm, t=7,5mm and t=10,0mm, according to sketch shown in Figure 1.

Observation of fractured surface was done using stereo microscope.

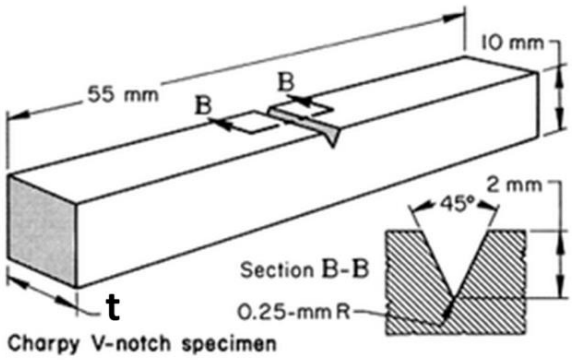

Figure 1. Sketch of Charpy impact specimen [7-8].

3.RESULTS

Fractured surface. Typical fractured surfaces obtained in quenched samples nad tempered samples are shown in Figure 2 and 3 respectively. Measured Charpy impact toughness for all specimens are given in Tables 2 and 3, respectively.

Table 2. Charpy impact energies for quenched samples

Thickness t, mm	Quenched, CVN, J	
	measured	Area normalized
5,0	6,8	6,8
7,5	9,1	10,2
10,0	14,2	13,6

In all three cases, fractured surface of quenched samples are flat and perpendicular to cross section. Crack initiation places are designated by arrow in each fractograph. Starting from crack initiation places, a network of river patterns stretch out (extend) to the edges of each sample [11,12].

At the lower edges of the samples, a small surface indicating presence of shear lips is present, and designated with white arrow on Figure 2.

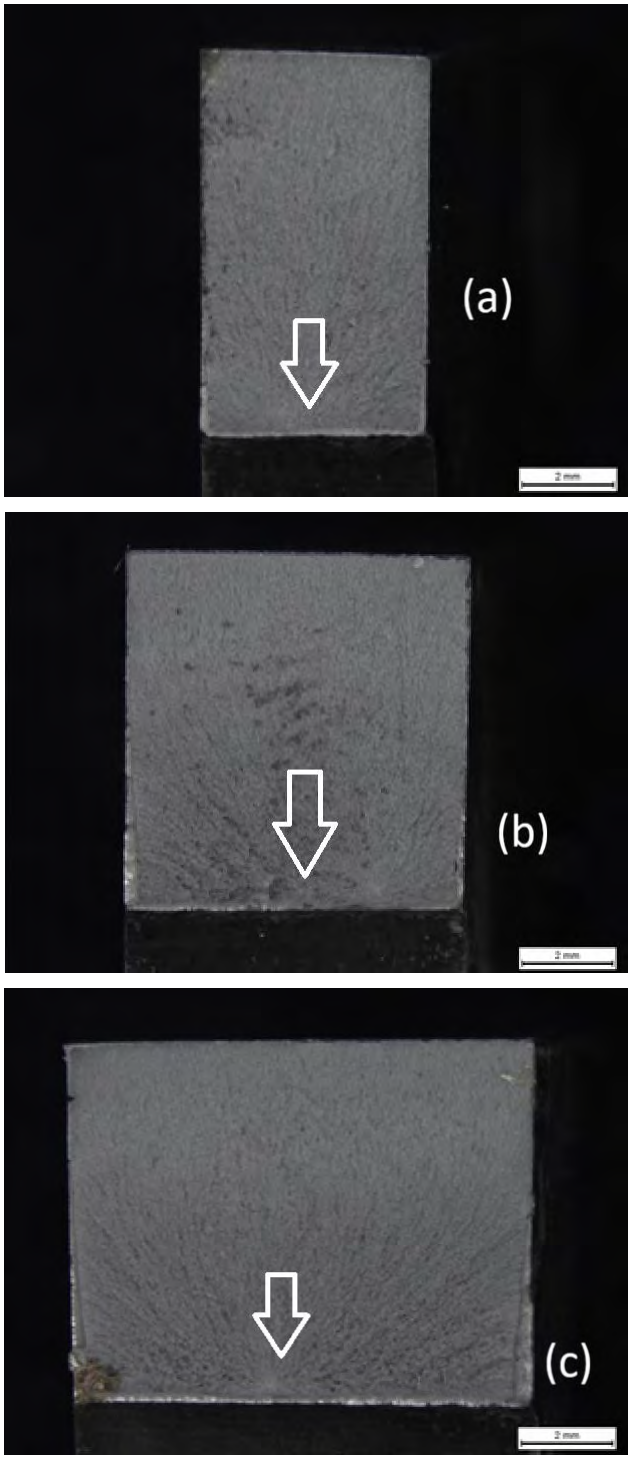

Figure 2. Fractographs of fractured surface of quenched Charpy impact specimens: (a) thickness 5,0 mm; (b) thickness 7,5 mm and (c) thickness 10,0 mm.

Every fracture consists of two stages: (i) crack initiation and (ii) crack propagation. Instrumented Charpy tester can differentiate energies for each stage. Also, it is assumed that every fracture starts with some plastic deformation, no matter how small it is. In the case of ductile fracture, plastic deformation that precedes fracture is considerable. This results in formation of shear lips at the edges of sample. On the other hand, when it comes to brittle fracture, shear lips are not developped, and flat surfaces of non-slip planes in grains are present [11,12].

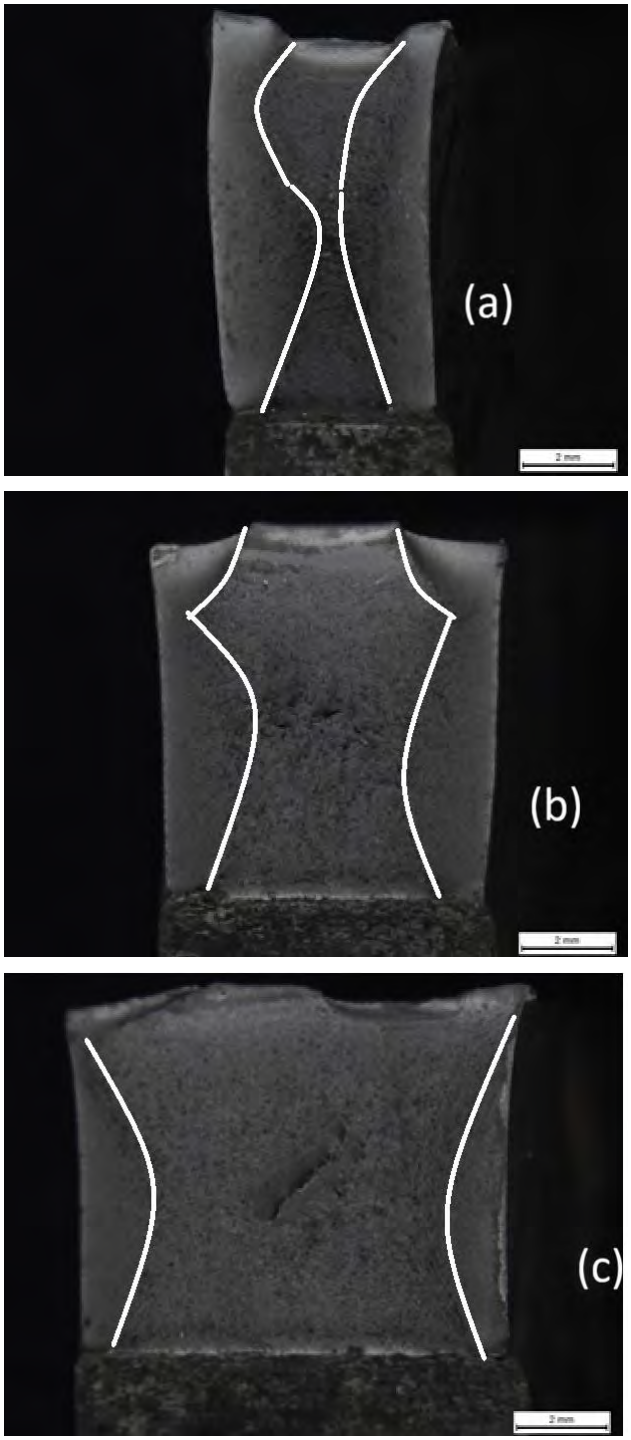

Figure 3. Fractographs of fractured surface of tempered Charpy impact specimens: (a) thickness 5,0 mm; (b) thickness 7,5 mm and (c) thickness 10,0 mm.

First notable feature on fractured surface of quenched and tempered samples is that place of crack initiation can not be unambigously determined, indicating that fracture occured just after attaining critical stress at the tip of crack, which is characteristic for ductile initiation. Also, surface exibits very clear shear lips, that cover substantial surface of cross section. This feature is present in all three samples. Area of shear lips is shown in figure 3 and

Table 3. Charpy impact energies

Thickness t, mm	Quenched and tempered, CVN, J	
	measured	Area normalized
5,0	34.4	34.4
7,5	56,2	51.6
10,0	69,1	68.8

annotated with white lines. Presence of shear lips is proof of ductile mechanism. Shear lips themselves are very pronounced and have position (slope) close to 45˚, confirming presence of plastic deformation that precedes fracture of sample. Interestingly, shear lips look very simillar in all three quenched and tempered samples [11,12].

In order to compare values of impact toughness, measured values were "normalized" by cross section areas. Measured values for 5 mm thick samples were multiplied by factor 1,5 and 2,0 to get value for 7,5 and 10mm, and given in Tables 2 and 3.

Diagram on Figure 4 shows measured data (closed symbols) and normalized values (open symbols) for quenched samples.

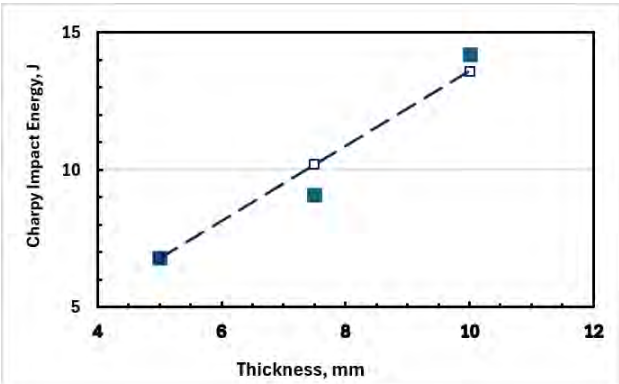

Figure 4. Influence of sample thickness on measured data (closed symbols) and normalized values (open symbols) of Charpy impact toughness for quenched steel.

Data show that there is no linearity and that one value has lower (7,5mm) value, while other is higher (10,0 mm) than expected. It is assumed that this behavior can be attributed dominantly to energy released during plastic deformation. No matter how small it is, due to low toughness (low overall impact energy), its effect is present and can not be neglected. Secondly, not less importantly, impact testing always requires sufficient number of samples to be tested in order to ensure statistical reliability.

Diagram on Figure 5 shows measured data (closed symbols) and normalized values (open symbols) for quenched and tempered samples.

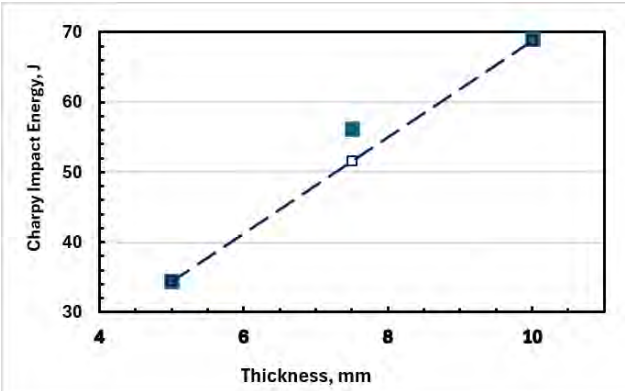

Figure 5. Influence of sample thickness on measured data (closed symbols) and normalized values (open symbols) of Charpy impact toughness for quenched and tempered steel.

Impact toughness in quenched and tempered steels is higher in comparison to quenched samples, as given in tables 2 and 3. This result is in good agreement with previously published data [13-16]. In the quenched sample, crack attain critical length during crack initiation proces, i.e. energy for crack propagation i close to zero. On the other hand, in tempered samples, due to presence of fine particles and grain boundaries, after crack initiation, considerable energy is spent on crack propagation [11-16], due to plastic deformation. Increase in thickness promotes brittle behaviour, but Figure 5 shows that value for 7,5mm is actually some higher than expected.

Data on Figures 4 and 5 show that there is no reliability in potential linking measured impact toughness for one thickness with prediction of its value for different area of cross section.

4. CONCLUSION

An attempt was made to evaluate impact energy as a function of thickness in quenched and tempered low alloyed steel correlate. Steel tested in this work was 42CrMo4 in both quenched and quenched and tempered state. Charpy testing was performed on samples with 5x10 mm2, 7,5x10 mm and 10x10 cross section areas.

In quenched state, cross section is completely flat, indicating brittle fracture and impact energy is small. At the edges of samples, some area that has ductile mechanism is registered. Increase of cross section does not follow any linear law. As a matter a fact, with increase, one value is higher and other smaller than expected. This is attributed to influence of energy absorbed during previous plastic deformation.

In quench and tempered state, impact energy is much higher. Pronounced shear lips on the fractured surface indicate ductile behavior. Their presence is attributed to plastic deformation before critical crack growth.

There is no reliability in potential linking measured impact toughness for one thickness with prediction of its value for different area of cross section, i.e. this prediction is unacceptable.

Abstract: *The financial sustainability of the defense system is one of the key conditions for the stable functioning of the state and the achievement of its security goals. In conditions of limited budgetary resources and increased demands for the modernization of the armed forces, efficient financial management and a reliable accounting system become necessary for the rational use of public funds. The subject of this paper is the analysis of the financial sustainability of the defense system of the Republic of Serbia with special emphasis on the budgetary and accounting aspects of financing. The aim of the paper is to examine the basic determinants of the financial sustainability of the defense system, as well as the role of budgetary planning, accounting recording and financial reporting in ensuring transparent and efficient management of financial resources. The methodological approach is based on the application of descriptive, analytical and comparative methods, using relevant scientific and professional literature, as well as available statistical and budgetary data. The analysis includes the role of financial management and accounting procedures within the Ministry of Defense of the Republic of Serbia and the financial functioning of the Serbian Armed Forces. The research results indicate the importance of establishing a stable and efficient system of budgetary planning, transparent accounting reporting and strong financial control mechanisms as key factors in the long-term financial sustainability of the defense system.*

Keywords: *defense system, financial sustainability, budget financing, accounting records.*

1. INTRODUCTION

The financial sustainability of the defense system is one of the central issues of modern public finance management, especially in the context of pronounced security challenges and limited fiscal capabilities of the state. The defense system, as a specific and complex component of the public sector, requires the existence of stable, predictable and long-term sustainable sources of financing, while ensuring efficient, rational and responsible management of available financial resources. In this regard, the processes of budget planning, accounting recording and financial reporting are of particular importance, which enable transparent monitoring and control of the spending of public funds. Of particular importance is the analysis of the manner in which these processes are implemented within the Ministry of Defense of the Republic of Serbia, as well as their impact on the overall functioning of the Serbian Armed Forces.

The subject of research in this paper relates to the financial sustainability of the defense system of the Republic of Serbia, with special emphasis on the budgetary and accounting dimensions of financial management. Within this framework, the research includes a detailed consideration of the process of planning, allocation, recording and control of budgetary funds intended for the defense system, while simultaneously analyzing their compliance with the basic principles of efficiency, economy and transparency in the use of public resources.

The research problem arises from the need to determine to what extent the existing system of financial and accounting management contributes to the preservation and improvement of the long-term financial sustainability of the defense system. In this context, the issue of the adequacy and development of the budget planning and accounting system, i.e. their ability to respond to contemporary challenges that include the needs of modernization, continuous growth of costs, as well as limitations arising from the overall state of public finances, is particularly considered.

The main objective of the paper is a comprehensive analysis of the financial sustainability of the defense system of the Republic of Serbia from the perspective of budgetary and accounting management. In addition, specific research objectives have been defined, which include the identification of key determinants of the financial sustainability of the defense system, analysis of the budget planning and execution process, examination of the role of the accounting system in recording and

Corresponding author: A. Savić;
E-mail: aleksandar22071993@gmail.com
DOI: 10.5937/OTEH26140S

controlling budgetary funds, assessment of the efficiency of financial resource management, recognition of the main challenges and limitations in financing the defense system, as well as the formulation of proposals for measures to improve financial sustainability and the accounting system.

Starting from the above objectives, the paper defines a general hypothesis according to which the financial sustainability of the defense system of the Republic of Serbia is directly conditioned by efficient budgetary and accounting management of financial resources. Based on the general hypothesis thus set, specific hypotheses were formulated:
H1: Efficient budget planning and adequate expenditure control significantly contribute to preserving the financial sustainability of the defense system.
H2: A developed, reliable and transparent accounting system has a positive impact on improving financial management in the defense system.
H3: Existing models of financing the defense system face significant limitations arising from the fiscal capacities of the state.
H4: Improving the financial control and audit system contributes to a more rational and responsible use of budget funds.

In order to gain a more complete understanding of the subject matter, the paper applies a combined methodological approach that includes several complementary scientific methods. The descriptive method is used to define the basic concepts and theoretical starting points of financial sustainability and financing of the defense system. The analytical method is applied in considering the budgetary and accounting aspects of financial management, as well as in analyzing the structure of expenditures and financial flows. The comparative method allows for a comparison of different approaches to financing the defense system, as well as the identification of relevant good practices. The content analysis method is used in the study of current legal and by-laws, strategic documents and financial reports. In addition, the statistical method is applied to process and interpret available data on the budget and expenditures of the defense system. The integrated application of the above methods allows for a comprehensive understanding of the financial sustainability of the defense system of the Republic of Serbia, as well as the identification of key factors that influence its improvement.

2. BUDGETARY AND ACCOUNTING FRAMEWORK FOR FINANCING THE DEFENSE SYSTEM

Financial sustainability in the public sector can be defined as the ability of a state to ensure the financing of its functions and the execution of its obligations in the long term, without jeopardizing fiscal stability and overall macroeconomic balance. It implies the existence of a balance between public revenues and expenditures, adequate control of the level of public debt, as well as efficient and rational management of budgetary funds (Schick, 2005). In modern conditions, this concept goes beyond a narrowly understood fiscal discipline and encompasses a broader framework that includes the quality of public spending, the level of transparency and the degree of accountability in the management of public finances (IMF, 2018). Within the defense sector, financial sustainability gains an additional dimension, as it refers to the state's ability to ensure continuous and stable financing of key security functions. This includes financing operational activities, the modernization process, and the development of military capabilities. Sustainable defense financing requires long-term planning, the existence of stable and predictable sources of financing, but also preserving the overall fiscal balance of the state (Hartley, 2011).

The financing of the defense system differs from the financing of other areas of the public sector primarily due to its strategic importance, high level of confidentiality and significant share of capital investments (Knežević et al., 2021). Defense expenditures include a wide range of costs, including current expenditures such as employee salaries, system maintenance and logistical support, as well as capital investments such as the acquisition of weapons and military equipment. These investments are usually long-term and require significant financial resources (Dunne & Perlo-Freeman, 2003). One of the key characteristics of defense financing is the fact that investments in this area do not generate a direct market return. Therefore, the efficiency of these expenditures is not measured through profitability, but through the level of achieved security and the ability to deter potential threats. In addition, defense financing is often strongly influenced by geopolitical circumstances and changes in the security environment, which can lead to significant and sometimes sudden changes in the amount of budget allocations (SIPRI, 2023a).

Budget planning in the defense sector is based on the principles of program budgeting, which provides a clear link between available financial resources, defined objectives and expected results. This approach contributes to improving transparency and increasing efficiency in the allocation of budgetary resources (Robinson, 2013). Within the Ministry of Defense of the Republic of Serbia, the budget process includes the phases of planning, execution and budget control, in accordance with the applicable normative framework, primarily the Law on the Budget System (Milunović et al., 2022). Financial management in this context implies the rational use of funds, continuous control of expenditures and monitoring the implementation of planned activities and goals. A particularly important element is medium-term planning, which enables more stable financing of capital projects and the modernization process of the Serbian Armed Forces (Stevanović et al., 2023). In this way, the risk of inefficient spending of budget funds is reduced and the long-term sustainability of the defense system is ensured.

The institutional framework for financing the defense system in the Republic of Serbia is based on a clearly divided competence between relevant state bodies. The central role is played by the Ministry of Defense of the Republic of Serbia, which is responsible for planning, managing and controlling financial resources allocated to

defense. In addition to this ministry, other actors, such as the Ministry of Finance, the State Audit Institution and various control bodies, play an important role, contributing to ensuring legality, transparency and accountability in the spending of budget funds (Savić et al., 2024a). The normative framework consists of laws and by-laws that regulate the budget system, public procurement and financial operations in the public sector. This institutional setting enables the alignment of strategic defense goals with the general fiscal policy of the state, thus creating conditions for sustainable and stable financing of the defense system. Control and audit play a key role in ensuring the legal, proper and efficient use of public funds. Within the defense system, internal control, internal audit and external audit are distinguished as interconnected oversight mechanisms. Internal control includes a set of procedures, rules and activities that ensure proper financial management and minimize the risk of irregularities, while internal audit is tasked with assessing the efficiency of operations and their compliance with applicable regulations (INTOSAI, 2019a). External audit in the Republic of Serbia is carried out by the State Audit Institution, which provides an independent and objective assessment of the financial operations of budget users. An effectively established control and audit system contributes to reducing the risk of abuse, increases transparency and strengthens public confidence in the functioning of the defense system.

The accounting system in the public sector is based on the principles of budget accounting, which includes recording, classifying and reporting on all financial transactions. In the defense system, accounting plays an extremely important role in monitoring budget execution and providing reliable and relevant information necessary for making management decisions. Financial reporting involves the preparation of periodic and annual reports on budget execution, which contain detailed data on revenues, expenditures and achieved financial results. These reports represent the basis for control, analysis and evaluation of financial operations (IPSASB, 2021). Within the Ministry of Defense of the Republic of Serbia and the Serbian Armed Forces, improving the accounting system, as well as the application of international public sector financial reporting standards (IPSAS), contributes to greater transparency, comparability and reliability of financial information. In this way, the financial sustainability of the defense system is further strengthened and the overall management of public resources is improved.

3. ANALYSIS OF THE FINANCIAL SUSTAINABILITY OF THE DEFENSE SYSTEM OF THE REPUBLIC OF SERBIA

The financial sustainability of the defense system of the Republic of Serbia is conditioned by a number of interrelated factors, among which the stability of budget financing, adequately structured expenditures, optimal level of investment investments, as well as efficient and responsible management of available financial resources stand out. In this part of the paper, attention is focused on the analysis of key elements of defense system financing, with special emphasis on the role of the Ministry of Defense of the Republic of Serbia, as the central institution in the process of planning and managing funds, as well as on the functioning of the Serbian Armed Forces as the main user of budget resources.

Budgetary allocations for defense of the Republic of Serbia in the previous period are characterized by a relatively stable upward trend, which is primarily a result of more complex security circumstances, but also the need for continuous improvement and modernization of the armed forces. The share of defense expenditures in gross domestic product (GDP) ranges from about 1.8% to 2.2%, which is comparable to the practice of most European countries (SIPRI, 2024). A particularly pronounced budget growth was recorded after 2018, when there were more intensive investments in the procurement of weapons and modern military equipment. Such budgetary stability enables more reliable and long-term expenditure planning, which at the same time reduces the risk of disrupting the fiscal balance and ensures the sustainability of the defense financing system (Ministry of Defense of the Republic of Serbia, 2024).

The structure of expenditures is one of the most important indicators of financial sustainability, since it indicates the way in which funds are distributed between current needs and development priorities. Within the defense system of the Republic of Serbia, three basic categories of expenditures are dominant: expenditures for employees, operating costs and capital expenditures, i.e. investments in equipment and infrastructure. The following paper presents the framework structure of defense system expenditures.

Table 1. Structure of defense system expenditures of the Republic of Serbia in the average amount for the period 2018-2025.

Expenditure category	Share (%)
Employee expenses	45–50%
Operating costs	25–30%
Investments and equipment	20–25%

Source: Prepared by the author based on data from the Ministry of Defense and the Stockholm International Peace Research Institute (SIPRI, 2024)

The relatively high share of personnel expenditures indicates a pronounced personnel component of the defense system, while the growth of capital expenditures in recent years clearly indicates an increased orientation towards modernization and technological improvement (SIPRI, 2024).

Investments represent a key pillar of the long-term financial sustainability of the defense system. These investments cover a wide range of activities, including the procurement of modern weapons and military equipment, the digitalization of management systems, as well as the improvement of infrastructure and logistics capacities (Mihajlović et al., 2023). In the previous period, the

Republic of Serbia has significantly intensified investments in the modernization of combat systems, the development of the domestic military industry and the strengthening of logistical support. Such investments have a double effect: on the one hand, they contribute to increasing the operational capabilities of the defense system, while on the other hand, they create additional pressure on the state budget. For this reason, it is of particular importance to establish a balance between investment needs and preserving fiscal stability (Petrović, 2021).

The efficiency of financial resource management is reflected in the ability of the defense system to achieve maximum results in terms of functionality and operational readiness with limited resources (Savić et al., 2025a). Key factors that influence the level of efficiency include the quality of budget planning, the application of the principles of program budgeting, the development of the accounting system, as well as the efficiency of internal and external control. The introduction of modern accounting standards and the improvement of the financial reporting system significantly contribute to greater transparency and accountability in the management of public funds (Đorđević, 2023). Also, the development of internal audit and financial control systems enables timely detection of irregularities and improvement of the resource management process. However, despite the progress made, certain challenges remain, especially in the areas of expenditure optimization, long-term investment planning and harmonization of the strategic goals of the defense system with the realistic fiscal constraints of the state. Efficient and responsible financial management remains a key prerequisite for ensuring stability and long-term financial sustainability of the defense system of the Republic of Serbia.

4. CHALLENGES TO THE FINANCIAL SUSTAINABILITY OF THE DEFENSE SYSTEM

The financial sustainability of the defense system is a complex and multi-layered concept that depends on a combination of internal resource management factors and external economic and security circumstances. Within the Ministry of Defense of the Republic of Serbia and the Serbian Armed Forces, these sustainability challenges are particularly evident in situations of limited public funds, continuous growth in modernization costs, and an increasingly dynamic and uncertain security environment (Savić et al., 2023).

One of the key challenges to the financial sustainability of the defense system relates to the limitations of the state budget. The defense budget represents a part of total public expenditures and largely depends on macroeconomic stability, the level of public debt, and the general fiscal policy of the state (Savić & Bonić, 2022). Given that the state must simultaneously provide financing for numerous sectors such as health, education, and social protection, defense allocations are often under pressure to be rationalized (Mowery, 2010). The Republic of Serbia, as a state with limited fiscal capacities, is faced with the need to align the real needs of the defense system with available budgetary opportunities. According to the Stockholm International Peace Research Institute, defense spending in developing countries is not stable but varies depending on economic cycles and political priorities (SIPRI, 2023b), which further indicates the importance of long-term and stable financial planning in the field of defense.

Modern defense systems require constant and significant investments in modernization and technological development. The costs of purchasing modern combat systems, equipment and supporting infrastructure represent a major burden on the defense budget. The modernization process of the Serbian Armed Forces involves the procurement of complex and financially demanding systems, the total costs of which often exceed the capabilities of short-term budget planning (Hartley, 2012). An additional challenge is reflected in the fact that defense investments are long-term in nature, with their effects not immediately visible, while expenditures are realized in a relatively short period of time. Such an asymmetry between investments and effects creates additional pressure on fiscal stability and requires careful and responsible planning of capital expenditures.

The efficiency of financial management in the defense system largely depends on the institutional framework and organizational structure. Within the Ministry of Defense of the Republic of Serbia, challenges relate to the need to improve coordination between different organizational units, as well as to strengthen the internal control and internal audit systems. Insufficiently developed accounting systems and limited transparency of financial reporting can negatively affect the efficiency of public fund management (Allen & Tommasi, 2001). In addition, the implementation of modern international standards in the public sector, including IPSAS, continues to be a challenge for a large number of countries in transition, including for the improvement of the financial accounting system in the field of defense (Young, 2018). The security environment has a direct and strong impact on the volume and structure of defense financing (Stojković & Glišić, 2020). Global geopolitical changes, regional tensions, and modern forms of threats, such as hybrid and cyber threats, require increased investments in defense capacities (Smith, 2020). In such circumstances, states are often forced to increase budget allocations for defense, which further burdens public finances. At the same time, the high degree of uncertainty regarding future security challenges makes long-term planning and optimal allocation of resources difficult.

Table 2. Budget allocation for the needs of the defense system of the Republic of Serbia

Year	Defense Budget (billion RSD)	% GDP
2018	70	1.6%
2019	80	1.7%
2020	95	1.9%

2021	102	2.0%
2022	120	2.1%
2023	138	2.2%
2024	158	2.3%
2025	261	3.5%

Source: Prepared by the author based on data from the Ministry of Defense and the Stockholm International Peace Research Institute (SIPRI, 2024)

The table shown indicates a clear trend of increasing defense spending, which on the one hand reflects the increased needs for financing the defense system, while on the other hand raises the question of long-term fiscal sustainability and the ability of the state budget to continuously support such growth.

5. POSSIBILITIES FOR IMPROVING THE FINANCIAL SUSTAINABILITY OF THE DEFENSE SYSTEM

The financial sustainability of the defense system of the Republic of Serbia requires continuous improvement of public resource management, with consistent application of modern budgetary, accounting and control instruments. Within the Ministry of Defense of the Republic of Serbia and the Serbian Armed Forces, improving financial sustainability implies a comprehensive and systemic approach that includes improving the budget planning process, strengthening the accounting system and financial reporting, developing financial control mechanisms, as well as adopting and implementing internationally recognized good practices in the field of public finance (Radivojević et al., 2022).

Budget planning is the main instrument used to ensure the financial stability of the defense system. The traditional budget planning model, based on an incremental approach, is often not fully adequate for modern challenges, and there is a need to improve it through the introduction of program and medium-term budgeting. Program budgeting allows for direct linking of expenditures with clearly defined objectives and expected results, which significantly improves transparency and efficiency in the use of public funds (Robinson, 2015). On the other hand, the Medium-Term Expenditure Framework (MTEF) contributes to more stable and predictable resource management, as well as better alignment of strategic defense objectives with the fiscal capabilities of the state (OECD, 2019). This approach is of particular importance in the defense sector, given that investments in weapons, equipment, and infrastructure require multi-year and continuous financial planning. Further improvement of budget planning also includes the development of analytical capacities for cost assessment, as well as the wider application of analytical methods such as cost-benefit and cost-effectiveness analysis, which contributes to more rational decision-making on the allocation of limited budgetary resources (Allen, Hemming, & Potter, 2013). An efficient accounting system is one of the key components of financial sustainability, as it enables accurate, timely, and transparent recording of all financial flows (Savić et al., 2024b). In the modern public sector, and therefore in the defense system, the transition from cash to accrual accounting is of increasing importance, in accordance with international public sector standards, such as IPSAS (International Public Sector Accounting Standards) (IFAC, 2021). The application of accrual accounting allows for a more realistic and comprehensive presentation of the financial position, including liabilities, assets and long-term costs, which is especially important for the defense system that manages extensive and valuable tangible assets. Transparent financial reporting contributes to strengthening public trust, as well as improving fiscal discipline and accountability in the management of public funds (Chan, 2010). Within the Ministry of Defense of the Republic of Serbia, improving the accounting system involves further digitalization of financial processes, integration of information systems and standardization of financial reporting, which enables more efficient resource management and better management decision-making (Savić et al., 2025b).

Financial control is an important mechanism that ensures the legal, economical and efficient use of budgetary funds. In the defense system, the importance of financial control is further emphasized due to the complexity and volume of financial flows and operations. The modern concept of financial control involves the development of an internal control and internal audit system, based on the principles of the COSO framework (Committee of Sponsoring Organizations of the Treadway Commission, 2017). The internal control system includes risk management processes, control activities and continuous monitoring, which reduces the risk of irregularities, abuse and inefficient spending of funds. In addition to internal control, external audit also plays an important role, contributing to a greater degree of transparency and accountability in the management of public finances (INTOSAI, 2019b). Strengthening cooperation between internal and external control mechanisms can significantly contribute to improving the overall system of financial supervision and control.

The application of international good practices is one of the key directions for improving the financial sustainability of the defense system. International organizations, such as the OECD and NATO, have developed recommendations and standards related to transparency, accountability and efficiency in defense budget management (OECD, 2019). One of the basic principles is the transparency of the defense budget, which implies the availability and clarity of data on the planning and execution of budget funds. In addition, the concept of "value for money", which refers to the optimal use of available resources while achieving maximum effects and results, is particularly important (Allen et al., 2013).

The experiences of developed countries show that integrated information systems, professionalization of personnel in the field of finance and accounting, as well as continuous education of employees, are key factors in

efficient management of public finances. In this regard, the defense system of the Republic of Serbia can further improve its capacities through the adaptation and implementation of the above practices, while harmonizing them with national institutional and fiscal specificities.

6. CONCLUSION

The financial sustainability of the defense system is a complex and multi-layered concept that involves harmonizing the security needs of the state with its available fiscal capacities. This paper analyzes the financial sustainability of the defense system of the Republic of Serbia, with a special focus on budgetary and accounting aspects. Based on the analysis conducted, it can be concluded that stable, responsible and efficient management of public finances is a basic prerequisite for the long-term and smooth functioning of the defense system.

The results obtained indicate that the level of financial sustainability of the defense system largely depends on the quality of the budget planning process, the reality in the assessment of necessary expenditures, as well as the consistent application of the principles of fiscal discipline. In this sense, the Ministry of Defense of the Republic of Serbia has a key role in establishing and implementing a system of planning, distribution and control of budgetary funds, while the Serbian Armed Forces are the main user of these funds, whose operational capability and efficiency largely depend on the rational and purpose-oriented spending of allocated resources.

An important role in ensuring financial sustainability is played by the accounting system, which enables precise recording of all financial flows, transparent financial reporting, and the creation of a reliable basis for making management decisions. The paper emphasizes that improving accounting procedures and the quality of financial reporting directly contributes to increasing transparency, strengthening accountability, and better control over the use of budget funds, thereby improving the overall efficiency of resource management and reducing the risk of irrational spending.

The analysis also showed that the key challenges in the area of financial sustainability of the defense system relate to the limited budget funds, the increasing costs of modernization and equipment, and the need for continuous improvement of material and technical capabilities. In addition, the dynamic and changing security environment imposes the need for a more flexible, but at the same time long-term sustainable approach to expenditure planning, while preserving the overall fiscal stability of the state.

In order to improve the financial sustainability of the defense system of the Republic of Serbia, it is necessary to further develop the program approach to budgeting, strengthen financial control and internal audit mechanisms, and improve the accounting framework in accordance with modern international public sector standards. Also, special importance should be given to long-term planning of investments and modernization processes, with clear definition of priorities and ensuring optimal allocation of available resources.

Finally, it can be concluded that the financial sustainability of the defense system is not a static category, but a continuous and dynamic process that requires constant adaptation to economic and security changes. Only through the coordinated operation of budget planning, financial management and accounting systems is it possible to ensure a stable, efficient and long-term sustainable defense system of the Republic of Serbia.

Abstract: *Ballistic testing represents the definitive method for quality control of personal ballistic protective equipment. Testing procedures are defined by relevant standards, yet in practice, deviations in results can occur, raising questions about the reliability of equipment quality assessments. This study analyzes results obtained from testing samples of personal ballistic protective equipment in three accredited European laboratories according to NIJ 0101.04 and STANAG 2920 standards. The comparison includes measurements of backface signature (BFS) and the V_{50} parameter, aiming to determine the extent of deviations among obtained values. The analysis considers factors that may influence observed differences, including the properties of the backing material (Roma Plastilina), projectile velocity measurement conditions, and the procedure for determining the V_{50} parameter. The results indicate that the observed deviations can be significant enough to affect the interpretation of test outcomes in quality control procedures. The study highlights the importance of systematically considering result variability and provides a basis for improving procedures for assessing the reliability of ballistic testing, contributing to a better understanding of the limitations and practical application of these methods in the quality control of personal ballistic protective equipment.*

Keywords: *clay, backface signature, probit method, inter-laboratory testing.*

1. INTRODUCTION

Ballistic testing represents the definitive method for the quality control of personal ballistic protective equipment. Although testing procedures are strictly defined by international standards such as NIJ 0101.04 and STANAG 2920, significant deviations in results can occur in practice, raising fundamental questions about the reliability of protective equipment quality assessments.

A primary source of variability in NIJ 0101.04 is the backing material, specifically Roma Plastilina No. 1 (RP#1) clay. Research [1] has shown that the correlation between projectile impact and Backface Signature (BFS) in this material is often low, whereas studies on human cadavers show a much higher correlation. Furthermore, no formal technical standards exist for the procurement and acceptance testing of RP#1, meaning its consistent quality cannot be guaranteed. Due to its non-Newtonian rheological properties, the mechanical behavior of the clay is highly sensitive to both temperature and its "shear history" or previous working [2]. Previous study [3] has already indicated that different production batches of the same clay can lead to significant variations in BFS depth during mandatory calibration .

This study is significant because it provides an analysis of inter-laboratory testing data, which has been largely unavailable until now, to demonstrate how these factors influence the assessment of ballistic protection standards. By analysing measurements of BFS and the V_{50} parameter across three accredited European laboratories, this paper aims to identify the extent of these deviations and provide a basis for improving the reliability of ballistic testing methodologies.

2. EXPERIMENT

The tests were conducted comparatively across three accredited laboratories:

1. Security Information Agency, Laboratory for Testing of Protective Equipment, Belgrade, Republic of Serbia,
2. Banco Nazionale di Prova per le Armi da Fuoco Portatili e le Munizioni Commerciali, Brescia, Italy,
3. AITEX, Research & Innovation Center, Alcoy, Spain.

For this study, ballistic panels with the following configuration were used, as observed from the strike face:

- 17 layers of UHMWPE Dyneema SB51,
- 1 layer of aramid FMS AT245,

Corresponding author: M. Milovanović;
E-mail: marko.milovanovic547@gmail.com
DOI: 10.5937/OTEH26141M

- 1 layer of UHMWPE Dyneema SB51,
- 1 layer of FMS AT245, and
- 3 layers of UHMWPE Dyneema SB51.

The UHMWPE Dyneema SB51 sheets were from batch number 2200275436, and the aramid FMS AT245 sheets from batch number 7126. Each panel sample measured (400×400) mm. Three samples were provided to each laboratory.

To ensure an unbiased analysis of the results, each participating laboratory was assigned a unique code (A, B, and C).

2.1 Method for determination of backface signature (BFS) - NIJ 0101.04

Ballistic testing was conducted in accordance with the methodology specified for evaluating the ballistic resistance of personal body armor against gunfire, as defined by the NIJ Standard 0101.04.

All shots were fired using a 9×19 mm test barrel, with 9×19 mm ammunition loaded with 8.0 g full metal jacket (FMJ) bullets. The reference velocity of the bullets was (436±9) m/s, in accordance with the standard requirements for protection level IIIA. Testing was performed on dry samples.

Impact locations were defined in Article 5.11.3 of the standard, and the shot layout is shown in Figure 1. Shots numbered 1, 2, 3, and 6 were fired at an angle of 0°, while shots 4 and 5 were fired at a 30° angle relative to the center of the sample.

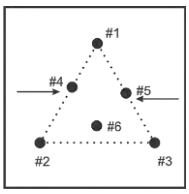

Figure 1. Impact position layout

Each sample was positioned 5 m from the muzzle of the test barrel, and bullet velocity was measured at a distance of 2.5 m from the sample.

2.2 Ballistic test method for personal armour materials and combat clothing - STANAG 2920

The testing was conducted in accordance with STANAG 2920, Edition 2. The sample panel was locked in a special steel frame, consisting of two metal frames that were tightened together. The frame-panel assembly was anchored to a support so that the panel could absorb all the kinetic energy possessed by the FSP at the moment of impact. All tests were performed on dry samples.

Shooting was performed by using a .22 caliber test barrel. Type 2 fragment-simulating projectiles (FSP) were used, with characteristics specified in Appendix 1 of Annex A (Category A2).

Test area ambient conditions complied with the requirements of Section 7.3.

For the velocity measurement all laboratories used optical light gates and measured the FSP velocity at 2.5 m from the sample. Since impact velocity is much lower due to air drag, it was calculated by using some of the special analytical solutions of flat-fire trajectories equations, which give the smallest error [4].

The fragments were fired from a distance of 5 m from the front face of the sample with an angle of incidence of 0°. The distance between the impact point and previous shots or the edge of the test specimen was at least 5 cm.

After each shot, checks were carried out to see whether the fragment had been stopped or had penetrated the witness plate. An aluminium sheet was used as a witness plate, with a thickness of 0.5 mm, and it was placed 150 mm from the rear face of the sample.

During the testing, six FSP impacts were performed, of which three resulted in complete perforations and three in non-perforations. The nominal initial velocity was set at 600 m/s, with a maximum velocity variation range of 40 m/s between the lowest and the highest achieved values. The final result was reported as the arithmetic mean velocity of the three complete perforations and three non-perforations, expressed to one decimal place.

3. RESULTS AND DISCUSSION

3.1 Method for determination of backface signature (BFS) NIJ 0101.04

The test results are presented in Table 1, showing the BFS values and impact velocities for shots 1, 2, and 3. In accordance with the NIJ Standard 0101.04, only these specific shots were considered for evaluation. Although the backing material was calibrated both before and after each test, the values reported in Table 1 refer specifically to the pre-test calibration. Individual shots are identified using Roman numerals. Table 2 provides the descriptive statistics for BFS values, organized by individual sample and aggregated by laboratory. In this table, mean values are denoted as x_{aver}, the range as D, and the standard deviation as σ. All statistical data processing was performed using Minitab v.21.4.2.

To ensure the integrity of the data, Dixon's and Grubb's tests were initially applied to identify potential outliers in BFS and bullet velocity measurements. These tests confirmed that all extreme values remained within permissible limits; specifically, p-values for Dixon's test were 0.553 and 0.162, while Grubb's test yielded p-values of 0.696 and 0.278. Consequently, the sample contains no outliers, indicating that the results are homogeneous and reliable—a finding further supported by the boxplot diagram in Figure 2.

Analysis of Table 1 reveals that BFS values range from 22 mm to 29 mm, resulting in a total spread of 7 mm. For individual samples, the ranges vary between 0 mm and 5 mm, though they typically average 4 mm. A similar trend is observed across laboratories, where ranges are generally 4 mm, with the exception of Laboratory C,

which recorded a range of 6 mm. Fisher's test for equality of variances confirmed that the standard deviations are not statistically significantly different.

Table 1. Test results for the determination of the backface signature

Laboratory code	Sample	Calibration, [mm]	Backface signature, BFS, [mm]			Bullet velocity, [m/s]		
			I	II	III	I	II	III
A	1	18.0	25	25	29	437.8	442.2	435.4
	2	17.4	26	23	28	441.1	435.3	444.2
	3	20.9	27	27	27	439.4	428.6	435.9
B	1	19.2	25	26	23	442.5	445.3	437.0
	2	19.6	23	25	27	437.3	437.8	442.9
	3	19.8	25	26	26	435.5	432.8	442.3
C	1	18.6	23	26	25	437.6	439.2	436.5
	2	18.6	22	26	26	432.6	445.4	440.2
	3	18.6	23	25	23	441.1	439.7	434.6

Table 2. Descriptive statistics on results of BFS (all measures are expressed in mm)

Lab. code	Sample	x_{aver}	D	σ	x_{aver}	D	σ
A	1	24.7	3	1.52	25.1	4	1.36
	2	25.0	4	2.00			
	3	25.7	1	0.33			
B	1	24.7	3	1.53	24.3	4	1.58
	2	24.7	4	2.31			
	3	23.7	2	0.67			
C	1	26.3	4	2.31	26.3	6	1.80
	2	25.7	5	2.50			
	3	27.0	0	0.00			

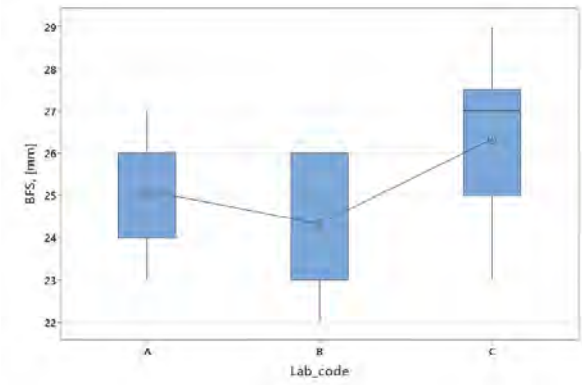

Figure 2. Boxplot and interval plot of BFS values

The boxplot in Figure 2 shows noticeable skewness in the results from Laboratories B and C. This is particularly pronounced for Laboratory C, where the median is significantly higher than those of the other two laboratories. At first glance, this suggests that the test results may vary significantly depending on the laboratory where the testing is conducted. To analyze this numerically, a one-way ANOVA was performed using the laboratory location as the primary factor (Table 3).

Table 3. ANOVA test for BFS

Source	DF	Seq SS	Contrib.	Adj MS	F-value	p-value
Lab	2	18.30	23.11%	9.148	3.61	0.043
Error	24	60.89	76.89%	2.537		
Total	26	79.19	100%			

The ANOVA test produced a p-value slightly below 0.05, indicating a statistically significant difference in test results between laboratories. To identify specific differences, Tukey pairwise comparisons and Hsu's Multiple Comparisons with the Best (MCB) were conducted. Both methods confirmed that the significant differences exist between Laboratories B and C. The model's coefficient of determination (R^2) was 23.11%, while the predicted R^2 was 2.68%, suggesting that the model provides insufficient precision for predicting new observations, likely due to the small group sizes.

Given the limited sample size, evaluating the residual plots to verify ANOVA assumptions is challenging. Therefore, the Ryan-Joiner test was applied to the residuals to confirm normality, alongside Bartlett's and Levene's tests for constant variance. The RJ test statistic was 0.985 ($p > 0.05$), providing insufficient evidence at the α=0.05 significance level to suggest a violation of the normality assumption. Similarly, p-values for Bartlett's and Levene's tests (0.747 and 0.754, respectively) indicate that the assumption of constant variance holds, further validating the initial Fisher's test results.

To determine the underlying causes of the observed BFS ranges, a multivariate regression analysis was conducted to examine the impact of bullet velocity and the initial hardness of the backing material. Additionally, the influence of the laboratory factor on the relationship between BFS, velocity, and calibration was analyzed (Table 4). The Pareto chart in Figure 3 shows that only the laboratory factor exceeds the critical threshold. Of the remaining variables, bullet velocity had a secondary influence, while calibration (initial hardness) had the least impact.

The results in Table 4 show that only the laboratory factor yielded a p-value below 0.05. This leads to the conclusion that BFS does not fundamentally correlate with bullet velocity or backing material calibration. Thus, while the initial hardness of the backing material varied across samples and laboratories, it did not statistically affect the results. This suggests that the behavior of the backing material—due to inherent non-homogeneity, previous test history, and mechanical treatment—is inconsistent across the entire contact surface. This inconsistency in calibration behavior is also evident across different

versions of the NIJ 0101 standard. In Version 3, calibration utilized a 44.5 mm diameter weight with an allowable indentation of (25 ±3) mm. In Version 4, the diameter is 63 mm with an allowable depth of (19 ± 2) mm, using the same 1 kg mass dropped from 2 meters.

Table 4. ANOVA test for regression analysis

Source	DF	Seq SS	Contrib.	Adj SS	F-value	p-value
Regression	4	26.1	32.98%	26.1	2.71	0.057
Velocity	1	3.83	4.84%	6.98	2.90	0.103
Calibration	1	0.16	0.20%	2.09	0.87	0.362
Lab	2	22.1	27.94%	22.1	4.59	0.022
Error	22	53.1	67.02%	53.1		
Total	26	79.19	100%			

Furthermore, the interaction between the sample and the backing material must be considered, particularly the energy transfer mechanism. Factors such as the mounting method, the rigidity of the attachment to the support, and any movement during testing represent laboratory-specific variables that must be minimized. Additionally, the operator's influence during BFS measurement is a factor, separate from the quantifiable uncertainty of the measuring instrument itself.

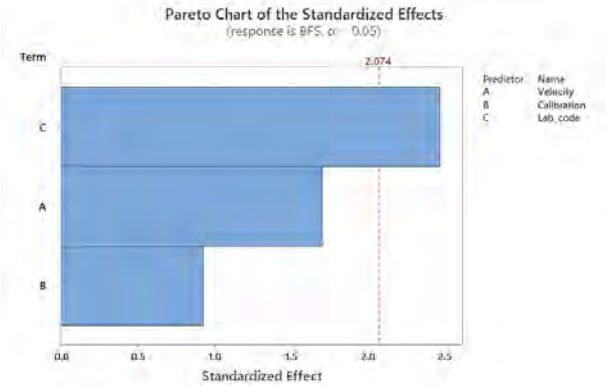

Figure 3. Pareto chart of the standardized effects

The reasoning for the laboratory's influence on the regression analysis is visible in the interaction plot for BFS (Figure 4). In Laboratory C, BFS remains virtually unchanged as bullet velocity increases. In contrast, Laboratory B shows the most significant increase in BFS relative to velocity. To further analyze this, a univariate regression analysis was conducted for each laboratory, focusing solely on velocity since backing material calibration results were proven non-influential (Table 5).

For Laboratory A, the R^2 was 0.4398 (Adjusted R^2 = 0.3598), meaning 43.98% of the variance is explained by the model, while the remaining 56.02% is attributed to random error. The linear regression graph for Laboratory A is shown in Figure 5. For Laboratory B, the R^2 was 0.1655 (Adjusted R^2 = 0.0463), significantly lower than Laboratory A. In Laboratory C, the R^2 was 0.0001, indicating that 99.99% of the model is random error.

Residual analysis for each laboratory confirmed that residuals were randomly and evenly distributed, satisfying the requirements for normality and lack of bias, with no residual exceeding two standard deviations. Since p-values for all three laboratories (especially Laboratory C) were greater than 0.05, it is confirmed that any apparent correlation between velocity and BFS is not statistically grounded at the 5% significance level. This conclusion implies that, when following the NIJ 0101.04 standard, a higher velocity in shots 2 or 3 does not necessarily result in a deeper indentation in backing material.

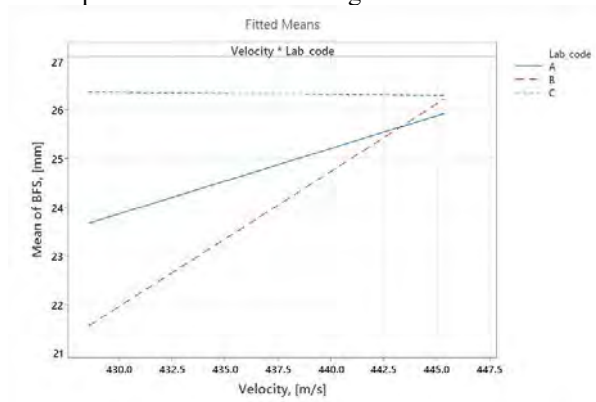

Figure 4. Interaction plot for BFS

Table 5. ANOVA test for univariate regression analysis

Lab. code	Source	DF	SS	MS	F-value	p-value
A	Reg.	1	8.80	8.80	5.50	0.052
	Error	7	11.2	1.60		
	Total	8	20.0			
B	Reg.	1	2.46	2.46	1.39	0.277
	Error	7	12.4	1.78		
	Total	8	14.9			
C	Reg.	1	0.00	0.00	0.00	0.979
	Error	7	26.0	3.71		
	Total	8	26.0			

While laboratories report measurement uncertainty regarding the depth measurement itself, the uncertainty of the method—which includes the backing material's characteristics—is often overlooked. The results of this study demonstrate that BFS variability is significantly higher than the measurement uncertainty of the instrument alone. This discrepancy raises questions about the reliability of quality assessments when results are near the maximum allowable limit of 44 mm.

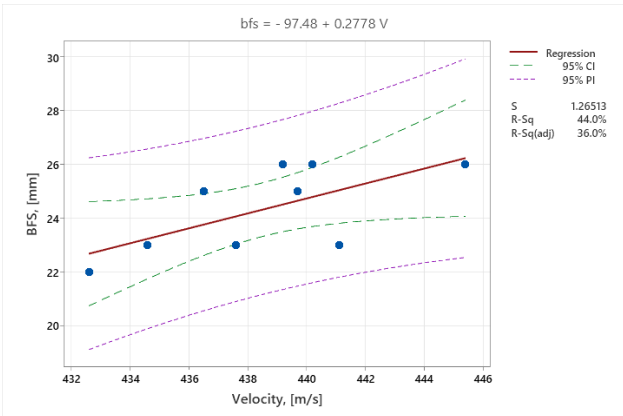

Figure 5. Fitted line plot – BFS vs. Velocity for Laboratory A

In this study, 9 mm ammunition was used with an average

impact energy of approximately 770 J. However, Level IIIA protection is also tested with .44 Magnum ammunition, which carries a nominal impact energy of 1478 J—nearly double that of the 9 mm. Consequently, BFS values could reach or slightly exceed the allowable limits, leaving it uncertain whether a failure is due to the sample's performance or the influence of the backing material's properties. While the latest NIJ 0101.07 standard addresses these issues through larger sample sizes and advanced statistical processing, it is not yet widely implemented. Many laboratories cannot yet meet these requirements for accreditation, leading manufacturers to continue opting for equipment certification under the NIJ 0101.04 version.

3.2 Ballistic test method for personal armour materials and combat clothing - STANAG 2920

The test results are presented in Table 6, where complete penetrations are denoted as CP and partial penetrations as PP. In addition to the standard method, the V_{50} value was also determined using the Probit method [5], which is known to provide reliable results, particularly in cases involving a wide range of velocity values.

Table 6. Test results for the determination of V_{50} value

Lab. code	Sample	CP, [m/s]	PP, [m/s]	V_{50}, [m/s]	V_{50}, probit [m/s]	D, [m/s]

	3	569.6 572.0 589.9	603.9 583.8 566.7	581.0	580.4	-32*

In Table 6, the range between the highest partial penetration velocity and the lowest complete penetration velocity is designated as D. It is observed that negative values (marked with an asterisk) indicate an overlap between these values. This phenomenon was especially pronounced in Sample No. 3 tested at Laboratory C, where the overlap spanned almost the entire velocity range, from 569.6 m/s to 603.9 m/s. Conversely, a distinct "zone of separation" was observed in Laboratory A, where no velocity overlap occurred.

Table 7 presents the descriptive statistics for each laboratory based on both V_{50} calculation methods. The mean V50 value for each laboratory is denoted as V_{50aver}, while the standard deviation is represented by σ. The corresponding boxplot and interval plot are illustrated in Figure 6.

Table 7. Descriptive statistics for V_{50} (all values are expressed in m/s)

Lab. code	Method STANAG 2920		Probit method	
	V_{50aver}	σ	V_{50aver}	σ
A	626.5	8.32	629.5	7.78
B	610.3	1.76	610.3	2.59
C	578.5	4.05	577.8	2.65

The statistical analysis was conducted using a one-way ANOVA, with the testing location (laboratory) as the primary factor. To ensure the validity of the results, an F-test for equality of variances was first performed as a fundamental prerequisite for ANOVA. The results indicated a significant difference in variance between Laboratories A and B (p=0.043) regarding the V_{50} results calculated per STANAG 2920. However, when analyzing the Probit method results, no variances were significantly different. This highlights the robustness of the Probit method and its ability to compensate for suboptimal velocity selections. Consequently, further analysis was conducted using an ANOVA test that does not assume equal variances, supplemented by the Kruskal-Wallis non-parametric test.

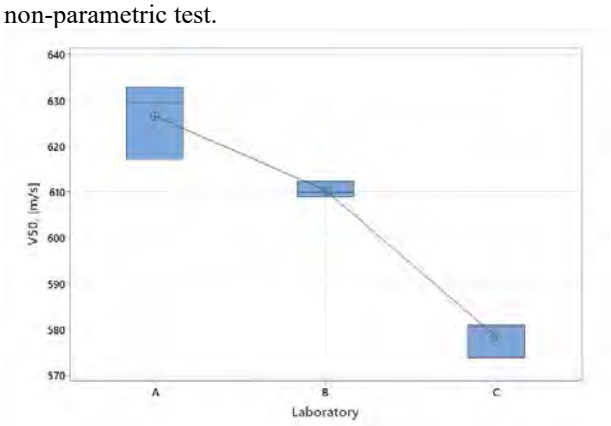

Figure 6. Boxplot and interval plot of V_{50} values

The ANOVA yielded a p-value of 0.002 (F=72.42), indicating a strong, statistically significant difference in test results between laboratories. The Games-Howell simultaneous test for differences of means confirmed that these significant differences primarily exist between Laboratory C and the other two facilities. The model's coefficient of determination R^2 was 95.29%, with a predicted R^2 of 89.40%, suggesting high precision for predicting new observations. The Ryan-Joiner test statistic for normality was 0.985 (p>0.05). Although there

appear to be large differences between Laboratories A and B, the high variance in Laboratory A combined with a relatively small sample size prevents a definitive conclusion regarding the statistical significance of the difference in their V_{50} mean values. The Kruskal-Wallis test corroborated the ANOVA results by confirming significant differences in medians between the laboratories, although this test cannot identify specific differing pairs.

These findings suggest that the "laboratory factor" plays a crucial role. This influence stems from several sources:

- Impact Velocity Determination: The velocity is not measured directly at the impact point but is calculated based on the velocity measured along the trajectory.
- Sample Mounting: The method of securing the sample and the impact of material degradation from previous hits on subsequent ballistic behavior.
- Velocity Range: The specific range of velocities used to calculate V_{50}.

The application of the Probit method resulted in values that were more consistent than those obtained through the classic arithmetic mean. To improve accuracy, laboratories should aim to achieve a sufficient number of hits to narrow the velocity range. While the STANAG 2920 prescribes a calculation based on six hits, numerical simulations suggest that a much larger number of impacts is required for a truly reliable V_{50} estimate. Furthermore, as noted in previous research [6], a higher variation in the response truth set (a larger zone of mixed results) leads to higher variation in the V_{50} estimate, reduced test efficiency, and a greater susceptibility to test-method-induced bias. This was practically demonstrated by the results from Laboratory C, particularly regarding Sample No. 3.

Due to the wide range of V_{50} values, a statistical analysis was performed in accordance with ISO 13528 to determine the measurement uncertainty. The procedure was based on the Robust Statistics Algorithm A. The results, shown in Table 8, include the standard (u) and expanded (U) measurement uncertainties. A coverage factor of k=1.96 was used for the expanded uncertainty, providing a confidence level of approximately 95%.

Table 8. Uncertainties of measurement for V50 (m/s)

Lab. code	A	B	C	Mean absolute
u	6.8	1.4	3.3	20.0
U	13.3	2.8	6.5	39.2

5. CONCLUSION

The testing conducted in accordance with the NIJ 0101.04 method indicates significant deviations in mean values depending on the specific laboratory, with the Roma Plastilina No. 1 backing material identified as the primary source of variability. This study has demonstrated and statistically proven that, for a selected threat, the correlation between projectile velocity and Backface Signature (BFS) is practically non-existent. In the given case, the linear regression and ANOVA models exhibited low R^2 values and low predictive power, likely due to the small group sizes in the study (three shots per panel). However, these models are consistent with earlier studies that also confirmed this behavior and the lack of correlation. As a result, the linear regression model cannot reliably predict BFS depth based on impact velocity. Therefore, it is recommended that laboratories, at least informatively, measure BFS for both shots (2 and 3) rather than exclusively for the shot with the higher velocity. To improve the reliability of quality assessments, manufacturers should define sample sizes and allowable BFS values based on statistically grounded test protocols, considering confidence intervals rather than isolated measurements.

The laboratory factor was also found to play a crucial role in V_{50} results, stemming from probably differences in mounting methods and velocity determination models. However, the application of the Probit method yielded results that were more consistent and robust than those obtained through the traditional arithmetic mean.

Furthermore, each laboratory must establish the measurement uncertainty of the method, which this study confirms is significantly higher than the uncertainty of the measuring instrument alone. Addressing these systemic variabilities is essential for a more accurate interpretation of ballistic protection levels, particularly when results are near the maximum allowable limits.

Abstract: *The subject of this paper is the assessment of the condition of the existing propulsion system of the auxiliary ship PBR-36 "Šabac" from the aspect of the occurrence of increased vibrations on the shaft lines for power transmission to the propeller. The paper presents a detailed and comprehensive approach aimed at detecting the source of increased vibration levels in the propulsion system, which consequently led to the failure of the ship and its decommissioning, which is part of the River Flotilla of the Land Forces. By implementing control vibration measurements, using measuring instruments and diagnostic equipment, the main source of increased vibrations was determined, based on which a recommendation was given for further measures to eliminate malfunctions in the propulsion system. After examining the condition and analyzing the measurement results, the ship PBR-36 "Šabac" was sent to docking, with a focus on repairing the propulsion system. After lifting the ship to the river dock and inspecting it in a disassembled state, the assumptions obtained by the diagnostic equipment were confirmed and the source of increased vibrations in the power transmission system from the engine to the propellers was determined (defective release bearing and misalignment of the propeller shaft). After the work on replacing the defective parts and assemblies of the propulsion system, as well as bringing the eccentricity of the propeller shafts to the permissible deviation limits, the ship was launched into the water, after which control measurements were performed again. A condition assessment was performed and a comparative analysis of the deviations of the measured vibration values after docking was given in relation to the previous report and the reference values defined by the standard. Finally, a conclusion was given with a condition assessment and a proposal for further work.*

Keywords: *propulsion system, vibrations, shaft line, docking, measurement.*

1.INTRODUCTION

The auxiliary river ship PRB-36 "Šabac" is in operational use as part of the 1st River Detachment, River Flotilla, Army.

A ship of this type is designed for demagnetizing ships, forming and maintaining a command post of the river detachment rank, patrolling and controlling river routes.

Figure 1. The auxiliary river ship PRB-36 "Šabac"

The ship is powered by two four-stroke diesel engines,

both with a power of 192kW, which provide the ship with a displacement of 115.8t with a maximum speed of 22 km/h.

The ship's propulsion system consists of two parallel diesel engines, which drive one bronze propeller with fixed blades each via a coupling, cardan shaft, and propeller shaft.

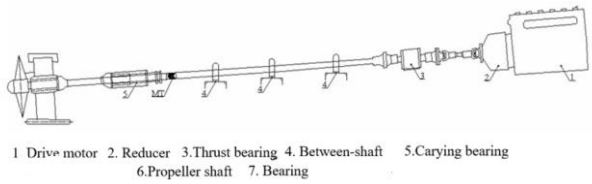

Figure 2. Sheme of propulsion

In this case, the drive motor (1), through a reducer with a coupling (2), drives a propeller with fixed blades. Between the reducer and the propeller is a thrust bearing (3), which receives the axial force from the propeller and transfers it to the ship. The propeller shaft consists of an

DOI: 10.5937/OTEH26142D

intermediate shaft supported on three roller-type support bearings (4), and a propeller shaft supported in sliding rubber bearings in the mast tube and the rudder (5).

Taking into account empirical indicators in operation, characteristic examples of failures of ship subsystems occur precisely in the system for transferring power from the engine to the propellers, which was the case here. After the malfunction of the ship's propulsion complex, as a consequence, operating parameter values outside the permissible range appeared in operation, which led to the occurrence of failures. Taking into account the experience of the crew, signs of failure in operation were identified in time, thus preventing major damage to vital ship sites.

2.FAILURE OF THE SHIP'S PROPULSION SYSTEM

During the regular operation of the ship, changes in the state of the ship's propulsion system were observed, in the form of increased vibrations transmitted to the ship's shell, a specific sound of a failed bearing, and an increased temperature of the thrust bearing housing. Based on empirical indicators of non-specific operation and characteristic deviation parameters, the ship's crew took measures to prevent further failure of vital ship systems by operating the ship within the empirically acceptable load range.

Based on the above, it was necessary to detect the degree of malfunction of the propulsion system of the auxiliary ship "Šabac", define the cause and consequences of the failure, and propose further measures that need to be taken to restore the ship to proper condition.

Detection of ship propulsion malfunctions included diagnostic measurements carried out by the Technical Testing Center, with the assistance of the ship's crew. For this purpose, and in order to obtain as realistic a picture of the problem as possible, a test run was carried out on the Danube River, in different sailing modes, which ensured a simulation of the propulsion system load in real conditions.

3.DIAGNOSTIC MEASUREMENTS

The content of the diagnostic measurements was determined by the symptomatic occurrences of failures as well as previous experience in detecting the cause of malfunctions of the ship's propulsion system on other ships of the River Flotilla. Based on the above, the diagnostic measurements included the determination of the following parameters, as a function of assessing the state of the propulsion system: torque and power measurements, linear vibration measurements and bearing temperature measurements on the ship's propeller shaft of the auxiliary ship PRB-36 "Šabac".

3.1 Measurement conditions

The measurement was carried out in upstream travel at approximately normal ship displacement (D= 110 t), on the left and right propellers. The measurement was carried out in three sailing modes, and with the restriction that the maximum mode of the propulsion engines was at 1400 rpm. The specified mode was empirically estimated as the maximum safe mode (according to the ship's commander's assessment), in which vibrations of the propulsion complex cannot cause damage to the propulsion elements and for which there is a very low risk of failure.

3.2 Measuring equipment

To measure the shaft deformation, on the basis of which the power delivered to the propeller was calculated, measuring tapes of the type XY21 6/120 (tape factor K=2.09), manufactured by Hottinger Baldwin Messtechnik, connected in a full Wheatstone bridge, were used.

To measure the number of revolutions of the propeller shafts, a tachometer TAC-10, manufactured by SPM, was used, while measurements of linear vibrations of the propulsion complex elements were performed using a portable vibrodiagnostic device Falcon and a three-axis accelerometer 0.1dB-Metravib SAS.

Measurements of the bearing housing temperature were carried out using a non-contact thermometer VOLCRAFT, IR-1000L.

4.RESULTS OF MEASUREMENT

4.1 Power measurement results on the left and right return lines

The results of the power measurements on the left and right propeller shafts were obtained based on the read values of the changes in the resistance of the tape, which is proportional to the deformation. Using the Spider 8 measurement acquisition device and the transmitted signal from the measuring tape, with prior calibration, the tangential and normal stresses were determined, and therefore the torque and transmitted power on both shaft lines.

Table 1. Result of power measurement

Nv (o/min)	Nmot (o/min)	M_v (Nm)	Pv (kW)	Nv (o/min)	Nmot (o/min)	M_v (Nm)	Pv (kW)
507	1014	668,21	35,46	509	1018	713,85	38,03
670	1240	1146,85	80,42	647	1294	1228	86,11
705	1410	1417,8	104,62	695	1390	1391,04	101,19

Nv – shaft speed, Nmot – drive motor speed, Mv – torque measured on the shaft, P v – power measured on the shaft (power delivered to the propeller).

Comparing the measured power values on the left and right shafts, it can be concluded that at lower driving modes the right engine is more loaded than the left. This is also supported by an insight into the measured values of the exhaust gas temperature of the left and right engines, where a constantly higher exhaust gas temperature of the right engine is observed compared to the left engine (the difference is up to 100 °C).

4.2 Linear vibration measurement

By analyzing the measured values given in Table 1, it is observed that the vibration level is above the values recommended by the American Bureau of Shipping (ABS) standard for vibration on marine propulsion devices, on the following elements of the return line: 1) right reducer, longitudinal and vertical, at 585 rpm; 2) left thrust bearing, longitudinal, at 605 rpm and 705 rpm; 3) right thrust bearing, vertical and longitudinal, at 500 rpm and 650 rpm.

4.3 Measuring temperature on bearings

Given the inaccessibility of the measurement site, the temperature was measured contactlessly on the bearing housing itself.

Table 3. The measured temperature values

rpm	Legft/Right thrust bearing	Legft/Right bearing between shaft	Legft/Right bearing shaft
500	33.3/42	21.3/18.1	27.3/24.4
600	34.9/43	22.6/19.5	28.7/27
700	36.6/47.2	24/19.7	34.1/29.8

4.4 Analysis of measurement results

After conducting diagnostic tests and performing measurements, and analyzing the measured operating parameters of the left and right return lines, the following conclusions were reached:

On the left shaft, values of impermissible vibration levels were observed at the thrust bearing, as well as the existence of angular misalignment in the axle assembly. The recommended permissible vibration speed value according to the ABS standard is 5 mm/s, while the measured values are up to 10.22 mm/s, at 705 rpm.

An irregularity was observed on the right shaft in the form of impermissible vibration levels on the gearbox and thrust bearing, which indicates the existence of angular misalignment of the shaft. The recommended permissible vibration speed value according to the ABS standard is 13mm/s, while the measured vibration speed values are 18.38 mm/s at 650 rpm. In addition, a malfunction of the left cardan shaft and the engine foot was detected. Taking into account the increased temperature value of the thrust bearing, the malfunction will also affect the service life, since thermal overload will occur in operating conditions over a longer period of time.

By comparing the condition values of the left and right thrust bearings, based on the frequency spectrum of axial vibration accelerations, a worse condition of the left thrust bearing is observed, which is in the zone of limited service life, i.e. there is the appearance of dominant frequencies in the zone of characteristic bearing frequencies, and the appearance of the so-called "carpet".

Taking into account that the measurements were carried out at modes lower than nominal, it is assumed that at higher modes, the values of the measured vibrations would be significantly higher.

Based on the conducted testing, docking of the ship and elimination of the malfunction were proposed.

5. DOCKING THE SHIP

Docking the ship and eliminating the malfunction, as shown in the previous chapter, was preceded by dismantling the malfunction, identifying the cause, and proposing defined works to be carried out in order to eliminate the causes and consequences of the malfunctions, identified during control measurements.

Figure 3. Docked ship

The observed defects during diagnostic testing and measurements carried out during the docking preparation process confirmed the assumptions regarding bearing defects, as well as return line misalignment.

Figure 4. Defective thrust bearing built

After troubleshooting in a disassembled state, it was determined that the thrust bearings had suffered serious mechanical damage, and that they had been exposed to operating conditions with improper cooling, and a similar condition was observed on the rolling support bearings of the return line after construction. Due to the general poor condition and worn out bearings, they were replaced with new ones. The condition of the propeller required machining, edge sharpening and balancing to bring the eccentricity within permissible limits.

Figure 5. Machined propeller bearings

As part of the final work on the docking of the ship, the painting of the ship's hull and plating was carried out.

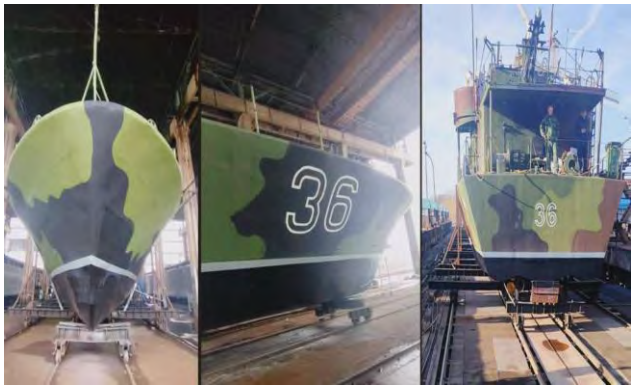

Figure 6. Appearance of the ship after docking

6. CONTROL MEASUREMENTS AFTER DOCKING

After the completion of docking and the elimination of malfunctions in the propulsion system, a test run was carried out as part of the handover works, during which control measurements were also performed to assess the condition of the ship's propulsion system.

The measurement was performed while sailing upstream at approximately normal ship displacement, on the left and right axle rows.

The measurement was performed in four sailing modes, with the note that the maximum mode was at 1590 rpm for the left main engine, and 1500 rpm for the right main engine. The specified mode was assessed as the maximum safe mode, according to the ship's commander, in which vibrations of the propulsion complex cannot cause damage to the propulsion elements.

Diagnostic measurements on the return lines included the determination of the following parameters:

- Measurement of linear vibrations on the supporting elements of the return lines;
- Measurement of temperatures on the supporting elements of the return lines.

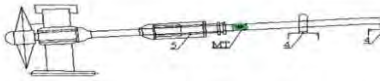

Figure 7. Position of measuring tapes on the return line

6.1 Linear vibration measurement

Linear vibration measurements were performed with the aim of establishing the vibration level, as well as comparing the measured values with the permissible values according to the American Bureau of Shipping standard.

Linear vibration measurements of the propulsion complex elements were performed using the Falcon portable vibration diagnostic device (сер.бр.10909) and the 0.1dB-Metravib SAS triaxial accelerometer, while the TAC-10 tachometer, manufactured by SPM, was used to measure the rotational speeds of the drive shafts.

795/750	5,17 /4,37	4,95 / 5,13	7,44 / 3,63	

By analyzing the measured values given in Table 4, it is observed that the vibration level is for the most part (in terms of measurement points and modes) within the limits recommended by the American Bureau of Shipping (ABS) standard for vibrations on marine propulsion devices.

Based on the measured results, it can be concluded that the extent of the work carried out on the docking of the ship was entirely aimed at eliminating the consequences and causes of the malfunction of the ship's propulsion system.

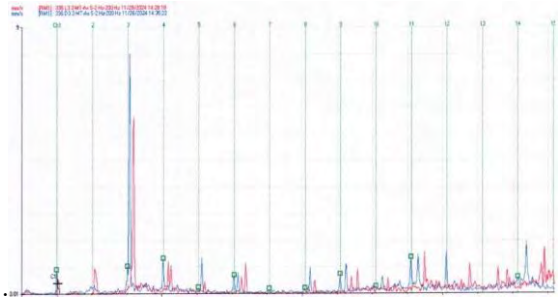

Figure 8. Frequency spectrum of the vibration on the thrust bearings

Figure 8 shows the frequency spectrum of vibration speeds, a comparison of axial vibrations on thrust bearings, for the case of the right engine 750 rpm, the left engine 795 rpm.

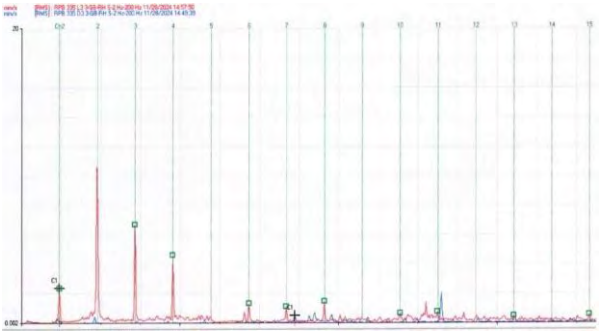

Figure 9. Frequency spectrum of the vibration on the on the first support bearing

Figure 9 shows the frequency spectrum of vibration speeds, a comparison of horizontal vibrations on the first support bearing, for the case of the right engine 675 rpm, the left engine 720 rpm.

6.2 Measuring temperature on bearings

Temperature measurement was carried out contactlessly, on the bearing housings, in four operating modes, and the VOLCRAFT IR-1000L instrument was used for this purpose.

Table 5. The measured temperature value

rpm	Left/right thrust bearning (t °C)	Left/right carying bearing 1 (t °C)	Left/right carying bearing 2 (t °C)	Left/right carying bearing 3 (t °C)
500	39,8 / 35,5	30,9 / 31,8	36,3 / 31,9	45 / 40. 1
600	37 / 31,6	29,4 ' 3 I,8	36,1 / 31,6	46,4 / 41,6
700	39,9 / 34	33,7 34,5	33,4 / 30,7	46,4 / 42.5
775	42,2 / 36,6	34,9 37,4	34,3 / 30,5	45,2 / 4 1,8

Comparing the measured temperature values, a slightly higher temperature of the last support bearings in the series is observed, but there are no results that significantly deviate from the measured temperature intervals. By reviewing the measurement results and comparing the bearing temperature values of the left and right return lines, it can be concluded that the values at different modes are approximately negligible differences for the left and right return lines, and that small differences in deviation can be attributed to the sensitivity of the measuring device.

7. EVALUATION OF MEASUREMENT RESULTS

By analyzing the measured operating parameters of the left and right shaft lines, the following conclusion is drawn:

The thrust bearing (behind the thrust bearing) of the left shaft line at driving modes above 1300 rpm had a horizontal vibration value exceeding the values recommended by the standard. The irregularity in the form of an impermissible vibration level, considering the order (second) and the direction of vibration (horizontal), indicates the probable existence of a parallel misalignment of the shaft line.

The thrust bearings on both shaft lines at maximum speed during operation had axial vibration values above the values recommended by the standard. The measured values, in accordance with previous experience and diagnostic measurements on Russian ships, are not unusual for the propulsion complex. By analyzing the frequency spectrum, it can be concluded that the higher level of vibration is caused by minor misalignments of the shaft line or unbalance of the propeller blades.

The measured bearing temperature values are within the permitted range and there are no values that significantly deviate from other measured temperatures on the return line bearings.

Empirically, from the perspective of the crew and experts from the River Flotilla who attended the test run, which lasted more than four hours at different operating modes, in upstream and downstream navigation conditions, the docking and repair work on the ship's propulsion complex met expectations and completely eliminated the consequences and causes of the failures.

It is particularly important to emphasize that early detection of failures in the operation of all subsystems is very important, because in this way the chain of failures of other subsystems and assemblies, causally and consequentially related to them, is prevented. Also, empirical understanding, understanding and "feeling" can often be crucial in cases of observing the state of health of ship subsystems, given that the assets under consideration (ships) represent complex technical systems, for which previously defined limitations and parameters do not coincide with actual operating conditions.

8. CONCLUSION

Warships are complex technical systems, which as such represent factors of a large number of subsystems.

The most important among them is the ship's propulsion system, which represents the "heart of the ship".

Ensuring the health of a ship's propulsion system involves a complex technical process of observing a number of parameters, as well as monitoring the health of components and return line elements. For this purpose, diagnostic tests are often carried out, in which measurements are carried out to determine quantitative indicators and assess the condition of the tested system, which was the case here.

The role of the crew was very important in the early detection of the failure of ship systems, so thanks to the timely reaction and diagnostic measurements, the malfunction of the ship's propulsion system of the auxiliary river vessel "Šabac" was confirmed, while maintaining the functional integrity of the ship by applying a limited mode of use (load).

After determining the malfunction of the ship's propulsion system of the auxiliary river vessel "Šabac" and analyzing the results of diagnostic measurements, the ship was docked and comprehensive work was carried out to eliminate the causes and consequences of the failure.

During the docking process, the ship's propulsion system components were disassembled and inspected, which allowed for a clear understanding of the causes and consequences of the malfunction. After the malfunction was identified, all defective components and assemblies of the ship's propulsion system were replaced, the return lines were processed to bring the eccentricity within the limits of permissible deviations, and the propellers were balanced.

After eliminating the observed malfunctions in the ship's propulsion system and the works envisaged by the scope of docking, a test run was carried out as part of the handover works, during which control measurements were carried out on the ship's propulsion system.

By analyzing and comparing the results of control measurements before and after docking, we conclude that the values of the measurement parameters after docking are within the limits of permissible deviations. Also, the empirical observation of the state of the ship's propulsion system by the ship's crew fully confirmed the drastic difference in ensuring the ship's maneuvering and propulsion characteristics after docking, which is in the function of ensuring the expected values.

MECHANICAL QUALIFICATION OF SINGLE SOURCE COMMERCIAL OFF THE SHELF (COTS) ASSEMBLIES FOR AEROSPACE AND DEFENCE ENVIRONMENTS

KONSTANTIN KOMATINA
Vlatacom Institute, Belgrade, konstantin.komatina@vlatacom.com

Abstract: *This paper establishes a test-based validation protocol to certify the "fitness for use" of a commercially available product that is subjected to aerospace and defense grade mechanical operating loads.*
Methodology rests on three pillars: Load characterization according to relevant standards; Testing based on those standards and Post load functional Verification.

Keywords: *mechanical qualification, COTS mechanical validation, structural integrity defence and aerospace MIL-STD*

1. INTRODUCTION

This paper establishes a rigorous validation protocol to certify the "fitness for use" of a specific commercial assembly subjected exclusively to aerospace-grade mechanical operating loads. In scenarios where other stressors like thermal and radiation are negligible, the primary risk to commercial hardware is structural failure or functional degradation due to launch-induced vibration and/or high-magnitude shock loads.

Commercial hardware is often chosen as a downgrade replacement for aerospace and defense grade components when such components are not readily available to design bureaus for various reasons. In aforementioned circumstances design bureaus must either rely that commercial components are sufficient for serious applications, or design and implement a validation protocol that will subject COTS to operating loads or verify failure modes in order to ensure reliable operation when time comes.

2. OPERATIONAL PROFILE AND WORK SCOPE

The test specimen in question is chosen due to being readily available, modestly priced and technologically familiar to engineers and technicians of various levels of expertise. This specific connector is available for purchase from web stores (1) for example.

Operational requirements of mentioned component are relatively unusual in practice and require clean separation and extraction during very short time period.
For this specific connector there are no available quality certificates, and certainly there are no datasheets that address the rigorous operating loads

Figure 1 – Push pull Connector

Thus, the next steps can be summed up as such:

- Define regulatory framework
- Define experimental design
- Define acceptance criteria

And in conclusion provide clear boundaries in COTS validation and applicability of industry standards to a specific engineering problem under severe test conditions.

Conclusion of this paper will be in comments about reliability of selected product according to MIL-DTL

DOI: 10.5937/OTEH26143K

3. REGULATORY FRAMEWORK

Starting point for any validation protocol is to define the regulatory framework that covers testing of the components. Unfortunately, what is readily available are standards that cover a wide range of tests in factory acceptance phase of the product development, such standards are MIL-STD-202 (2) for electronic and electrical components and parts, and MIL-STD 810 (3) for an even wider group of products.

These standards are not applicable to the scenario that is described.

What can be used is Detail specification MIL-DTL-24308G. This specification covers requirements for nonenvironmental, polarized shell, miniature, rack and panel connectors having pin and socket, for a -55 ^{0}C to +125 ^{0}C range (2). This range is compliant to operating temperature range per MIL-STD-810 (3).

4. EXPERIMENTAL DESIGN, ACCEPTANCE CRITERIA

Purpose of using aforementioned standard is to define a range of mating and unmating forces that are to be expected. These forces must be replicated during the test and based on those values, a simple PASS/FAIL Criteria is defined.

Mating forces are dependent on shell size of the connector and also its internal design (2).

There are alternative ways to verify (4) connector mating forces, however, such methods are more suited to the designers of the specific connector and not to end users or design enginners that intend to incorporate such products in their design.

Of equal importance is to define unmating speeds. Unmating speed in operating conditions cannot be replicated in laboratory conditions, and in this particular case would require a moderately expensive rig and a lot of resources to perform. MIL standard offers us a range of unmating speeds that can be replicated.
Those are given in a table bellow

Table 1 - Table from MIL-DTL

	low end	high end	Note
Unmating Force [N]	3	27	Per MIL DTL
Unmating speed [mm/s]	0.4	4	Test performed at unmating speeds of 2mm/s

During the experiment following items are used:

- Pair of calibrated 50gr, 100gr and 500gr weights for load cell calibration
- Number 6 Allen key
- Number 17 wrench
- Commercially available tensile test rig that has a load cell that measures forces up to 1000N

Figure 2 - Calibrated weights

Figure 3 - Number 6 Allen key

Figure 4 - Number 17 wrench

Figure 5 - Tensile test machine with load cell

Acceptance criteria is based upon visual confirmation that the push pull connector has extracted under all angles of attack. During the test, connector is subjected to loads under angles of attack of 0, 15, 30 and 45 degrees to verify across the entire expected range of operation. In order to achieve such alignment, a number of fixtures are manufactured.

Inside the connector the pins and soldered joints should not be damaged.

Damage to the outer shell is allowed.

Figure 6 - 45 degrees of extraction

Figure 7 - Connector pins

5. CALIBRATION, RESULTS

Before the start of the test load cell calibration is needed to produce a calibration curve. This curve will be used later on the determine correct force that was applied during the test

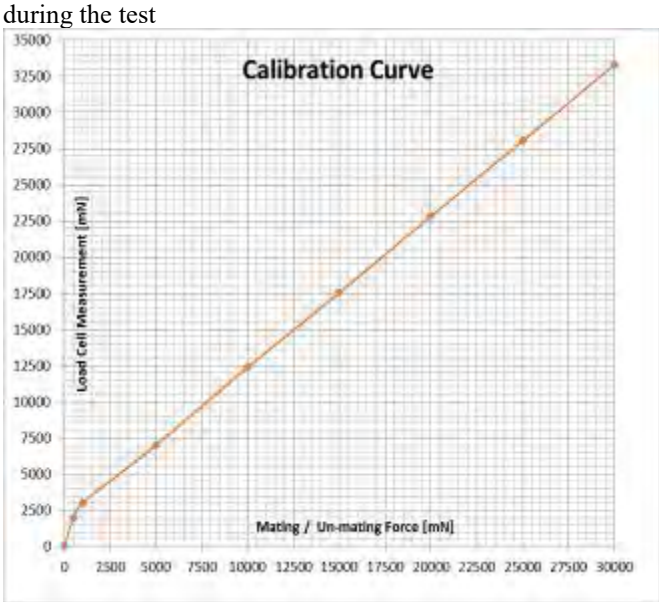

Figure 8 - Calibration curve

Force that is acting upon the connector is divided in 2 components – Fy component is the mating force and Fx component is the lateral component that will come into play as the angle of attack rises.

$$Fx = F * \sin(a) \quad (1)$$

$$Fy = F * \cos(a) \quad (2)$$

Only three of four mentioned angle of attack results will be shown in this chapter. Case number 4 will be discussed in the Conclusions section

Table 2 - Case 1 AOA 0 degrees

Drag angle [deg]		0	
#	Load cell	Unmating Force	Pass/Fail
/	N	N	/
1	14	14	Pass
2	14	14	Pass
3	15	15	Pass
4	17	17	Pass
5	17	17	Pass
6	18	18	Pass
7	18	18	Pass
8	18	18	Pass
9	19	19	Pass
10	20	20	Pass

Table 3 - Case 2 AOA 15 degrees

Drag angle [deg]		15		
#	Load cell	Unmating Force	Lateral Force	Pass/Fail
/	N	N	N	/
1	18	17	5	Pass
2	22	21	6	Pass
3	22	21	6	Pass
4	22	21	6	Pass

9	311	269	156	Pass
10	267	231	134	Pass

6. ANALYSIS AND CONCLUSION

Tabelar results are provided for only 3 of 4 tested cases.

- Case # 1 verified values retrieved from MIL-DTL (2), however prescribed durability of 500 cycles of mating and unmating wasn't tested as being deemed incompatible with real world operation
- Case #2 provided an insight in safety margins that were used when designing the Detail specification given that with the added increase in force, upper limit from MIL-DTL wasn't reached

From both these cases it can be concluded that MIL-DTL is very useful when verifying operation up to 15 degree pull angles.

Other two cases, Case #3 and Case #4 go beyond the industry standard, and are considered separately. Comments about the failure modes and effects on reliability will be provided in section below.

Case #3

Case #3 shows a great increase in force that results in damage to the lanyard that is used to pull the connector – see the figure bellow, and to the leaf springs that give the connector the push pull capability

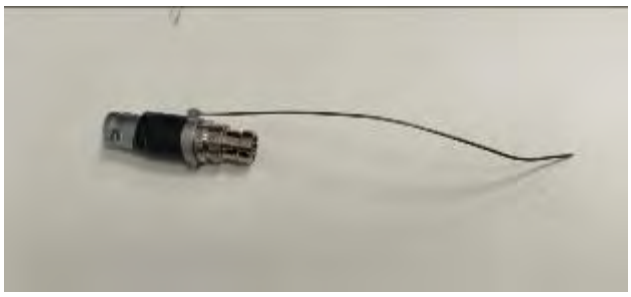

Figure 9 - Lanyard failure

Failure of the lanyard or damage to the leaf springs is not covered by MIL-DTL. Main failure mode identified by Detail Specification is damage to the pins and soldered connections inside the connector – **In this case, they are intact**

Reliability Inference

Connector can be still used with minor modifications to the lanyard – thicker cable and swaged joint will prevent the failure of the lanyard.

Thus connector should still be capable of MIL-DTL recommendation of 500 mating and unmating cycles.

However this would need to be verified.

Case #4 – 45 degree angle

This load case is the most severe of all provided.

To prepare the sample for the test, new lanyard must be engineered.

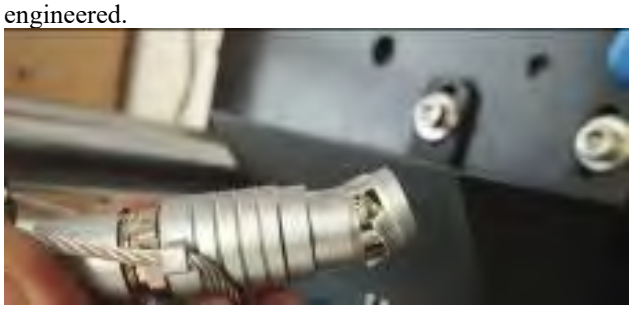

Figure 10 – Case #4 – Connector break

Table 5 - Case #4 AOA 45 degrees

Drag angle [deg]		45		
#	Load cell	Unmating Force	Lateral Force	Result
/	N	N	N	/
1	728	515	515	Fail
2	907	641	641	Fail

Distinct failure mode can be observed, lower part of the shell has completely broken, however the pins and soldered connections inside are still usable – unfortunately this connector is not.

Due to severe damage further tests at 45 degrees pull angle were not performed.

Reliability Inference

This connector is not usable and must be immediately replaced with one in working condition.

In this case, 500 mating cycles that are recommended in MIL-DTL are not achievable and this connector is single use only.

Abstract: *This paper presents the results of research related to the combined application of the Fault Tree Analysis (FTA) and Failure Modes and Effects Analysis (FMEA) methods for analyzing the reliability and safety of technical systems. FTA is a deductive (top-down) method in which, for a defined top event, the causal events that lead to it are identified. FMEA is an inductive (bottom-up) method for conducting reliability and safety analysis from lower to higher system levels. The individual application of these methods is time-consuming and does not provide a complete insight for reliability analysis and risk assessment. The combined application of FTA and FMEA enables the full utilization of the advantages of both methods while minimizing their limitations. Through the sequential application of FTA and FMEA across structural levels and their recursive application from the top to the bottom of the technical system structure, critical components that limit reliable and safe operation can be rapidly identified. The combined application of FTA and FMEA is illustrated through a case study involving the identification of critical components in the control system of light commercial vehicles. The paper concludes with directions for future research in this field.*

Keywords: *failure analysis, FTA, FMEA, combined application.*

1. INTRODUCTION

Reliability analysis of technical systems is based on the failure analysis of their components. Numerous methods have been developed to analyse failures in technical systems and their components. Among these methods, Fault Tree Analysis (FTA) and Failure Modes, Effects, and Criticality Analysis (FMECA) are the most widely used. [1, 2].

Fault Tree Analysis is a deductive analytical method in which, for a predefined top event representing the failure of the considered structural unit or system, the causal events leading to that failure are identified. The basis of Fault Tree Analysis is the representation of physical systems by means of structural logical diagrams.

The FTA method was developed in the early 1960s in the United States for the reliability and safety assessment of military systems [3, 4]. The method was conceived by H. A. Watson of Bell Telephone Laboratories**.** During 1961 and 1962, Watson developed and applied the method to the safety analysis of missile launch systems for the U.S. Air Force. Since the mid-1960s, FTA has been extensively applied to reliability and safety assessment, as well as fault diagnosis, of a wide range of complex technical systems. The method is particularly suitable for analyzing systems whose failures could result in catastrophic effects for human life and the environment.

Failure Modes and Effects Analysis (FMEA) is an inductive method for performing a qualitative analysis of the reliability and safety of a system, proceeding from the lowest to the highest system level [5]. It is based on the examination of all potential failure modes of the system components and their effects on the overall system, with the objective of identifying those failure modes that have the most severe impact on system performance.

FMEA was originally developed for military applications in the United States as a reliability assessment technique for determining the consequences of different failure modes in technical systems. As an official document in the form of a U.S. military standard, the method dates back to November 9, 1949, under the designation MIL-P-1629, entitled Procedures for Performing a Failure Mode, Effects and Criticality Analysis.

The standalone application of Fault Tree Analysis (FTA) and Failure Mode and Effects Analysis (FMEA) methods for risk assessment is time-consuming and does not provide a comprehensive insight into the criticality of system components and their failure modes. Combining these methods leverages their respective strengths while simultaneously minimizing their limitations.

A significant contribution to this field is presented in [6], which proposes a method where FTA and FMEA are applied recursively across different system levels. In this approach, FTA is first utilized to identify potential causes of system failures, after which FMEA is applied to assess the criticality of the identified failures. This procedure is repeated at various levels of the system hierarchy, thereby enabling a detailed analysis of system behavior and a more efficient identification of critical components.

Corresponding author: D. Ćatić;
E-mail: caticd@kg.ac.rs
DOI: 10.5937/OTEH26144C

Further development of integrated methods is presented in [7], which proposes an integrated FTA-FMEA model for risk analysis in complex engineering systems. In this approach, the minimal cut sets identified by FTA are used to determine the importance of individual events within the system. The obtained values are then used to modify the Risk Priority Number (RPN) index within the FMEA, resulting in a more accurate risk assessment and better identification of critical system components.

The combined application of FTA and FMEA methods in this paper is illustrated through a criticality analysis of steering system components in light commercial vehicles. Through the sequential and recursive application of FTA and FMEA methods across the structural levels of the system, the components that restrict safe and reliable operation were determined.

2. FAULT TREE ANALYSIS

An analysis of relevant FTA standards and the literature presented in [4] resulted in the following FTA methodology:

1. Define the system of interest and specify any assumptions to be used in the analysis.
2. Establish the boundaries and objectives of the system,
3. Define the top event of the fault tree. Depending on the analyzed system, it can be general, in the form of a system failure, or a specific case involving only a few failures of the system or its components.
4. Systematically collect and analyze system data (including documentation, calculations, catalogues, service instructions, user complaints etc.).
5. Verify and refine the fault tree. If the fault tree does not accurately reflect the actual system, if all significant events are not included, or if there is no logical relationship between the basic events and the top event, collect additional system data and revise the fault tree accordingly.
6. Perform a qualitative and/or quantitative analysis. Depending on the objective of the analysis, perform a qualitative and/or quantitative evaluation once the fault tree has been verified. For quantitative fault tree analysis, determine the minimal cut sets, which form the basis for most quantitative analyses.
7. Determine appropriate corrective measures. Based on obtained and adopted results through the fault tree, one should provide suggestions for corrective measures aimed at eliminating the perceived defects or proposals for alternative solutions.
8. Whenever the project changes, update and verify the fault tree and the associated analysis.
9. Document the analysis process and follow up on the implementation of identified corrective actions.

In the following basic approach, the development tree, analysis and eventual recommendations for corrective actions are presented as separate steps. In actual practice, there is a great deal of interactions between the steps listed. As a result, the fault tree that evolves includes additions and/or changes reflecting an improved understanding of the various faults.

A fault tree is constructed using event symbols, logic gates, and transfer symbols [5]. A variety of event symbols are employed to distinguish between intermediate (developed) events and basic initiating events. Intermediate events are represented by rectangles. Among the symbols used for basic events, the most common are the circle, representing a component state determined by its inherent characteristics, and the diamond, representing an undeveloped event. The logic gate symbols in a fault tree define the logical relationships and dependencies between events at different hierarchical levels. For example, an OR gate produces an output if one or more input events occur, whereas an AND gate produces an output only if all input events occur. Transfer symbols facilitate the construction of complex fault trees by linking the main fault tree to one or more subtrees.

3. FAILURE MODES AND EFFECTS ANALYSIS

FMEA is fundamentally a procedure for the qualitative assessment of the reliability of technical systems. A logical extension of FMEA is the quantification of failure-related parameters of system components and the evaluation of their criticality. This extension, which focuses on assessing the degree of criticality of individual components with respect to the system or its mission, is referred to as Criticality Analysis (CA). Criticality is generally defined as a relative measure that combines the severity of the consequences of a failure mode with its frequency of occurrence. Combining FMEA and CA results in Failure Modes, Effects, and Criticality Analysis (FMECA).

FMECA can be applied at various stages of a product life cycle. According to the literature, it is most commonly used to analyze technical system components during the product development phase and to evaluate operational data collected during product service.

When failure data for the components of a technical system are available from operational experience, or when the relevant failure indicators can be reliably estimated, the quantitative FMECA procedure is performed in three steps [1, 8]:

1. Determination of criticality of failure mode j of component i is to be done by categories of failure effects k (k = 1, 2, 3, 4), using:

$$C_{ij}^{(k)} = \alpha_{ij} \cdot \beta_{ij}^{(k)} \cdot \lambda_i \cdot t_i \tag{1}$$

where α_{ij} is a relative portion (frequency measure) of failure mode j of component i ($0 \le \alpha_{ij} \le 1$, $\sum_j \alpha_{ij} = 1$); $\beta_{ij}^{(k)}$ is conditional probability that failure mode j of component i will cause category k failure effect according to the adopted classification (values are taken from Table 1; $\lambda_i = \sum_j \lambda_{ij}$ is failure rate of component i; λ_{ij} is part failure rate of mode j of component i, and t_i is operating time of component i.

Table 1. Values of conditional probabilities

Degree of occurrence of the *k*-th failure effect category	$\beta_{ij}^{(k)}$ [-]
Certain event	1
Probable event	0.1 ... 1
Most probably would not happen	0 ... 0.1
Practically doesn't happen	0

Calculated values of $C_{ij}^{(k)}$ are the initial basis for determination of other quantitative properties of component criticality. They make it possible to rank the component failure modes according to effects in order to evaluate the most critical system failure modes from the aspect of safety.

2. Determination of failure criticality of component *i*, which causes the *k*-th category of failure effects:

$$C_i^{(k)} = \sum_j C_{ij}^{(k)} \tag{2}$$

Calculation of $C_i^{(k)}$ enables the identification of the most critical components whose failures lead to specific categories of effects.

3. Criticality of the *k*-th system effect category, determined by summing the criticalities of all component failure modes for the specified effect category:

$$C_k = \sum_i \sum_j C_{ij}^{(k)} \tag{3}$$

Calculated values of C_k are statistical indicators of the representation rating of the individual category of effects.

For quantitative FMECA of technical systems, a computer program was developed as part of this study.

This software consists of a routine for calculation of failure modes criticality and effect categories and their ranking, a subroutine for transformation of components of arbitrary array into descending series and a routine for forming of input files.

4. COMBINED APPLICATION OF FTA AND FMEA METHODS

The standalone application of FTA and FMEA methods has certain limitations.

The way the top event in the fault tree is defined greatly influences the success of the analysis. If the event is too general, the analysis becomes cumbersome and unmanageable. Conversely, if the event is too specific, the analysis does not provide sufficient insight into the system. Constructing a fault tree for complex technical systems is time-consuming, leading to delayed results during the product development phase. The focus of fault tree analysis is placed on analyzing the root causes of failures that lead to system failure. The consequences of failures on the potential system breakdown, people, and the environment are not considered. In addition, the FTA method has limited capabilities regarding component criticality analysis.

FMEA focuses on the analysis of individual components and often neglects complex interdependencies between various events within the system. FMEA is not suitable for application in complex technical systems.

Consequently, numerous researchers have proposed integrated approaches that combine FTA and FMEA to leverage the advantages of both methods and mitigate their individual limitations.

The combined FTA and FMEA method utilizes deductive and inductive approaches as needed. The constructed fault tree for the adopted top event, the constituent components, and their functions are considered in parallel. The objective of the method is to perform a comprehensive analysis of the causes, modes, and consequences of component failures based on the constructed fault tree and the completed FMEA worksheet. The fault tree enables a complete analysis of cause-and-effect relationships between events. Procedures defined within the FMEA method are used to analyze the criticality of component failure modes. It should be emphasized that these procedures significantly differ between FMEA based on product operational data and FMEA in the development phase. In the product development phase FMEA, the following parameters are determined for each identified component failure mode: Severity, Occurrence, and Detection. Based on these parameters, the Risk Priority Number (RPN) is calculated using the formula:

$$\text{RPN} = \text{Severity} \times \text{Occurrence} \times \text{Detection} \tag{4}$$

The obtained RPN values are used to rank the identified component failure modes and to prioritize the implementation of corrective actions.

The results of the quantitative fault tree analysis, in the form of minimal cut sets of events, enable the correction of RPN values and an improved risk assessment.

The combined method is particularly suitable for analyzing component failures in complex technical systems. It enables the precise identification of critical components. The proposed integrated approach allows for a more efficient system reliability analysis by combining the benefits of both approaches.

The columns of the FMEA worksheet regarding failure modes, causes, and consequences of component failures are filled out based on the constructed fault tree. This implies that the results of the FTA method are used as an input for the FMEA analysis, representing a sequential approach. To reduce the time required to obtain results on the criticality of complex technical system components and to decrease analysis complexity, it is expedient to conduct the described analysis procedure recursively across the structural levels of the system.

In the combined application of FTA and FMEA methods, the synergistic effect is fully realized. Namely, the contribution of the integrated application of FTA and FMEA in terms of work efficiency and effectiveness, as well as minimizing the time required to achieve the desired results, is significantly greater than the sum of the results of their individual applications.

5. CRITICALITY ANALYSIS OF STEERING SYSTEM COMPONENTS USING THE COMBINED FTA AND FMEA METHODS

5.1. Criticality analysis of system components

As part of the master's thesis [9], the research findings of which were published in [10, 11, 12, 13], the failures of the steering system of light commercial vehicles were analyzed using the FTA and FMEA methods. By constructing the fault tree, a cause-and-effect relationship was established between system failures and the failures of components at the lowest structural level. This approach made it possible not only to identify the most common failure modes of the system components but also to determine their ultimate effects.

With the objective of identifying the critical components that limit the reliable and safe operation of the steering system, a quantitative FMECA of the steering system components of commercial vehicles was performed using operational data. This analysis was based on a comprehensive dataset, part of which is presented in Table 2. The third column of Table 2, listing the failure modes of the system components, was derived from the fault tree. Furthermore, the effect categories assigned to the individual component failure modes (Column 7) were determined based on the intermediate events identified in the fault tree. The procedure used to collect the remaining data presented in Table 2 is described in detail in the cited references.

Table 2. Excerpt from the data table for the quantitative FMECA of the steering system of light commercial vehicles

Component name	Q [-]	Failure mode	Failure mode code	Rel. rate α_{ij} [-]	Loss prob. β_{ij} [-]	Final effect	t_{srj} [km] x10^3	t_{sri} [km] x10^3
Steering wheel 61001	1	Damage Insufficient tightening of screws	N.06 N.31	0.02 0.01	1.0 0.1	*k*.4 *k*.2	20 3	873.4
Steering shaft bushing 61005	1	Cracked bushes Increased clearance	N.06 N.35	0.3 0.7	1.0 1.0	*k*.3 *k*.3	200 100	130
Rubber insert 61011	1	Cracking	N.06	1	1.0	*k*.3	200	200
Worm shaft 61103	1	Damage of the teeth Cracking - fracture Damage of grooves	N.05 N.06 N.07	0.006 0.0005 0.001	1.0 1.0 0.8	*k*.3 *k*.1 *k*.3	300 350 200	895.4
The lever of the longitudinal tie-rod with ball joint 62110	1	The deformation of the lever Cracking - fracture Damage of the thread Loose connections Increased clearance	N.02 N.06 N.07 N.31 N.35	0.0005 0.0007 0.003 0.001 0.9948	0.6 1.0 0.8 1.0 1.0	*k*.3 *k*.1 *k*.2 *k*.2 *k*.3	30 100 100 15 100	99.9
Tie-rod ball joint 62210	1 1 1	Body joint deformation Fracture of the eyeball or the ball joint body Damage of the thread Loose connections Increased clearance	N.02 N.06 N.07 N.31 N.35	0.0002 0.0007 0.003 0.001 0.9951	0.3 1.0 0.8 1.0 1.0	*k*.3 *k*.1 *k*.2 *k*.2 *k*.3	40 100 100 15 100	99.9

By processing the data presented in Table 2, using the software program for conducting quantitative FMECA, the following results were obtained:

- degree of criticality of the failure modes of the steering system components, regardless of their effects,
- degree of criticality of the steering system components according to the effects of their failure modes, and
- degree of criticality of the final effects of failures of the steering system components.

Based on the degree of criticality of the final effects of failures in the steering system components, 99.38% of the components are associated with failure modes classified within the third effect severity category (the input and output parameters of the steering system exceed the permissible limits; examples of such deviations include increased backlash, steering wheel torque requirements that exceed normal operating values and misaligned wheel geometry resulting from the deformation of steering linkage components). Table 3 presents an excerpt from the criticality ranking of the steering system components according to failure effects, specifically referring to the components assigned to the third effect severity category.

Table 3. Degree of component criticality by effects on *k*.3

No.	Code	Component name	Criticality
1	62210	Tie-rod ball joint	0.5995E-03
2	62110	Lever with ball joint	0.5995E-03
3	61005	Steering shaft bushing	0.4608E-03
4	61011	Rubber insert	0.3003E-03
5	61110	Shaft with segment	0.3986E-05
6	61002	Steering shaft	0.8208E-06
7	61107	Slide bearing of output shaft	0.6707E-06
8	61104	Roller bearing of the steering head	0.5429E-06
9	61012	Flange on the worm shaft	0.4567E-06
10	61103	Worm shaft	0.4558E-06
11	61004	Steering shaft bracket	0.4027E-06

Figure 1 shows Pareto analysis of criticality of the steering system components with failure modes that have a third category of effects.

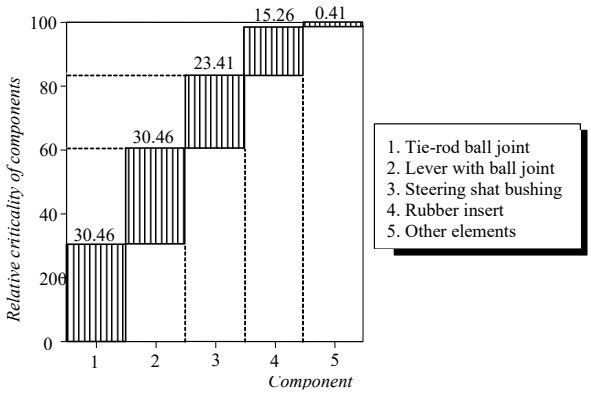

Figure 1. Pareto analysis of criticallity rate of components for category of effects *k*.3

Based on the results of the program for a quantitative analysis of the degree of criticality and Figure 1, it can be concluded that the most critical components of steering system in terms of durability and safety are: tie-rod ball joint, the lever of the longitudinal tie-rod with ball joint, steering shaft bushing and rubber insert of coupling. All other components are within 0.41% of criticality.

5.2. Criticality analysis of the tie-rod ball joint

Based on the previous analysis, it was determined that the tie-rod ball joint and the lever with the ball joint are the most critical components of the steering system. It should be emphasized that the criticality of the lever with the joint is conditioned by the criticality of the joint. In the further study, by applying a combined FTA and FMECA method, the criticality of failure modes and parts of the tie-rod ball joint was determined [9, 13]. To identify potential failure modes of the tie-rod ball joint, a fault tree was formed, shown in Figure 3. In this way, potential failure modes were recorded and their effects determined. The results of the FTA analysis were used to complete Table 4 with data for quantitative FMECA of the tie-rod ball joint parts.

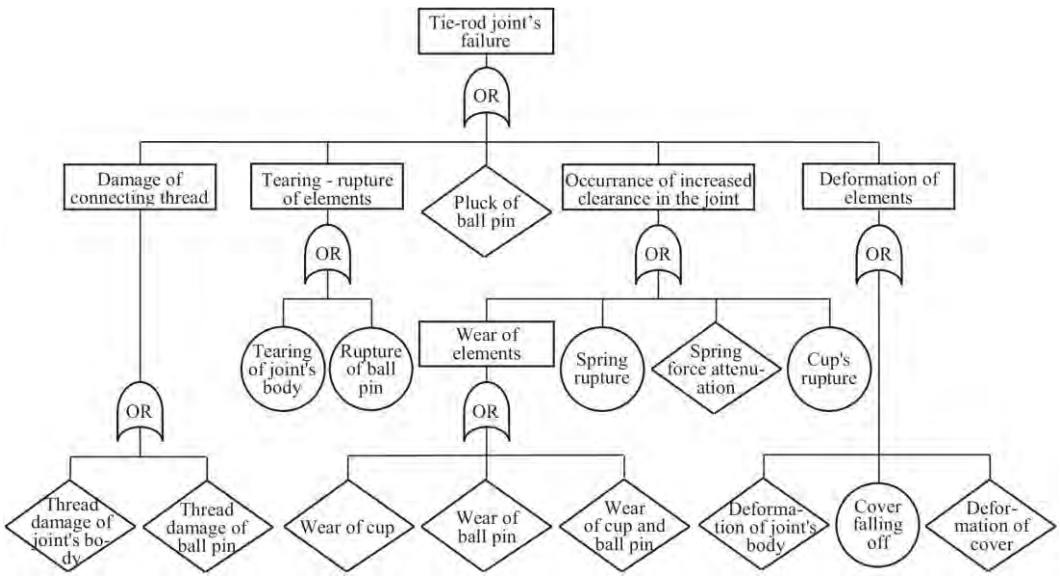

Figure 2. Independent failure tree of the light commercial vehicle steering tie-rod ball joint

Table 4. Basics of the FMECA procedure for components of the tie-rod ball joint for light trucks

Component name	Q [-]	Failure mode	Failure mode code	Rel. rate α_{ij} [-]	Loss prob. β_{ij} [-]	Final conseq.	t_{srj} [km] x10^3	t_{sri} [km] x10^3
Joint body 62211	1	Deformation Tearing of joint body Thread damage	N.02 N.06 N.07	0.0001 0.0007 0.003	0.3 1.0 0.8	*k*.3 *k*.1 *k*.2	200 200 100	≈100
Ball pin 62212	1	Rupture (tearing)of ball pin Thread damage Pluck of ball pin Wear	N.06 N.07 N.29 N.77	0,0007 0.0030 0.0002 0.9961	1.0 0.9 1.0 1.0	*k*.1 *k*.2 *k*.1 *k*.3	200 100 100 100	≈100
Cup 62213	1	Cup rupture Wear	N.06 N.77	0.003 0.997	0.7 1.0	*k*.3 *k*.3	150 100	≈100
Spring 62214	1	Spring rupture Spring force attenuation	N.06 N.12	0.0008 0.001	1.0 0.8	*k*.3 *k*.3	200 20	100
Cover 62215	1	Deformation Cover falling off	N.02 N.29	0.0002 0.0004	0.7 1.0	*k*.3 *k*.3	100 200	≈100
Sealing cap 62216	1	Total rupture Falling off Appearance of small rifts	N.06 N.29 N.37	0.002 0.007 0.004	1.0 0.9 0.2	*k*.4 *k*.4 *k*.4	30 150 20	99.89

By processing the data presented in Table 4 using the software program for conducting quantitative FMECA, the following results were obtained:

- degree of criticality of the tie-rod ball joint components failure modes, regardless of their effects,
- degree of criticality of the tie-rod ball joint components according to the effects of their failure modes, and
- degree of criticality of the final effects of failures of the tie-rod ball joint components.

Based on the degree of criticality of the ultimate failure effects of the tie-rod ball joint component, 99.21% of the total criticality sum of the components refers to failure modes of components with the third category of effects. Table 5 presents the ranked criticality values of parts for effect category *k*3.

Table 5. Degree of component criticality by effects on *k*.3

No.	Code	Component name	Criticality
1	62213	Cup	0.5986E-03
2	62212	Ball pin	0.5965E-03
3	62214	Spring	0.9598E-06
4	62215	Cover	0.3239E-06
5	62211	Joint body	0.1796E-07

Figure 3 shows distribution of criticality degree of the tie-rod components for effect category *k*.3. As it may be seen in Figure 3, failure of the tie-rod ball joint in the largest number of cases appears due to failure of the cup or the ball pin, while only 0.11% is due to other components.

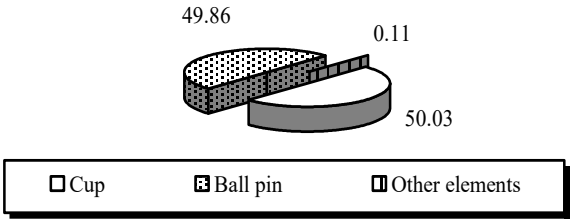

Figure 3. Distribution of degree of criticality for components of the steering system tie-rod ball joint for category of effects *k*.3

Analysis of the causes of failures in steering system tie-rod ball joint components can help identify appropriate measures to minimize or eliminate the causes of failures, or to reduce their effects.

6. CONCLUSION

The research results show that the integrated application of FTA and FMEA methods represents an effective approach for reliability analysis and risk management in complex technical systems. The combination of FTA and FMEA enables the identification of critical system components as well as more precise risk ranking based on the system structure and the characteristics of individual failures. The proposed methodology can be applied in various industrial fields, including manufacturing systems, electronic devices, and complex technical systems. As a direction for future research, the integration of this methodology with other risk analysis methods, such as probabilistic models, fuzzy logic, and Bayesian networks, is proposed to enable even more accurate quantitative risk assessment in complex technical systems.

This research was supported by the Faculty of engineering, University of Kragujevac [grant number 451-03-34/2026-03/200107, dated February 05. 2026].

A QUALITY ASSURANCE FRAMEWORK FOR METAL ADDITIVE MANUFACTURING

SRDJAN ŽIVKOVIĆ
Military Technical Institute, Belgrade, srdjan.zivkovic@mod.gov.rs

SLOBODAN MALBAŠIĆ
Ministry of Defence – Defence Technologies Department, Belgrade, slobodan.malbasic@mod.gov.rs

MILOŠ STEPANOVIĆ
Military Technical Institute, Belgrade, hunter.milos@gmail.com

Abstract: *From a defense perspective, Additive Manufacturing (AM) has evolved from a rapid prototyping technology into a strategic capability and has become one of the key enablers of military modernization. Its applications include replenishing spare-part inventories for legacy platforms, enhancing supply chain agility, supporting forward operational logistics through on-site production of spare parts and rapid repairs, and improving overall operational readiness. Original Equipment Manufacturers (OEMs) and defense industries must rapidly adapt to AM technologies and comply with a comprehensive set of qualification and certification requirements to become qualified AM producers capable of manufacturing and delivering critical spare parts.*

The qualification of AM processes and parts is a highly challenging and demanding task, primarily defined by ***ISO/ASTM 52920:2023****, the international standard for quality assurance in additive manufacturing. Within the Quality Assurance (QA) framework, certification and qualification serve as essential tools for verifying and validating that manufacturing processes, parts and personnel comply with established standards and specified requirements.*

This paper provides a brief overview of the certification and qualification process for AM processes and components. Furthermore, it discusses the key challenges associated with conventional and AM-specific qualification approaches, as well as a novel qualification methodology currently being developed by the U.S. National Institute of Standards and Technology (NIST). Finally, the paper presents a basic framework for the qualification of AM parts intended for use in the armament and military equipment of the Serbian Armed Forces (SAF).

Keywords: *Quality Assurance, Additive Manufacturing, Qualification, Certification.*

1. INTRODUCTION

Quality standards, in the broadest sense, are established to ensure the consistent quality of industrial products over an extended period. When machine parts are manufactured using additive manufacturing (AM) technologies, it is essential to verify that they meet all specified technical and quality requirements. This requires that every stage of the production chain (Figure 1) be designed and controlled to ensure the consistent and repeatable quality of manufactured parts.

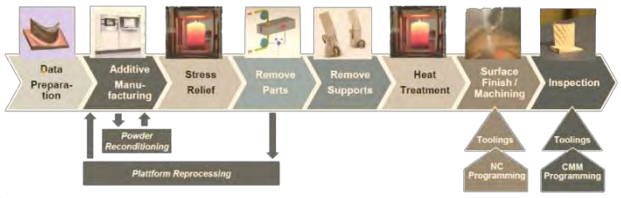

Figure 1. AM operations flow diagram

Quality Assurance (QA) is a comprehensive and systematic approach aimed at preventing defects and ensuring that a product or service fully complies with specified standards and user requirements before it reaches the end user.

Unlike Quality Control (QC), which focuses on detecting defects in finished products, QA encompasses the entire manufacturing process. It ensures process quality and stability during machine operation (in-process QA), as well as throughout the pre-process phase (input material verification and process preparation) and the post-process phase (inspection and testing of the finished part).

Quality Assurance (QA) uses Certification and Qualification as key tools to ensure and validate that processes meet set standards. The certification process is to assure the compliance with qualified parameters and standards. The qualification process is to demonstrate the ability to fulfil specified metal AM requirements, [1].

A specific aspect of quality assurance in additive manufacturing concerns production facilities and infrastructure, which must comply with stringent environmental control requirements. In addition, personnel involved in AM processes must possess appropriate qualifications and competencies.

The rapid adoption of metal additive manufacturing has introduced numerous technical challenges related to

Corresponding author: S. Živković;
E-mail: srdjan.zivkovic@mod.gov.rs

DOI: 10.5937/OTEH26145Z

ensuring product quality and confidence in component performance. Despite significant technological advances, concerns remain regarding whether metal AM parts can reliably replace components manufactured using conventional production methods, particularly in safety-critical applications. Nevertheless, additive manufacturing technologies are steadily becoming an integral part of modern manufacturing alongside conventional production technologies.

To achieve reliable and continuous quality management in industrial AM production, manufacturing equipment must be qualified in accordance with ISO/ASTM 52920:2023 [2], while programmers and machine operators must be qualified in accordance with the applicable personnel qualification standards [3,4]. Both qualifications are mandatory prerequisites for the certification of metal AM parts. Only after successful certification manufactured components (particularly those intended for load-bearing or mission-critical applications) can be integrated into military equipment.

Additive manufacturing is transforming defense procurement, from rapid prototyping and field repair to the production and deployment of qualified end-use components. Armed forces increasingly employ AM to enhance operational readiness by reducing supply chain vulnerabilities and enabling agile, on-demand, and localized manufacturing.

The primary AM technologies currently used in defense applications include, [5]:

- Polymer AM**,** particularly Material Extrusion (MEX) systems, which are widely adopted because of their relatively low acquisition cost, compact size, ease of operation, and plug-and-play capability.
- Metal Additive Manufacturing (MAM) technologies, including Laser Powder Bed Fusion (L-PBF), Directed Energy Deposition (DED), and Cold Spray. Although these technologies require significantly more complex infrastructure and logistics, they are rapidly advancing and are becoming increasingly important for the production of high-performance metal components.

The remainder of this paper is organized as follows. Section 2 provides an overview of the primary standards governing additive manufacturing. Section 3 reviews the conventional qualification process for parts manufactured using traditional production technologies and proposes a qualification new framework for AM components intended for military applications. Section 5 discusses personnel qualification requirements for Metal Additive Manufacturing. Finally, Section 6 outlines the infrastructure requirements for AM facilities and addresses the health and safety (H&S) aspects associated with metal additive manufacturing.

2. AM RELATED STANDARDS

ISO/TC 261 (International Organization for Standardization – Technical Committee) classifies AM standards into three levels, [6]: 1) *General standards:* which define general concepts, common requirements, or provisions applicable to most AM materials, processes, and applications, 2) *Category standards:* which specify requirements applicable to a particular material category (e.g., metal powders) or process category (e.g., Powder Bed Fusion), 3) *Specialized standards:* which define requirements for specific materials (e.g., aluminum alloy powders), specific processes (e.g., Material Extrusion using ABS), or application-specific sectors (e.g., aerospace, medical, or automotive industries).

To date, ISO/TC 261 has published 27 international standards**,** while 32 additional standards are currently under development, [7]**.** The large number of standards reflects the complexity and rapidly evolving nature of additive manufacturing technologies. As AM continues to mature and expand into new industrial sectors, further standardization activities are expected.

The development of AM standards is carried out jointly by ISO and ASTM International (formerly the American Society for Testing and Materials) through close cooperation between their respective technical committees. Such collaboration is essential to ensure that multidisciplinary expertise is incorporated into internationally recognized standards and to promote harmonized industrial practices worldwide.

The ISO/ASTM 52920:2023 standard establishes a comprehensive quality assurance framework that integrates system qualification, process monitoring, and part verification throughout the additive manufacturing process, Figure 2.

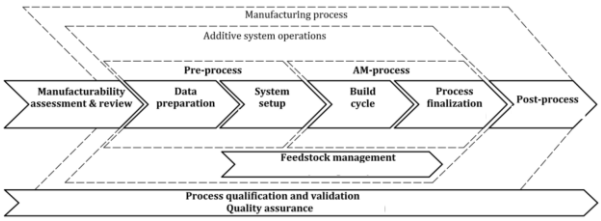

Figure 2. Overview of AM relevant processes in an AM production site

Furthermore, the standard defines the AM-related processes performed within an AM production facility and specifies the corresponding quality requirements for each process. The framework is organized into the following core technical areas, [2]: 1) Infrastructure of the part manufacturer; Manufacturability assessment and review; 2) Qualification of additive manufacturing system operations**,** focusing on machine qualification and risk assessment; 3) Quality-relevant process steps**,** addressing the control of production operations and material management; 4) Quality assurance**,** including personnel competence, final part verification, and the management of nonconforming products.

The minimum requirements for a Quality Management

System (QMS) are specified in ISO 9001. However, several industrial sectors have established sector-specific quality management standards that include additional requirements reflecting their particular regulatory and operational needs.

The most widely recognized examples include IATF 16949 for the automotive industry, ISO 13485 for medical devices, and EN/AS 9100 for the aerospace and defense industries. For organizations intending to supply AM components to the aerospace industry, certification according to EN/AS 9100 is generally considered a mandatory prerequisite, [8].

Based on the principles of ISO 9001, the EN/AS 9100 standard introduces additional requirements that are particularly relevant to aerospace and defense applications. For components manufactured using additive manufacturing technologies, these include: 1) Configuration management and process parameter control, 2) Complete material traceability throughout the manufacturing process, 3) Comprehensive risk management, 4) First Article Inspection (FAI), 5) Supplier qualification and control.

3. CERTIFICATION PROCESS DESCRIPTION AND PROPOSED FRAMEWORK

The certification of Metal Additive Manufacturing (MAM) parts is a complex and multidisciplinary process that typically involves several organizations and institutions. Outsourcing specific qualification activities to pre-qualified organizations can significantly reduce both the time and cost required for part certification while ensuring compliance with applicable standards.

Laser Powder Bed Fusion (L-PBF) is currently the most extensively researched additive manufacturing technology for aerospace applications and is therefore at the forefront of qualification and certification activities.

The National Aerospace and Defense Contractors Accreditation Program (Nadcap) was among the first certification bodies to establish a dedicated audit and accreditation program for Powder Bed Fusion technologies for the application in aviation, defense, and space programs. The Nadcap AM audit evaluates powder management, machine calibration, process control, and part qualification.

3.1 Certification procedure within the Serbian Ministry of Defense of the Republic of Serbia

Within the Serbian Ministry of Defense (MoD), the certification procedure for parts manufactured by the Original Equipment Manufacturer (OEM) is governed by the Regulation on Conformity Assessment in the Production of Armament and Military Equipment (AME) together with the corresponding Implementation Instructions, which provide detailed guidance for the execution of the conformity assessment procedure.

The conformity assessment is performed according to an approved Test Plan and Test Program by the relevant national institutions, including the Overhauling Facility Čačak, the Aeronautical Institute "Moma Stanojlović", the Technical Test Center (TTC), the Military Technical Institute (MTI), and, where appropriate, the relevant OEMs from the Serbian defence industry.

Upon successful completion of the certification activities, the OEM submits the required documentation to the Department for Defense Technology, including the test report, conformity assessment report, and evidence of compliance with applicable management system requirements, primarily the Quality Management System (QMS). Following a technical review of the submitted documentation, the Department issues the final Certificate of Conformity together with the approval for serial production.

3.2 Proposed framework for the certification of AM parts

The proposed framework is intended to optimize the qualification effort throughout the certification process while incorporating internationally recognized best practices for the industrial implementation of Additive Manufacturing.

At present, Serbia does not have a dedicated certification body accredited for the qualification of metal AM components. The institutions from MoD with the highest level of competence in this field are the Technical Test Center (TTC) and the Military Technical Institute (MTI). The proposed certification framework therefore should assume close cooperation between these two institutions. Although neither of these institutions individually possesses the competencies required to perform the complete qualification process, together they can provide comprehensive coverage of the required activities.

For additively manufactured components, conventional qualification procedures originally developed for traditional manufacturing technologies cannot be directly applied without modification. Consequently, a new qualification framework should clearly distinguish part verification from process and production-site qualification, including facility qualification.

The proposed qualification methodology consists of four sequential stages, Figure 3: 1) Process qualification, 2) Part qualification, 3) Functional testing under operational conditions, 4) Issuance of the Certificate of Conformity and production approval.

Process qualification verifies that materials, equipment, manufacturing parameters, and production workflows consistently produce components that satisfy the specified technical and quality requirements. The qualification methodology follows the internationally accepted three-stage approach consisting of Installation Qualification (IQ), Operational Qualification (OQ), and Performance Qualification (PQ), [9].

IQ confirms that the AM machine, software, auxiliary equipment, and supporting infrastructure are installed, calibrated, and maintained in accordance with the OEM's

specifications. This stage also verifies that environmental conditions, including temperature, humidity, ventilation, and safety systems, satisfy the required operating conditions.

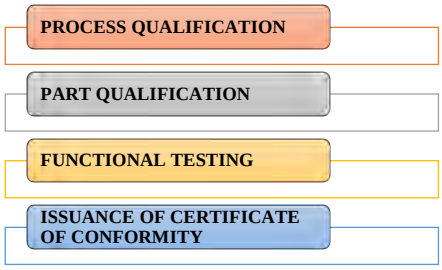

Figure 3. Framework proposal for am part qualification

OQ evaluates the critical process parameters, including laser power, scanning speed, layer thickness, hatch spacing, and other process variables. Qualification specimens are manufactured and tested to verify material properties, process capability, and manufacturing repeatability.

PQ demonstrates that the complete manufacturing process—from design and feedstock preparation to printing, post-processing, and inspection—can repeatedly produce conforming parts over multiple production runs. Qualification specimens are subjected to dimensional inspection, non-destructive testing (NDT), destructive testing, and mechanical property evaluation.

Regardless of the selected production model, whether components are manufactured in-house or supplied by an external supplier, the manufacturing organization must comply with the requirements of ISO/ASTM 52920:2023. These requirements are independent of the material system, manufacturing route, or final application. Major OEMs increasingly use this standard as the basis for auditing and approving contract manufacturers.

The certification of the manufacturing process and the qualification of an individual AM component are closely interconnected and cannot be treated as independent activities. An additively manufactured component cannot be qualified unless the complete manufacturing process has first been successfully qualified. Consequently, part qualification represents the final stage of the certified manufacturing process.

According to ISO/ASTM 52920:2023, part qualification includes the following key activities: 1) verification of the manufactured geometry against the approved CAD model, 2) strict configuration and change management to preserve the qualified ("frozen") manufacturing process, 3) validation through co-built witness coupons and First Article Inspection (FAI), including dimensional inspection, non-destructive testing, destructive testing, and mechanical property evaluation. The standard further requires requalification whenever any significant change is introduced into the manufacturing process, equipment, materials, or process parameters.

Upon completion of the qualification activities, the component is subjected to functional testing under representative operating conditions in accordance with the approved Test Plan and Test Program. Only after successful completion of all qualification and testing activities the Certificate of Conformity and the approval for production can be issued.

3.3 Future trends in C&Q

One of the major challenges facing Metal Additive Manufacturing (MAM) is achieving consistent process repeatability. Components manufactured on different machines (even when using the same process parameters and feedstock) may reveal variations in microstructure, mechanical properties, and dimensional accuracy. This lack of reproducibility significantly complicates and prolongs the qualification and certification process.

Another major challenge is the continued reliance on conventional qualification methodologies based primarily on extensive experimental testing. Although these approaches have proven effective for conventionally manufactured components, they are often unsuitable for additive manufacturing because they require large numbers of physical test specimens, resulting in high qualification costs and lengthy development cycles, particularly in highly regulated sectors such as the aerospace and defense industries.

To address these challenges, new qualification methodologies are currently being developed. One of the most significant initiatives is the Computational Materials for Qualification and Certification (CM4QC) program led by the National Institute of Standards and Technology (NIST), U.S. Department of Commerce. The objective of this program is to integrate validated computational models into the qualification process, enabling the prediction of component properties and performance while substantially reducing the dependence on costly physical testing, [10].

This model-based qualification approach relies on high-fidelity numerical simulations capable of predicting the influence of manufacturing parameters on the final characteristics of additively manufactured components. For such simulations to be accepted by certification authorities, their predictive capability must first be experimentally validated. To support this objective, NIST has established the Additive Manufacturing Benchmark Test Series (AM-Bench), an internationally recognized benchmark platform for validating computational models. AM-Bench consists of carefully designed experiments performed under strictly controlled conditions, generating high-quality reference datasets that enable researchers to evaluate and compare the accuracy of simulation tools worldwide.

Consequently, the AM-Bench datasets constitute the scientific foundation for establishing confidence in computational models and are expected to play a key role in the future implementation of model-based qualification and certification of additively manufactured components for aerospace, defense, and other safety-critical industries.

4. MAM PERSONNEL QUALIFICATION

Qualified personnel represent one of the most critical resources in additive manufacturing (AM), as in all advanced manufacturing technologies. Similar to other industrial fields, such as welding, the qualification of AM designers and machine operators requires a structured combination of theoretical education and practical training. Practical training is conducted under the supervision of qualified personnel and is followed by a formal qualification assessment consisting of written, oral, and practical examinations. Successful candidates receive certification authorizing them to perform specific AM-related tasks.

In addition to machine operation, other activities associated with additive manufacturing (including post-processing, machining, destructive testing, and non-destructive testing (NDT)) also require appropriately qualified personnel in accordance with the applicable qualification standards, [3].

4.1 Qualification of Operators for PBF-LB

The qualification of operators for Laser Powder Bed Fusion (PBF-LB) systems shall be performed in accordance with a documented qualification procedure or manufacturing plan. Prior to qualification, candidates shall complete the prescribed theoretical and practical training specified by the relevant qualification standard, [4].

The practical examination demonstrates that the operator possesses the knowledge and practical skills required to independently perform all manufacturing activities associated with a specific production task.

Upon successful completion of the qualification process, the operator shall be competent to understand and perform the following activities: 1) principles and operational aspects of the selected AM technology, 2) feedstock handling, storage, and material management, 3) AM system setup, calibration, and preparation, 4) build preparation, process monitoring, and manufacturing operations, 5) post-processing activities, including part removal, cleaning, and inspection.

4.2 Tasks and Competencies of the AM Designer

An **AM Designer** is a professional who applies knowledge of additive manufacturing process capabilities to develop optimized geometrical, functional, and manufacturing-oriented component designs for metal additive manufacturing, without necessarily being responsible for the execution of the manufacturing process [3].

An AM designer should possess both general manufacturing knowledge and specialized expertise in additive manufacturing technologies. In addition, the designer should be proficient in Computer-Aided Design (CAD), Computer-Aided Manufacturing (CAM), and the software tools required to support the complete AM workflow.

The wide variety of engineering challenges associated with metal additive manufacturing directly influences the competencies required of an AM designer. These include occupational health and safety (OH&S) considerations, material behavior, process limitations, geometric inspection, qualification testing, post-processing, and manufacturing economics.

Since Metal Additive Manufacturing (MAM) technologies differ significantly in terms of process characteristics and manufacturing constraints, the designer must understand how these differences influence component design. Typical design considerations include machining allowances for post-processing, build orientation, support structure design, residual stress mitigation, and the selection, location, and orientation of qualification specimens.

An AM designer should be able to understand and perform the following tasks: 1) understand the fundamentals of additive manufacturing technologies and their operating principles, 2) apply Design for Additive Manufacturing (DfAM) principles, 3) develop component designs optimized for additive manufacturing, 4) perform pre-processing and build data preparation, 5) define process control requirements during manufacturing, 6) identify appropriate post-processing methods based on functional requirements, 7) evaluate manufacturing costs while considering technical and quality requirements, according to [3].

5. INFRASTRUCTURE AND OH&S CHALLENGES

5.1 Infrastructure challenges

The highest level of qualification for an organization involved in Additive Manufacturing (AM) extends beyond the qualification of manufacturing processes and includes the organization's overall quality infrastructure. The scope of qualification depends on the company's activities and production portfolio.

For example, the MTI has implemented an Integrated Quality Management System (IQMS) comprising certification according to several internationally recognized standards, including ISO 9001 (Quality Management System), ISO 14001 (Environmental Management System), ISO 45001 (Occupational Health and Safety Management System - OH&S), ISO/IEC 27001 (Information Security Management System), and accreditation of testing laboratories in accordance with ISO/IEC 17025.

In addition to implementing an Integrated Quality Management System, the introduction of advanced Metal Additive Manufacturing technologies, such as Laser Powder Bed Fusion (PBF-LB/M), requires additional qualification procedures. In particular, qualification of the production facility in which the AM equipment is installed is mandatory.

A qualified AM production facility should include dedicated areas for design and engineering activities, production, metrology, post-processing, material handling and storage, quality inspection, and supporting activities

required throughout the AM workflow illustrated in Figure 1.

Ultimately, a qualified AM production facility consists of qualified personnel, qualified equipment, and qualified manufacturing processes operating within an integrated quality management framework to consistently produce components that satisfy all specified requirements, [9].

5.2 OH&S challenges

The use of metallic powders in additive manufacturing introduces a number of new occupational health and safety challenges. Although many metallic alloys employed in AM present relatively low health risks, fine aluminum and titanium powders represent significant fire and explosion hazards because of their high reactivity and large specific surface area. As metal additive manufacturing continues to expand across industrial sectors, organizations must identify, assess, and mitigate these hazards through systematic risk management.

Risk mitigation should follow the internationally accepted **Hierarchy of Controls**, which consists of five levels: 1) Elimination, 2) Substitution, 3) Engineering Controls, 4) Administrative Controls, 5) Personal Protective Equipment (PPE).

Before implementing Metal Additive Manufacturing technologies, organizations should perform a comprehensive occupational health and safety assessment covering all stages of powder handling, machine operation, post-processing, maintenance, waste management, and emergency response procedures, [11].

6. CONCLUSION

The qualification and certification of metal components manufactured by AM represent a new and strategically important field for the Republic of Serbia, particularly in the context of defence applications. The implementation of internationally recognized qualification principles is essential for ensuring the reliability, repeatability, and traceability of AM processes and for enabling the safe integration of additively manufactured components into military equipment.

This paper has presented an overview of the qualification and certification requirements for Metal Additive Manufacturing (MAM), with particular emphasis on the requirements defined in ISO/ASTM 52920:2023**.** The proposed framework aligns the requirements of international AM standards with the existing national conformity assessment system and identifies the complementary roles of the Technical Test Center (TTC) and the Military Technical Institute (MTI) in establishing a future national certification capability.

The paper also discussed the differences between conventional and additive manufacturing qualification approaches and highlighted emerging trends, including model-based qualification initiatives currently being developed by NIST.

Future research will focus on validating the proposed qualification framework through representative case studies, establishing standardized testing procedures for AM components intended for military applications, and supporting the development of an accredited national certification capability.

Abstract: *The character of modern warfare has been significantly affected by the widespread use of unmanned aerial vehicles and loitering munitions. Their use as weapon carriers introduces safety challenges that differ from those encountered in conventional artillery, mortar and rocket ammunition. Traditional fuzing systems commonly rely on setback acceleration, rotational motion, centrifugal effects or a combination of such mechanical conditions to achieve safe arming after launch or firing. In contrast, many UAV-based configurations do not provide comparable mechanical arming environments. This creates a need for a dedicated safety approach for warheads integrated with unmanned platforms, particularly when electrical or electromechanical fuzes are used. This paper reviews the safety rationale behind existing fuze-related standards, identifies limitations of direct transfer of conventional fuze safety assumptions to UAV-borne warheads, and proposes a layered safety concept. The proposed framework combines administrative control, positive physical safety, platform-state verification, electrical and command interlocks, built-in test functions, fault response and abort-related safe-state logic. An illustrative Electronic Safe-and-Arm Device (ESAD) state-transition model is presented as a verification-oriented example. The paper does not propose a detailed fuze design, but provides a conceptual, system-safety and standardization-oriented framework for future assessment of electromechanical fuzing systems used with loitering munition warheads.*

Keywords: *loitering munition, electromechanical fuze, ESAD, safety analysis, UAV-borne warhead, standardization, built-in test, system safety.*

1. INTRODUCTION

Fuzes and safety-and-arming devices are among the most safety-critical subsystems of any munition. Their function is not limited to initiating a warhead at the required moment. They must also prevent unintended initiation during manufacture, transport, storage, handling, integration, launch preparation and all pre-arm conditions.

In artillery and mortar ammunition, arming is commonly linked to launch conditions. Setback acceleration generated during firing may release or enable internal mechanical elements only after the munition has left the weapon system. In spin-stabilized ammunition, rotational motion and centrifugal effects may also contribute to the arming sequence. Similar principles are applied in many rocket and missile systems, where launch acceleration or other launch-related parameters provide a clear physical distinction between a safe handling state and an armed flight state.

The increasing use of unmanned aerial vehicles and loitering munitions changes this safety context. A UAV is an aircraft-like platform that may be assembled, loaded, powered, checked, launched, flown, aborted or recovered under operational conditions that differ substantially from those of classical ammunition. In many cases, the acceleration profile is too low to be used as a reliable arming parameter. Rotational arming is also generally not applicable.

This paper discusses why existing fuze safety concepts

Corresponding author:857 N. Nikolić;
E-mail: nikolanikolic953@gmail.com
DOI: 10.5937/OTEH26146A

cannot be transferred directly to UAV-borne warhead applications and proposes a layered framework for safe integration, handling, pre-launch control, mission-state management and verification of warheads with electromechanical fuzes.

The central argument of the paper is that the safety of an electromechanical fuze for a UAV-borne warhead should not be assessed as an isolated component problem. It should be assessed as a platform-integrated system safety problem, where the fuze, UAV platform, electrical interfaces, command logic, operator procedures and mission state form one safety-relevant system.

2. METHODOLOGICAL APPROACH

This paper applies a conceptual system-safety methodology based on four complementary steps.

First, the paper compares the conventional fuze arming environment with the mission and integration environment of UAV-borne warheads. This comparison is used to identify safety assumptions that may no longer be valid when a conventional warhead or fuze concept is adapted to an unmanned platform.

Second, the paper interprets existing fuze and munition safety standards from the perspective of UAV integration. The objective is not to replace established standards, but to determine which safety principles remain directly applicable and which principles require additional interpretation in the UAV-borne warhead context.

Third, the paper decomposes the lifecycle of a UAV-borne warhead into storage, transport, integration, pre-launch preparation, flight, abort and post-mission handling. Each lifecycle block is considered in relation to credible unsafe states and the safety layers required to prevent or mitigate them.

Fourth, the paper uses a simplified ESAD state-transition model to illustrate how safety-related states and mission-readiness states may be coordinated. The model is verification-oriented. It is not intended to represent a complete fuze design, electrical circuit, firing chain or detailed implementation.

This methodological approach is suitable for a conference-level standardization and safety analysis paper because it combines comparative analysis, lifecycle reasoning, hazard-barrier mapping and state-transition modelling without disclosing design-sensitive implementation details.

3. CONVENTIONAL FUZE SAFETY PRINCIPLES AND LIMITATIONS

Fuze safety standards are built around the principle that the i train must remain interrupted or otherwise controlled until a valid arming environment has been achieved. This principle is supported by mechanical barriers, environmental discrimination, arming delay, safety distances, qualification tests and verification of safe handling conditions. Standards such as MIL-STD-1316, MIL-STD-331 and related NATO ordnance publications provide a strong foundation for this approach.

The limitation in UAV applications arises from the fact that the expected arming environment may be absent, weak or fundamentally different from that of the original munition. In gun-launched ammunition, firing creates a short and intense acceleration environment. In spin-stabilized ammunition, rotation provides an additional physical input. By contrast, UAVs often experience gradual acceleration, low launch shock and relatively smooth flight profiles.

A second limitation is related to mission variability. A projectile normally follows an irreversible trajectory after firing. A UAV-based system may remain in flight for an extended period, loiter before engagement, receive operator commands, abort a mission or return to a predefined area.

A third limitation is the integration of the fuze into an electrically powered platform, with dependencies on power supply, avionics, data links, command logic and system interfaces. In such a system, electrical safety cannot be treated only as the presence or absence of power. It must also include power validity, command validity, logic enable conditions, fault detection, reset behavior, loss-of-power response, electromagnetic immunity and defined safe-state behavior.

Therefore, the direct adaptation of a conventional fuze or safety-and-arming philosophy to a UAV-borne warhead can be unsafe if the original assumptions about launch environment, trajectory, operator interaction and post-launch irreversibility are no longer valid.

Table 1. Conceptual comparison of conventional and UAV-borne warhead safety environments

Aspect	Conventional munition	UAV-borne warhead
Launch event	Strong firing or launch signature	Low or variable launch signature
Rotation	May be present in spin-stabilized projectiles	Usually absent
Mission profile	Mostly irreversible after firing	May include loiter, delayed engagement, abort or recovery
Power and interfaces	Mainly fuze-contained or weapon-system related	Platform power and mission-state dependencies
Operator interaction	Mainly before firing	May continue before and during mission
Environmental exposure	Defined by munition class	Defined by air vehicle and carrier context

Safety assumption	Valid arming environment is physically distinct from handling state	Valid arming environment must be defined by combined platform, command and mission-state conditions

4. PROPOSED LAYERED SAFETY CONCEPT

A suitable safety concept for electromechanical fuzes in UAV-borne warhead applications should combine procedural, mechanical, electrical and system-level controls. The purpose is not to replace existing fuze safety standards, but to adapt their safety philosophy to the operational environment of UAV platforms.

The proposed concept is based on the principle that no single safety layer should be treated as sufficient on its own. Safety should be achieved through a controlled sequence of independent and mutually reinforcing barriers, covering human procedures, physical safety features, platform status, electrical command logic, fault detection and response to abnormal mission conditions.

Figure 1. Proposed layered safety concept for UAV-borne electromechanical fuzes.

The first layer is administrative and procedural control. It defines responsibility, authorization, configuration control and the conditions under which the warhead may be handled, integrated or prepared for mission use.

The second layer is positive physical safety. This layer provides an independent non-electrical barrier and is particularly important because electrical systems may be affected by power faults, software faults, electromagnetic interference, electrostatic discharge or incorrect interface states.

The third layer is platform-state verification. The warhead and fuze should not be allowed to progress toward an unsafe state unless the UAV platform is in a valid mission state and all defined preconditions are satisfied.

The fourth layer consists of electrical and command interlocks. These interlocks should support controlled application of power, valid logic enable states, authorized command paths and rejection of invalid or ambiguous command conditions.

The fifth layer includes built-in test and fault response. Built-in test should support detection of safety-critical faults before launch and, where applicable, during mission execution. Fault response should be biased toward a defined safe state.

The sixth layer includes abort and safe-state logic. This layer is especially important for UAV-borne warheads because the mission may be interrupted, delayed or aborted. Unlike conventional projectiles, a UAV-based system may require defined transitions back from an unsafe intermediate state to a controlled safe or less unsafe state.

Table 2. Proposed safety layers for UAV-borne electromechanical fuzes

Safety layer	Function	Safety role
Administrative and procedural control	Responsibility, authorization and configuration control	Controls human-factor and organizational risk
Positive physical safety	Independent safety barrier	Provides non-electrical protection against premature unsafe transition
Platform-state verification	Valid platform and mission state	Prevents arming outside approved platform states
Electrical and command interlocks	Controlled power, logic enable and valid command conditions	Mitigates electrical, interface or command faults
Built-in test and fault response	Detection of safety-critical faults	Supports fail-safe or safe-state behavior
Abort and safe-state logic	Response to abnormal mission outcomes	Controls residual risk during abort, delay or post-mission handling

5. SAFETY RISK ANALYSIS FRAMEWORK

The safety analysis should cover the complete lifecycle of a UAV-borne warhead, from storage and transport to integration, pre-launch preparation, flight, mission abort and post-mission handling. Each phase should be assessed against credible initiating events, possible unsafe states and the safety layers required to prevent or mitigate them.

The proposed analysis is structured around three questions: which unsafe state may occur, in which lifecycle block it may occur and which safety layer provides the primary barrier. This approach keeps the assessment system-oriented and avoids treating the fuze as an isolated component. The safety of an electromechanical fuze depends on its interaction with the UAV platform, electrical interfaces, command logic, operator procedures and environmental exposure.
For conference-level assessment, a compressed hazard-barrier-verification structure is useful because it links the unsafe state to the lifecycle phase, the primary safety barrier and the type of evidence needed for verification.

Table 3. Lifecycle structure of safety risk analysis

Lifecycle block	Main safety concern	Control focus
Storage and transport	Loss of safe configuration	Physical safety, packaging and configuration status
Integration and pre-launch	Incorrect assembly or premature transition	Procedure, visible status, platform checks and BIT
Flight and mission execution	Unintended command, fault or unsafe transition	Interlocks, authorization, BIT and state monitoring
Abort and post-mission handling	Unsafe residual state	Safe-state logic and status confirmation

Table 4. Example hazard-barrier-verification matrix for UAV-borne electromechanical fuzing safety

Hazard scenario	Lifecycle phase	Primary safety barrier	Verification evidence
Premature transition toward arm-ready state	Integration / pre-launch	Platform-state verification and procedural control	Pre-launch checklist, platform status confirmation and BIT result
Invalid or unintended electrical command	Pre-launch / flight	Electrical and command interlocks	Interface test, command validity check and logic verification
Loss of power or voltage instability	Flight / abort	Safe-state logic and power validity monitoring	Power interruption test and reset behavior verification
Ambiguous state after mission abort	Abort / post-mission handling	Abort logic and status indication	Safe-state confirmation and operator procedure
Electromagnetic or electrostatic disturbance affecting safety-critical logic	Integration / flight	EMC/ESD qualification and fault response	MIL-STD-461-oriented EMC assessment and ESD test evidence
Incorrect configuration during integration	Integration	Administrative control and physical safety	Configuration checklist and independent status confirmation
Built-in test detects safety-critical fault	Pre-launch / flight	BIT and fault response	Fault-insertion or diagnostic response verification
Environmental exposure affects electrical or mechanical integrity	Storage / transport / flight	Environmental qualification	Temperature, vibration, shock, humidity or salt-fog test evidence

6. ILLUSTRATIVE ESAD STATE-TRANSITION EXAMPLE

In order to complement the proposed layered safety concept with a concrete technical illustration, Fig. 2 presents a simplified ESAD state-transition example influenced by the loitering-munition mission state. In this paper, ESAD is used in the sense of an Electronic Safe-and-Arm Device. The figure is not intended to represent a complete system specification. It is a reduced verification-oriented model showing how safety-related states and mission-readiness states may be coordinated.

The model should be understood as a state-management example, not as a circuit diagram or detailed fuze design. It separates three categories of states: safe-for-handling states, controlled unsafe intermediate states and terminal unsafe states. This distinction is important because UAV-borne warheads may remain associated with the platform for a longer period and may be subject to mission changes, operator commands or abort conditions.

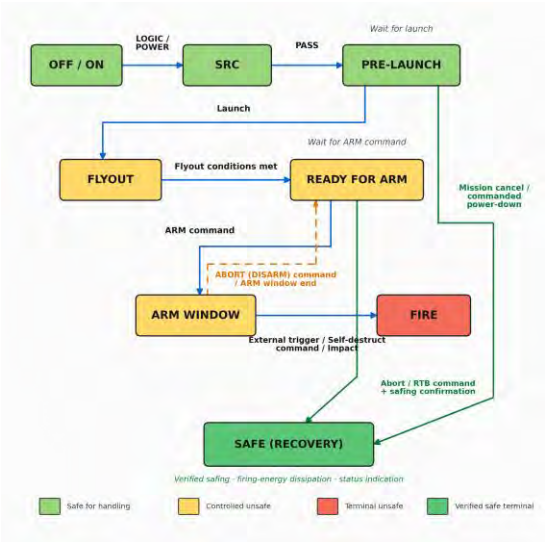

Figure 2. Illustrative ESAD state-transition example influenced by loitering-munition mission states.

The example begins with the OFF state, followed by POWER ON / LOGIC ENABLED. The system then enters FSC, representing the Final System Check of the complete platform-warhead configuration. The purpose of FSC is to confirm that required readiness and safety conditions are satisfied before the system can proceed to the PRE-LAUNCH state.

After successful completion of the final system check, indicated by PASS, the system enters the PRE-LAUNCH state. In this state, the system remains safe for handling and waits for the launch condition. Following the Launch transition, the system proceeds to FLYOUT. Once the required flyout conditions are met, the logic transitions to READY FOR ARM.

The READY FOR ARM state represents a controlled intermediate condition. In this condition, the warhead with electromechanical fuze is no longer treated as a normal handling state, but it is not yet within the final arming window. The transition from READY FOR ARM to ARM WINDOW requires an explicit ARM command and valid mission-state conditions. The ARM WINDOW state is therefore treated as a restricted state in which terminal transition to FIRE may occur only under defined event conditions represented in the simplified model as External Trigger, Self-Destruct Command or Impact.

The return path from ARM WINDOW to READY FOR ARM, initiated by an ABORT / DISARM command or by ARM Window End, illustrates the importance of controlled state management. Unlike conventional projectiles, a UAV-borne warhead may be associated with mission interruption, delayed engagement or abort-related conditions. For this reason, the state logic should support clear differentiation between safe handling states, controlled unsafe transition states and terminal unsafe states.

This example demonstrates how safety may be implemented not only through a fuze mechanism, but also through coordinated interaction between ESAD logic and the mission state. In this way, the state-transition model supports risk reduction by preventing premature arming, requiring readiness verification before launch, separating flyout from arming authorization and providing defined paths for abort-related state control.

For verification purposes, each state and each transition should have defined entry conditions, exit conditions, permitted commands, prohibited commands, fault response and status indication. In particular, the system safety case should address loss of power, voltage instability, logic reset, invalid command sequence, communication fault, electromagnetic disturbance and operator-visible status after abort.

7. STANDARDIZATION CONSIDERATIONS

Existing standards provide a strong foundation for fuze safety, environmental qualification and testing. MIL-STD-1316 defines safety criteria for fuze design, while MIL-STD-331 addresses environmental and performance testing of fuzes, ignition safety devices and related components. MIL-STD-810 provides a broader framework for environmental engineering considerations and laboratory tests. MIL-STD-461 defines requirements for the control of electromagnetic interference characteristics of subsystems and equipment. These standards are directly relevant to electromechanical fuzes, but their application to UAV-borne warheads requires careful interpretation.

The main standardization challenge is not the absence of general safety principles. The challenge is the lack of a dedicated framework for applying those principles to warheads integrated with unmanned platforms. These systems combine characteristics of ammunition, aircraft systems, electrical subsystems and mission-controlled platforms. Their safety assessment should therefore integrate ordnance safety, air vehicle integration, electrical interface control, environmental qualification and operational safety procedures.

A future standard or guidance document should define minimum expectations for safe-state definition, positive physical safety, platform-state criteria, electrical and command interlocks, built-in test requirements, critical fault response, operator status indication, electromagnetic compatibility and immunity, electrostatic discharge protection, loss-of-power and reset behavior, abort logic, post-mission safe-state confirmation, and verification and validation evidence.

Environmental requirements should be treated as safety-relevant. UAV-borne systems may be exposed to vibration, shock, temperature variation, humidity, salt fog, electrostatic discharge and electromagnetic effects. These conditions may influence electrical interfaces, mechanical integrity and the reliability of safety-critical functions. Environmental testing should therefore be part of the overall safety case, not only a durability issue.

The standardization framework should also recognize the difference between design qualification and operational safety. A fuze or ESAD may satisfy component-level requirements and still present system-level risks if the

platform interface, command logic, operator procedure or abort state is not adequately controlled. For this reason, standardization should require a system-level safety case covering both component qualification and platform integration.

8. DISCUSSION

The proposed layered concept has two main advantages. First, it preserves the safety philosophy of existing fuze standards by maintaining the principle that no hazardous state should be reached without valid and verified conditions. Second, it adapts this philosophy to the specific operational reality of UAV-borne warheads, where launch signature, rotation and irreversible ballistic trajectory cannot be assumed.

The most important implication is that electromechanical fuzing safety should be treated as a system property. It is not sufficient to qualify only the fuze hardware. The UAV platform, power supply, electrical interfaces, command architecture, mission logic, operator procedures and environmental exposure must also be included in the safety assessment.

A second implication is that built-in test should not be treated merely as a maintenance or readiness feature. In UAV-borne warhead applications, BIT may become part of the safety argument because it can prevent continuation of the mission sequence when a safety-critical fault is detected. However, BIT itself must be carefully verified, because a false pass, false status indication or ambiguous diagnostic result may create additional risk.

A third implication is that abort and post-mission handling require special attention. Conventional ammunition safety logic often assumes an irreversible post-launch trajectory. UAV-borne systems may not follow this assumption. Therefore, standards should explicitly address mission interruption, delayed engagement, return-to-area conditions and operator confirmation of safe state after abort.

The proposed framework is intentionally conservative. It does not rely on a single command, a single sensor, a single software condition or a single operator action. Instead, it requires mutually reinforcing safety layers and objective verification evidence.

9. CONCLUSION

The integration of warheads and electromechanical fuzes into UAVs and loitering munitions creates a distinct safety problem. Classical fuze arming principles rely heavily on launch acceleration, setback forces or rotational effects. These parameters are often absent or insufficient in UAV applications. As a result, the direct adaptation of conventional ammunition to unmanned platforms may create unacceptable safety risks if the original safety assumptions are no longer valid.

This paper proposes a layered safety concept for warheads with electromechanical fuzes used in UAV-borne applications. The proposed concept combines administrative control, positive physical safety, platform-state verification, electrical interlocking, built-in test functions, fault response and abort-related safe-state logic. The illustrative ESAD state-transition example shows how these principles can be translated into a verification-oriented state model.

The principal contribution of the paper is the proposal that UAV-borne warhead fuzing safety should be assessed as a platform-integrated system safety problem, rather than as a direct adaptation of conventional fuze qualification logic. Further work should include detailed hazard analysis, verification and validation methods, test evidence structure and development of operational safety protocols aligned with established munition safety principles.

Abstract: *From the perspective of water supply, the inhabitants of the Republic of Serbia largely (over 75%) meet their needs from groundwater. The estimated reserves of groundwater across the entire territory of Serbia amount to about 68 m³/s, of which only one third is currently utilized, i.e., around 23 m³/s of the total available potential of this strategic resource. These reserves are not uniformly distributed throughout Serbia, and therefore they are not equally accessible to all inhabitants. Considering that climate change has a significant impact on this resource, the paper will present a comparative analysis of direct (surface), base (groundwater) runoff, as well as the baseflow index analyzed over different time periods. As a pilot area, the Crnica River basin was selected, which belongs to river courses with one of the longest periods of water level and discharge monitoring. Today, about 40,000 inhabitants of the Municipality of Paraćin and part of the population of the settlement of Ćuprija use groundwater from this basin for water supply purposes. Monitoring of quantitative parameters on this river began in 1925 and continues to this day. For the purpose of analyzing the impact of climate change on the water regime of this river, three different 30-year time periods were distinguished: Period I (1931–1960), Period II (1961–1990), and Period III (1991–2020).*

Keywords: *direct runoff, baseflow, baseflow index, climate change, Crnica River*

1. INTRODUCTION

The Crnica catchment is in the central part of Serbia. It is delineated by the valley of the Velika Morava to the west, the Sisevac Basin, Kučaj and Samanjic to the east, and the catchments of the Ravanica to the north and the Jovanica River to the south. In its source, upper part (eastern section), the catchment has a wide, arcuate shape, while in the lower part (western section), towards the Velika Morava into which the Crnica River flows, the catchment narrows wedge-like. In the observed area of the Crnica River catchment, from a hydrogeological standpoint, all types of aquifers are present, among which the karst type aquifer plays a more significant role (Figure 1).

The dominant karst aquifer type in the upper part of the Crnica River catchment (yellow area in Figure 1), owing to cavernous porosity encompassing systems of fractures, caverns, and cave channels, enables the formation of considerable reserves of groundwater. The ability of the terrain to retain water infiltrated into the catchment and subsequently return it to the river flow represents a key hydrogeological characteristic, which largely determines the runoff regime during dry periods. The process of groundwater depletion is described by the shape of the recession limb of the hydrograph, i.e., the recession curve. The very character of the recession curve is determined by analyzing the falling limbs of a larger number of flood wave hydrographs. Accordingly, the total runoff is formed as the cumulative value of direct and base runoff. Direct runoff arises during intense precipitation and is present (dominant) mainly during flood waves. In contrast, base runoff occurs because of the river flow being recharged by groundwater (Prohaska, 2004).

2. METHODOLOGY

For the purposes of preparing this paper, all available data on monthly and annual precipitation sums, mean monthly and annual air temperatures, as well as mean monthly and annual discharges of the Crnica River were collected. The total observed period available was from 1949 up to and including 2022 (meteorological data), and from 1926–2022 (hydrological data). Since the observed discharge consists of direct runoff, which is the consequence of precipitation, and base runoff, which is formed through the recharge of surface flow by groundwater, direct runoff was first separated from base runoff. For this purpose, the software BFI+ (Hydro Office, 2020) was applied, using the Local Minimum method (Wahl & Wahl, 1995). This method identifies days with the lowest flow within a defined time interval — half of the observed period reduced by one day before and after the analyzed day. If the flow on that day is the lowest, it is marked as a local minimum and connected by straight lines with neighboring minima. The base flow between these points is estimated by linear interpolation, whereby the lowest values on the hydrograph are connected into a simplified curve (Sloto & Crouse, 1996).

For monitoring climate change, the World Meteorological Organization proposed and adopted a thirty-year reference period, namely 1961–1990. In this regard, for the analysis of the homogeneity of time series by examining mean values, Student's t-test (for sample size $n < 30$) and the Normalized Z-test (for sample size $n > 30$) may be used. Since in the specific cases we will have separated time series of size 30: the first sample from 1961–1990 and the second from 1991–2020; both of size 30 ($n = 30$), Student's t-test was employed for the homogeneity analysis, in which the criterion for evaluating mean values is obtained using the following expression (Prohaska, 2004):

$$t = \sqrt{\frac{n_1 \cdot n_2 \cdot (n_1 + n_2 - 2)}{n_1 + n_2}} \cdot \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{n_1 \cdot \sigma_{X_1}^2 + n_2 \cdot \sigma_{X_2}^2}} \quad (1)$$

Where n_1 and n_2 are the sizes of time series 1 and 2, $\bar{x}_1$ and $\bar{x}_2$ are the mean values of time series 1 and 2, and σ_1 and σ_2 are the standard deviations of time series 1 and 2.

The variable t follows Student's distribution with $n_1 + n_2 - 2$ degrees of freedom. In this case, the null hypothesis is accepted, i.e., the series is homogeneous, if:

$$t_{\frac{\alpha}{2}} < t < t_{1-\frac{\alpha}{2}} \quad (2)$$

Where α is the significance threshold, and in the specific case the value $\alpha = 0.05$ was taken.

For testing homogeneity through variances, Fisher's F-test was applied. The criterion for the equality of two dispersions is the F statistic, which is calculated using the following expression (Prohaska, 2004):

$$F = \frac{\sigma_1^2}{\sigma_2^2} \quad (3)$$

with the condition that $\sigma_1^2 \geq \sigma_2^2$. If the opposite holds, then the F statistic is calculated as:

$$F = \frac{\sigma_2^2}{\sigma_1^2} \quad (4)$$

Thus, the F statistic, which follows Fisher's distribution with degrees of freedom calculated as $n_1 - 1$ and $n_2 - 1$, always has a value greater than 1. The null hypothesis is accepted if:

$$F < F_{1-\alpha}(\nu_1, \nu_2). \quad (5)$$

3. RESULTS

Recharge of the existing aquifers, primarily karst ones, is to the greatest extent carried out through infiltration of atmospheric precipitation, and for that reason emphasis was placed on the analysis of the pluviographic regime as well as the temperature regime (due to the presence of snow cover) characteristic of the catchment area of the Crnica River. For this purpose, precipitation and air temperature values observed at the meteorological station Ćuprija for the observation period 1949–2022 were taken.

Based on the available data on daily precipitation sums observed at the meteorological station Ćuprija, it was determined that the average multi-year precipitation for the observation period 1949–2022 amounts to 666.2 mm. The year with the highest precipitation sum was 2014, with a value of 961.5 mm, while the lowest annual precipitation sum was recorded in 2011, amounting to 432.6 mm. Based on the annual precipitation sums for the observed period, it can be noted that the trend line indicates a slight increase in precipitation amounts (Figure 2).

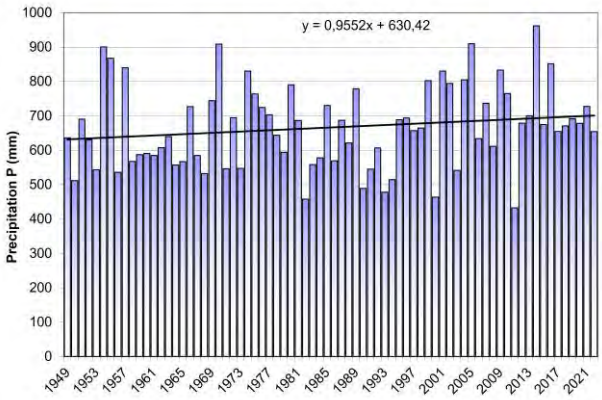

Figure 2. Annual precipitation sums with trend line, meteorological station Ćuprija, period 1949–2022

The graph of intra-annual precipitation distribution (Figure 3) indicates that the rainiest month is June, with an average value of 78.3 mm, followed by May, during which an average of 77 mm falls. The driest months are February (44.3 mm), March (44.9 mm), and August (45.5 mm). In addition, average monthly precipitation amounts below 50 mm are also recorded in January (48.5 mm) and October (47.3 mm). During the observed period, the maximum monthly precipitation sum was recorded in June 1969, amounting to 226.5 mm, while August 2012 stands out as a month without recorded precipitation (0 mm).

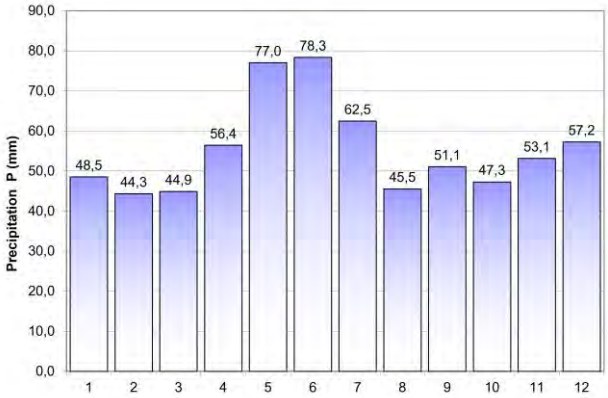

Figure 3. Intra-annual precipitation distribution, meteorological station Ćuprija, period 1949–2022

With regard to mean seasonal precipitation sums, Table 1 presents their basic statistical parameters (mean value, standard deviation, coefficient of variation and skewness, as well as recorded extreme values). In Table 2, the equations of the trend lines for each individual season are given, and based on these equations, the values of expected precipitation sums related to the time horizons 2050 and 2100 were calculated.

Table 1 Statistical parameters of mean seasonal precipitation sums, meteorological station Ćuprija, period 1949–2022

	Winter	Spring	Summer	Autumn
P_{av}	137.7	211.8	159.1	157.7
St.dev.	49.1	71.9	69.5	53.1
Cv	0.4	0.3	0.4	0.3
Cs	0.4	0.8	1.2	0.7
Max	258.0	417.9	400.3	322.0
Min	50.9	77.2	55.2	60.2

Table 2 Trend line equations of analyzed precipitation sums (annual and seasonal) and calculation of their expected values for the time horizons 2050 and 2100

Period	Trend equation	Time horizons		Difference over 100 years
		2050	2100	
Annual	P = 0.9552x+1230.3	727.8	775.6	95.5
Spring	P = -0.0136x+238.7	210.8	210.1	-1.4
Summer	P = 0.0584x+43.129	162.8	165.8	+5.8
Autumn	P = 0.2667x-371.85	174.9	188.2	+26.7
Winter	P = 0.6437x-1140.3	179.3	211.4	+64.4

Based on the results presented in Table 2, it can be concluded that the precipitation trend is generally positive (except in spring, when a distinctly slight negative trend is obtained). The most pronounced increase is expected during the winter months (around 65 mm) and autumn months (around 27 mm on a 100-year scale).

For analyzing air temperature in the Crnica River catchment, mean monthly and annual air temperatures observed at the meteorological station Ćuprija (123 m a.s.l.) during the period 1949–2022 were analyzed. The average multi-year air temperature in the observed period amounted to 11.3 °C. The maximum mean annual value (13.3 °C) was recorded in 2019, while the lowest mean annual value (9.8 °C) was recorded in 1976. In general, the lowest air temperatures occur in the winter months, and the highest during the summer months (July and August). The maximum mean monthly value (25.7 °C) was recorded in August 1952, while the minimum (–7.7 °C) was recorded in February 1956.

In Figure 4, the mean annual air temperatures are presented, together with the trend line, which clearly shows a positive trend of mean annual air temperatures, indicating that during the observed period there was an increase in air temperature of about 1.2 °C. It should also be noted that the increase in air temperature is more pronounced in the last 20 years. More precisely, since the year 2000, only 2005 had a mean annual air temperature lower than the multi-year average, while the others had either the same value (2004, 2006, and 2011) or higher.

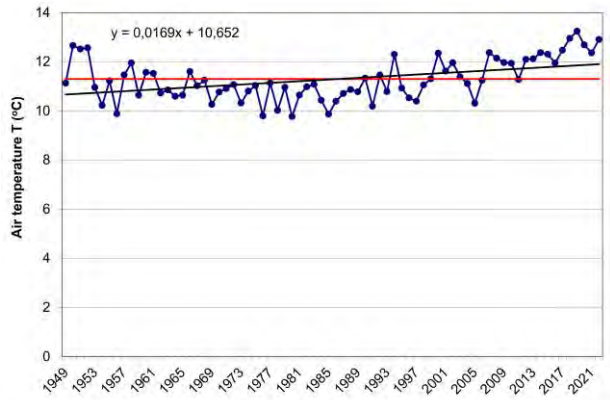

Figure 4. Mean annual air temperatures, meteorological station Ćuprija, observation period 1949–2022

On average, the warmest month is July (21.6 °C), while the coldest is January (0.0 °C) (Figure 5). Regarding the seasons, the warmest is summer (19.9 °C), while the coldest is winter (2.7 °C).

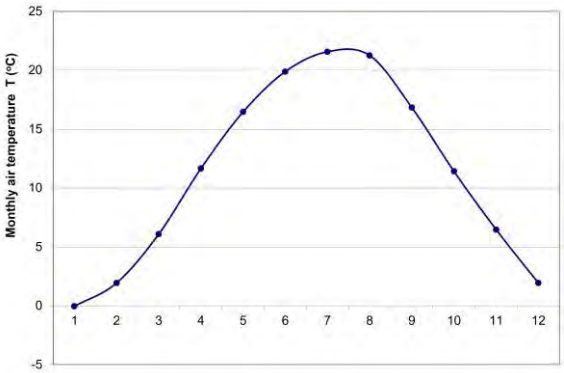

FIgure 5. Intra-annual distribution of air temperature, meteorological station Ćuprija, period 1949–2022

By the same principle as for precipitation sums, Table 3 presents the statistical parameters as well as the trend line equations of mean annual and seasonal air temperatures (Table 4). From Table 4 it can be concluded that the trends are positive in all cases, with the most pronounced trend related to the winter months (the expected increase by the end of this century is 2.7 °C), while the smallest expected increase in temperature during the autumn months (only 0.4 °C).

Table 3 Statistical parameters of mean seasonal air temperatures, meteorological station Ćuprija, period 1949–2022

For the application of homogeneity tests, mean values of precipitation and air temperature as well as standard deviations were first calculated for both separated periods (I: 1961–1990 and II: 1991–2020) — see Tables 5 and 6.

Table 5 Statistical parameters (mean value and standard deviation) of annual and seasonal precipitation sums for the considered separated periods

Based on expression (1), the values of the criterion t for Student's t-test were calculated, whose numerical values are given in Table 7 for the mean multi-year value and mean seasonal values for the separate periods of precipitation and air temperature. For defining whether the series is homogeneous or not (expression (2)), the critical limits $t_{\frac{\alpha}{2}}$ and $t_{1-\frac{\alpha}{2}}$ were determined, which in the specific case, for the significance threshold $\alpha = 0.05$ and the number of degrees of freedom $\nu = 58$, amount to $t_{\frac{\alpha}{2}} = -2.00$ and $t_{1-\frac{\alpha}{2}} = 2.00$.

Table 7 Values of the t statistic calculated for the purpose of adopting homogeneity of the analyzed precipitation and air temperature series

	Precipitation	Air temperature
Annual	-1.198	-5.708
Spring	0.283	-3.602
Summer	-0.524	-5.434
Autumn	-1.532	-2.154
Winter	-1.056	-1.792

Note: Grey-shaded fields indicate series that are not homogeneous

Furthermore, based on expressions (3) and (4), the values of the criterion F for Fisher's F-test were calculated, whose numerical values are given in Table 8 for the mean multi-year value and mean seasonal values for the separate periods of precipitation and air temperature. For defining whether the series is homogeneous or not (expression (5)), the critical limit $F_{1-\alpha}(\nu_1,\nu_2)$ was determined, where the numbers of degrees of freedom are $\nu_1 = 29$ and $\nu_2 = 29$ which in the specific case, for the significance threshold $\alpha = 0.05$, amounts $F_{1-\alpha}(29,29) = 1.153$.

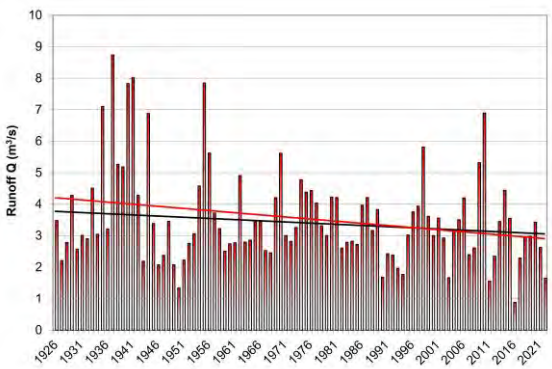
The hydrological station Paraćin, established on the Crnica River, began operation in 1925 when a staff gauge was installed. Later, in 1959, a limnigraph was set up for continuous monitoring of water levels. The analysis of Crnica River discharges characteristic of the Paraćin hydrological station was carried out for the period 1926–2022. The graphical representation of mean annual discharges with trend lines is given in Figure 6.



Fugure 6. Mean annual discharges of the Crnica River observed at the profile of the Paraćin hydrological station with trend lines: red line for the period 1926–2022, black line for the period 1949–2022

Based on the analyzed data for the observation period, the mean multi-year discharge of the Crnica River amounts to 3.56 m³/s. On an annual scale, discharges ranged from 8.749 m³/s (1937) to 0.89 m³/s (2016). The discharge trend line for the entire observation period (1926–2022) indicates a decrease in discharge (Figure 6, red line). The same figure also shows the trend line for the period 1949–2022, i.e., the period for which meteorological data were available (black line). This trend line is also negative, indicating that the discharge of the Crnica River tends to decrease. Since the precipitation trend line is positive, this negative discharge trend may be a consequence of the evident increase in air temperature, particularly pronounced during the summer months, resulting in increased evaporation, as well as increased water demand for irrigation of agricultural land present in the lower part of the Crnica River basin.

Considering the intra-annual distribution (Figure 7), the months with the highest discharges are March and April (slightly below 7.4 m³/s), while September and October are the months when the Crnica River at the Paraćin profile averages only 1.25 m³/s. On a monthly scale, the lowest measured discharge was in November 1990 and 2021, amounting to only 40 l/s, while May 2014 was the month with the highest discharge, amounting to 30.20 m³/s, as well as April 1935, when a discharge of 30.14 m³/s was recorded.

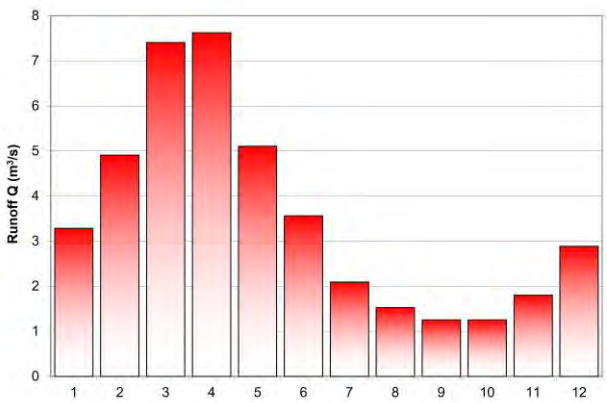


Figure 7. Mean monthly discharges of the Crnica River observed at the Paraćin hydrological station profile, observation period 1926–2022

Based on the observation of discharges by seasons (Figure 8), it can be stated that discharge is disproportionately distributed. In the first part of the year, during winter (37 %) and spring (38 %), about 75 % of the total water volume flows. Summer is the driest season (11 %), followed by autumn (14 %); together, during these two seasons, about 25 % flows, which is approximately three times less compared to the spring and winter periods. The percentage of water volume flowing by seasons indicates that in the non-vegetation period 50.5 % flows, while in the vegetation period 49.5 % flows.

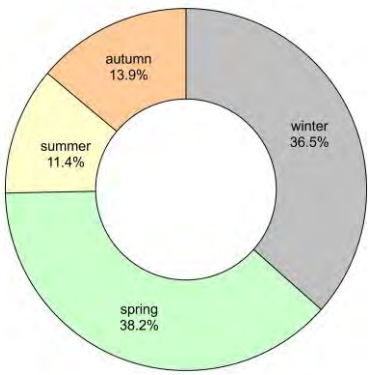

Figure 8. Percentage share of water volumes of the Crnica River separated by seasons

As with precipitation and air temperature, Table 9 presents the statistical parameters as well as the trend line equations of mean annual and seasonal discharges of the Crnica River (Table 10). Based on the trend line equations, it can be concluded that the trends of annual and seasonal discharges are negative. For example, during spring the most pronounced negative trend is observed, i.e., it is expected that by the end of this century the Crnica River will carry even less than 1.74 m³/s during this season. A similar trend is present in autumn, with the expected reduction in discharge during the 21st century being about 1.27 m³/s.

Winter	P = -0.0083x+21.62	4.61	4.19	-0.83

For the application of homogeneity tests of discharges, mean values and standard deviations were first calculated for both separated periods (I: 1961–1990 and II: 1991–2020) — see Table 11.

Table 11 Statistical parameters (mean value and standard deviation) of annual and seasonal discharges of the Crnica River for the considered separated periods

	Period I		Period II	
	Q_{av}	□	Q_{av}	□

Autumn	1.78	1.33	1.64	1.00
Winter	4.90	1.82	5.10	3.16

Furthermore, by the same principle as in the homogeneity analysis, the t and F statistics were calculated using expressions (1–5), and their results are presented in Table 12.

Table 12 Values of the t and F statistics calculated for the purpose of adopting homogeneity of the analyzed annual and seasonal discharges of the Crnica River for the considered separated periods

	Statistic *t*	Statistic *F*

Summer	1.858	1.658
Autumn	0.453	1.769
Winter	-0.295	3.015

Note: Grey-shaded fields indicate series that are not homogeneous

Finally, following the method described in the section devoted to methodology, baseflow and direct runoff separation was performed. The calculation period for which daily values of total discharge were available is 1961–2022, and for this period values of direct and base runoff were calculated. Accordingly, Figure 9 shows the representation of total and calculated baseflow for the period 1961–1970. The entire period 1961–2020 is not presented graphically due to the length of the time series and the impossibility of displaying all data in a single diagram. Based on the results obtained, Table 13 presents the statistical parameters of the calculated mean annual values of direct and base runoff, with calculated statistics related to the separated periods (I and II).

Table 13 Statistical parameters of mean annual values of direct and base runoff of the Crnica River calculated for the selected time periods: I (1961–1990) and II (1991–2020)

4. DISCUSION WITH CONCLUSION

Based on the calculated mean monthly and annual precipitation sums and air temperatures, and the applied trend and homogeneity tests, it has been confirmed that by the end of this century mean precipitation will not change significantly; however, extreme events will become more pronounced and frequent, as indicated by the homogeneity test of variance. Trend analysis showed that on the annual scale the expected increase in precipitation will be only 9.5 mm, i.e., over 100 years this value amounts to 95.5 mm. When this value is distributed by seasons, it can be concluded that precipitation will increase by 2.7 mm during autumn, 6.4 mm during winter, while during summer and spring there will be almost no change. Thus, based on the analyses obtained, it can be stated that no significant changes in mean multi-year precipitation should be expected at either the annual or seasonal level.

Regarding air temperature, homogeneity tests indicate that a statistically significant change in the homogeneity of temperature series has occurred. Trend analysis showed that the expected 100-year increase in temperature will be about 1.7 °C. A similar situation is observed in spring and summer; more precisely, increases of 1.5 °C (spring) and 1.9 °C (summer) are expected. During autumn, no significant increase in air temperature is expected (0.4 °C); however, during winter months the increase may reach almost 3 °C (2.7 °C). Thus, it can be stated that air temperature will increase both annually and seasonally, with the most pronounced increases occurring in summer and winter. These changes, indicating further warming, will lead to increasingly frequent absence of snow cover. Since recharge of aquifers is largely dependent on snowmelt and spring precipitation, due to rising temperatures and the general absence of snow precipitation, this component will have a diminishing effect on groundwater recharge. As more than 75 % of the population in Serbia is supplied with water from groundwater, the population will inevitably face this problem soon.

In addition to mean monthly and annual precipitation, seasonal values of mean discharges were calculated by the same principle. In general, the discharge trend by seasons is negative, with the steepest slope of the trend observed for the summer season, while the mildest decrease can be expected during the winter months. More precisely, if the obtained trend line equations are applied for the entire period and for each season individually, it can be stated that on the annual scale discharge will decrease by about 42 %. During winter months the expected decrease will be only 16.5 %, during spring 35 %, during autumn 81 %, while during summer it amounts to 132 %. By applying the trend equation, it is obtained that the expected discharge during summer will be –0.38 m³/s in the year 2100, which means that the Crnica River will dry up during summer months by the end of this century.

It should be noted that trend analysis generally depends on the selected period itself. The overall trend for the entire observation period has already been presented. However, if trend analyses of mean annual discharges are performed for selected periods (1931–1960, 1961–1990, 1991–2020), a completely different picture is obtained for individual periods (Figure 10). For example, the trend analysis of Period I (1931–1960) shows that during this period there was an exceptionally negative trend. More precisely, if someone had conducted a trend analysis of this period in 1961, they would have concluded that the Crnica River would begin to dry up during summer months by 2016. We are witnesses to say that this was not the case. Furthermore, the discharge trend in Period II is still negative but with a much milder decrease, which is far more acceptable compared to the trend of Period I. Finally, the trend of Period III indicates that in the future an increase in discharge can be expected, i.e., completely opposite to the trends of Periods I and II and the overall period.

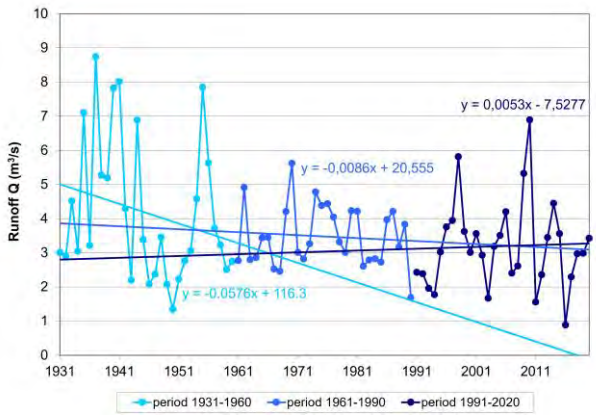

Figure 10. Trend analyses of mean annual discharges calculated for separated time series

The conducted homogeneity analyses of mean values of the separated discharge time series indicate that no statistically significant changes occurred, i.e., the test showed that the time series are homogeneous.

By applying the homogeneity test of variances of the examined samples of annual and seasonal mean discharges of the Crnica River calculated for the considered periods, it is obtained that all analyzed time series are not homogeneous. Such results are certainly influenced by the fact that the presence of extreme events is increasingly pronounced in the case of precipitation and consequently in discharge.

Finally, trend analysis of direct and base runoff was performed, as well as homogeneity testing of these time series. Accordingly, Figure 11 presents the diagram of changes in mean annual values of direct runoff, while Figure 12 presents base runoff. From the diagram of changes in direct runoff (Figure 11), it can be stated that during the analyzed period no significant change in the homogeneity of this time series occurred on the one hand, while trend analysis indicates that no significant changes are expected regarding the mean values of direct runoff. However, the homogeneity test performed using the F-test indicates that the time series is not homogeneous, i.e., it shows that increasingly pronounced extreme events are present.

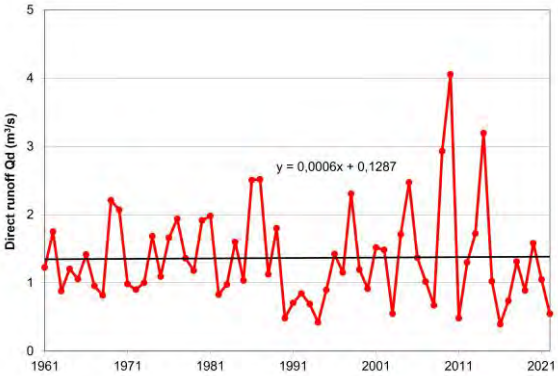

Figure 11. Diagram of changes in mean annual values of direct runoff of the Crnica River

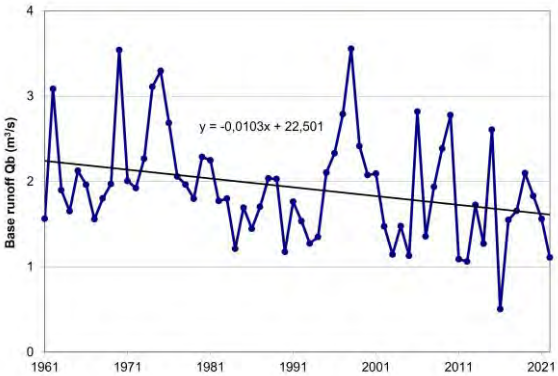

Figure 12. Diagram of changes in mean annual values of base runoff of the Crnica River

Baseflow is important because it is formed from groundwater present in the catchment. The intensity of groundwater recharge decreases over time depending on catchment characteristics, geological structure of the terrain, and hydrogeological conditions, i.e., aquifer types. Trend analysis of mean annual values of baseflow indicates that a decrease of this component of runoff can be expected over a longer period. However, homogeneity tests indicate that the separated time series belong to the same population, whether the t-test or F-test is applied. Thus, the analyzed impact of climate change on meteorological data will not have a significant effect on baseflow. The negative trend is most likely a consequence of the expected increase in temperatures during winter months, when snow cover will be increasingly absent, thereby reducing groundwater recharge. This will affect aquifers poor in dynamic groundwater reserves (fractured aquifers or so-called terrains poor in groundwater). Supporting this is the fact that in 2024 water was delivered by cisterns to livestock grazing on Stara Planina (fractured aquifer present). The reason was that most springs, which had never dried up before, dried up in 2024 due to the absence of snow and snow cover during winter months and a long period without rainfall during summer with extremely high temperatures.

In contrast, karst aquifers have significant porosity and can therefore store considerable dynamic groundwater reserves, which during dry periods are discharged through karst springs over a longer time, so that rivers originating from karst springs baseflow will be more significant, i.e., these streams will not dry up in most cases. In the specific case, the upper part of the Crnica River catchment is predominantly composed of karst terrains (Figure 1).

Finally, it is important to note that if static groundwater reserves exist in karst aquifers (reserves located in the catchment below the elevation of aquifer outflow/discharge), by regulating the karst aquifer these reserves can be used for water supply or other purposes (e.g., irrigation). These reserves will be replenished during rainy periods.

Abstract: *The residual phase noise (also known as the noise floor) of a phase noise analyzer directly determines the sensitivity of that standard, as well as the overall performance of the phase noise measurement system. Since the ML 02 laboratory of the Technical Test Center possesses this standard within its frequency stability and phase noise measurement system, the aim of this research was to experimentally determine whether the specified noise floor is achievable, and whether the actual noise floor is lower than the specified values. This provides insight into the real performance of the existing system and the minimum level of phase noise that can be measured using this setup. This article presents the system noise floor results obtained for different measurement times across the entire frequency offset range of the analyzer, as well as the measurement method and conditions under which these results were obtained.*

Keywords: *phase noise, noise floor, residual phase noise, frequency stability.*

1. INTRODUCTION

Phase noise arises from small, random fluctuations or uncertainties in the phase of an electrical signal. The limitation of dynamic range due to the presence of phase noise directly constrains the performance of various systems. In radar systems and telecommunications, this manifests as reduced system sensitivity; in image processing, as diminished resolution; while in digital systems, for instance, it appears as an increased bit error rate [1]. In analog audio communication systems, the impact of unwanted noise is perceived as a “whistling” within the system’s frequency range [2]. Considering the influence of phase noise on the performance of individual systems or their components, it is essential to measure this parameter in order to assess their reliability.

Phase noise in oscillators originates from random noise sources including flicker noise, shot noise, thermal noise etc. These mechanisms dominate over different offset frequency ranges, and their contributions depend on the oscillator architecture and the underlying component technology.

Due to physical implementation, every oscillator or frequency generator can be regarded as a filtered noise source [3]. Consequently, noise exists around the fundamental frequency and represents the equivalent of random amplitude and frequency modulations of an ideal signal.

However, it is important to distinguish continuous (random) phase variations of the signal from discrete ones. Discrete phase changes give rise to discrete signal components, known as spurious, which do not constitute phase noise. Phase noise is caused by continuous phase

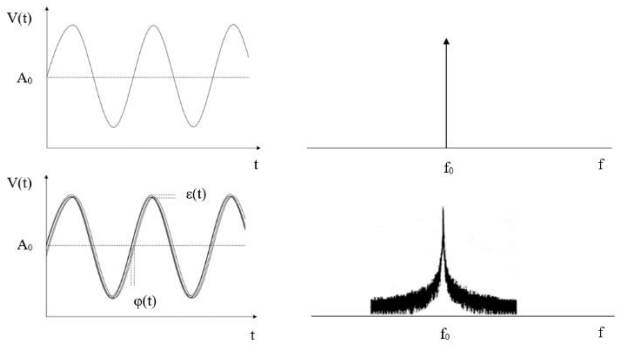

Figure 1. The ideal signal (top) and the real signal in the presence of amplitude and phase fluctuations (bottom), represented in both the time and frequency domains

fluctuations, which in the frequency domain are observed as a broadening of the signal spectrum [4]. Figure 1 illustrate the ideal (top) and real (bottom) electrical signal in both the time and frequency domains.

Phase noise is formally defined as the ratio of the noise

E-mail: nedamilivojcevic@yahoo.com
DOI: 10.5937/OTEH26148S

power measured within a 1 Hz bandwidth at an offset frequency close to the carrier (P_n) to the total power at the carrier frequency (P_c), according to Equation (1) and Figure 2. In technical specifications, this parameter is commonly expressed as single-sideband (SSB) phase noise. It is most commonly denoted as L(f), in units of dBc/Hz.

$$\mathcal{L}(f) = 10log(\frac{P_n}{P_c}) = P_n\left(dBc/_{Hz}\right) - P_c(dBm) \qquad (1)$$

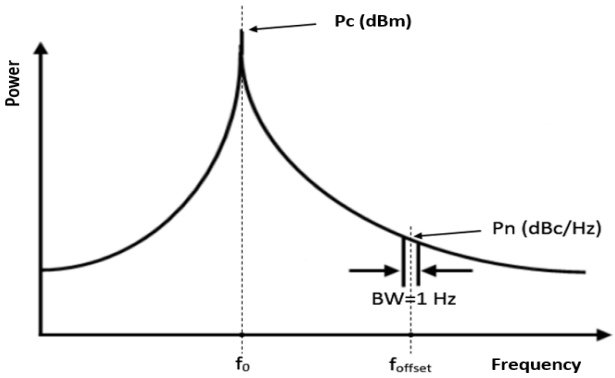

Figure 2. Phase noise, defined as the ratio of the noise power within a 1 Hz bandwidth to the total signal power.

The most common classification of phase noise measurement methods distinguishes six fundamental approaches: the use of a frequency spectrum analyzer, delay line discriminators, quadrature techniques, FM discriminators, cross-correlation methods, and direct digital measurement. These approaches differ depending on whether phase noise is assessed directly, through signal measurement, or indirectly, by calculation from other parameters. They also vary with respect to the number of oscillators employed, specifically whether they require the use of a reference oscillator with known phase noise characteristics [2][5].

At the Technical Test Center, within the Laboratory for Microwave Technics, Time and Frequency (ML 02), a system for measuring phase noise and frequency stability in the time domain has been established. This system employs a phase noise analyzer and an ultra-stable quartz oscillator as a reference standard. In order to assess the actual sensitivity of the system, the analyzer's noise floor as one of its primary limiting factors was measured. In this paper it is also denoted as residual phase noise or internal noise. Through careful selection of measurement method and appropriate configuration settings, the minimum level of phase noise that can be measured with this analyzer was determined.

2. MEASUREMENT METHOD

The implemented phase noise measurement system is based on the use of the phase noise analyzer. The analyzer operates on the principle of digital signal processing, employing a cross-correlation method for signal comparison. In contrast to analog methods, which rely on converting phase fluctuations into proportional voltage levels that are subsequently sampled and processed using Fourier analysis, the digital processing in this system is performed directly on samples obtained from the original test and reference signals, while phase difference detection is carried out digitally.

The phase noise analyzer operates by comparing two signals, while one of them serves as a reference. For this reason, in addition to the analyzer, the measurement system includes an ultraclean quartz oscillator as reference standard. The application of a specific cutting technology of the quartz makes this standard a suitable reference in terms of short-term frequency stability and phase noise. These two standards, each with its own performance characteristics, jointly determine the overall performance of the phase noise measurement system. This system constitutes a unique configuration for direct phase noise measurement within the country. The system for frequency stability and phase noise measurement is configured as shown in Figure 3.

Figure 3. System for frequency stability and phase noise measurement

In order to eliminate the influence of environmental interference, the system is placed inside a modular Faraday cage whose frequency range goes up to 1 GHz and attenuation exceeds 85 dB across the entire frequency range. During measurements, the cage door remains closed, while the environmental conditions are maintained within required limits. The start and stop of the measurement process can be performed either manually or controled via PC and Putty software.

The system noise floor was determined by comparing two identical signals, that represent two copies of a single quartz oscillator output, as shown in Figure 4.

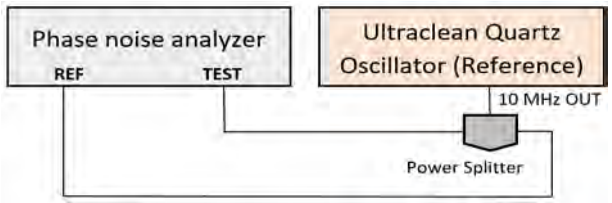

Figure 4. The block diagram of the measurement method

The 10 MHz signal from the output of the quartz oscillator is simultaneously applied to the reference and test inputs of the analyzer through symmetrical power splitter. Although quartz oscillator signals were used for this purpose, in general, the procedure can be performed using any two identical signals.

The analyzer measures the phase noise of input signals with nominal frequency from 2 MHz to 100 MHz, at offset frequency range from 1 mHz to 1 MHz. The signal levels of the test and reference signals must lie within the range of −10 dBm to +20 dBm, while their input levels and nominal frequencies can be different.

The noise floor of the phase noise analyzer, and consequently of the implemented phase noise measurement system, was evaluated for different measurement time: 5 minutes, 15 minutes, and 30 minutes.

During measurements, it is essential to properly configure specific analyzer parameters. The equivalent noise bandwidth (ENBW) should be set to its minimum value of 5 Hz. This increases the capability of measuring very low noise levels and their fine fluctuations. In addition, the thermal compensation and threshold options must be disabled in order to obtain realistic information about the actual internal noise of the analyzer. Enabling the option for thermal compensation suppresses drift and noise caused by temperature variations during the normal operation of analyzer. The threshold option implies rejection of signals below a predefined level in order to separate the analyzer's internal noise from the measured noise of the DUT (Device Under Test). Since the aim of this measurement is to detect all noise components of the analyzer, including its smallest fluctuations, disabling these options ensures that the entire internal noise of the analyzer is involved in the measurement and is not masked.

3. MEASUREMENT RESULTS

The measured residual phase noise of the analyzer for a measurement interval of 15 minutes, presented in the form of a report, is shown in Figure 5. Very low values of residual phase noise can be observed, even at offset frequencies close to the carrier, reaching levels of −191 dBc/Hz within the offset frequency range up to 1 MHz.

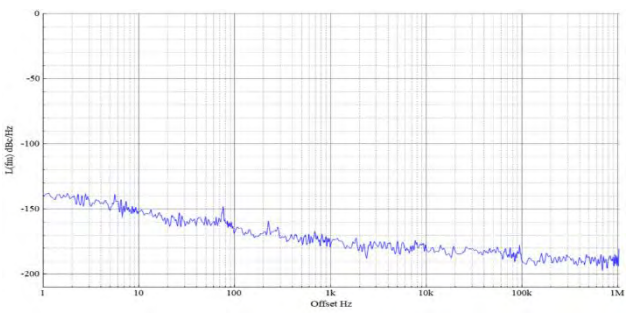

Figure 5. Residual phase noise, 15 min measurement time

Similar results were obtained for measurement intervals of 5 minutes and 60 minutes. The measured values, together with their associated measurement uncertainties and in comparison with the values specified by the manufacturer, are presented in Figure 6. At certain offset frequencies, the measured residual phase noise is up to 7 dB lower than the specified values. The system measurement uncertainty is 2.3 dB, with the dominant contribution arising from the phase noise measurement accuracy of the analyzer. Although the typical value of this accuracy is 1 dB, the manufacturer specifies 2 dB as the guaranteed accuracy of the analyzer [6].

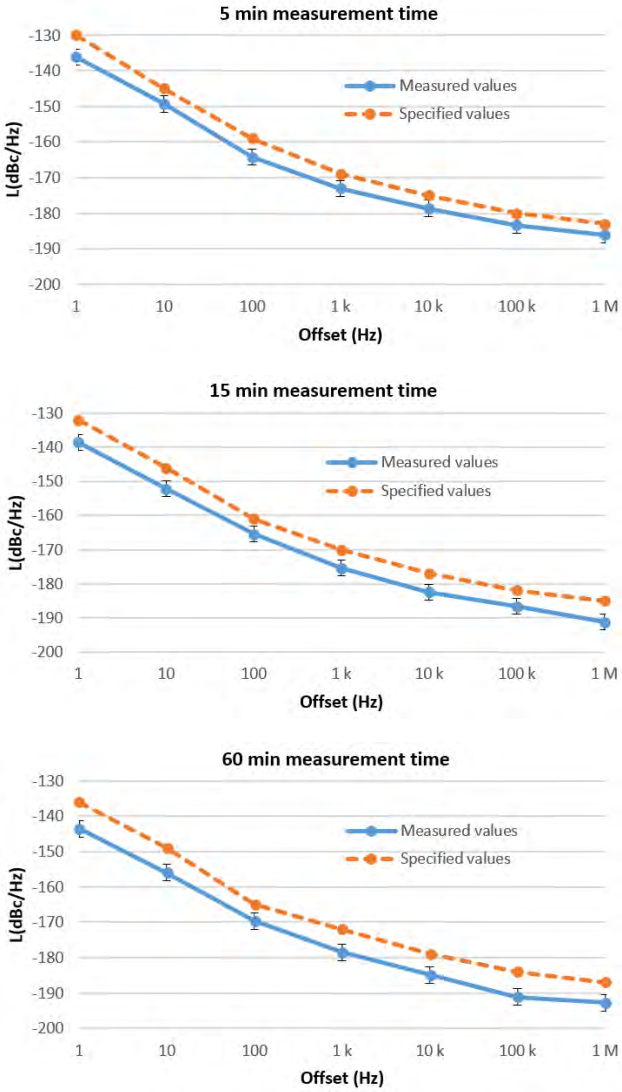

Figure 6. Residual phase noise results in comparison with specifications

Experimental results show that the measured residual phase noise of the analyzer for these measurement intervals (5 min, 15 min, and 60 min) is lower than the specified values, thereby confirming the analyzer specifications. Therefore, such a system enables phase noise measurements of the highest-quality oscillators that are calibrated in the ML02 laboratory.

5. DISCUSSION

Section 3 describes conditions and analyzer settings required to ensure the most realistic measurement of its noise floor (residual phase noise). This includes using of the power splitter, disabling thermal compensation and threshold correction functions, as well as applying the lowest possible equivalent noise bandwidth.

Although these correction functions brings some benefits in the phase noise measurement of the DUT, in the case of internal noise evaluation, they may introduce additional

noise or systematic measurement errors. Consequently, the influence of these factors and their proper settings on the measurement of the analyzer's residual phase noise has been analyzed.

Figure 7 illustrates the difference in residual phase noise when thermal compensation and threshold correction functions are enabled, compared to the case in which these corrections are disabled. Corresponding difference is dominant at higher offset frequencies from 100 kHz and above.

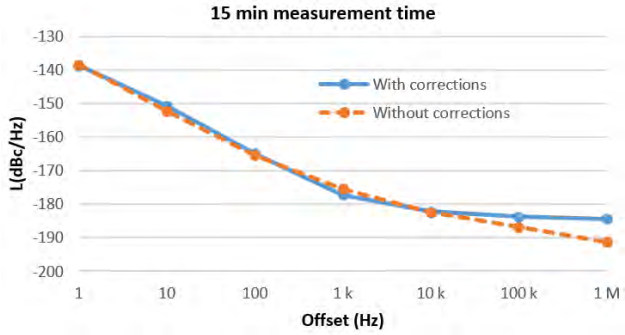

Figure 7. Effects of applying thermal compensation and threshold correction functions on residual noise measurement

Figure 8 presents comparative results of the residual phase noise obtained with the equivalent noise bandwidth (ENBW) set to its maximum value of 500 Hz and its minimum value of 50 Hz. The observed difference is greatest at the 1 MHz offset frequency and amounts to 2.5 dB. Although this parameter does not contribute in obtaining more realistic residual phase noise results in the same manner as the previously described factors, its influence should nevertheless be taken into account in order to achieve the highest possible measurement precision.

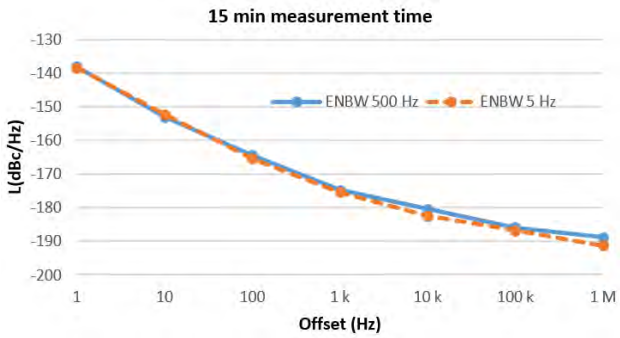

Figure 8. Effects of ENBW on residual phase noise measurement

In Figure 9 is shown comparative results of the analyzer residual phase noise obtained using a power splitter and by applying the 10 MHz signal from two physically separated outputs of the quartz oscillator. Presented results show that the use of a splitter is crucial and necessary for measuring the internal noise of the analyzer. The difference between the presented results is particularly significant at offset frequencies higher than 1 kHz.

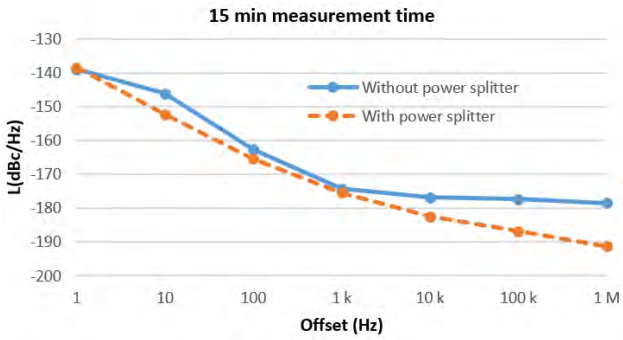

Figure 9. Influence of power splitter on residual phase noise measurement

Considering the finite noise floor of the analyzer, care must be taken to ensure that the phase noise of the oscillator under calibration is not close to this limit. Thanks to the very low noise floor of the applied analyzer, being significantly lower than the phase noise of the oscillators under test, this analyzer fully satisfies the current laboratory requirements for phase noise measurements.

5. CONCLUSION

The paper presents the experimental procedure for determining the residual phase noise of a phase noise analyzer, which defines the noise floor and the effective performance of the phase noise measurement system in the metrological laboratory of the Technical Testing Center. The described method includes the specific measurement conditions and setup that must be met in order to obtain relevant values for the noise floor. The obtained results confirmed the specifications and demonstrated the actual capabilities of both the analyzer and the entire system. The existing system fully meets the measurement requirements for phase noise, serving both the ML 02 laboratory and the entire system of defense.

Abstract: *This paper presents a low-cost implementation of an HP-IB (GPIB, IEEE 488) interface based on the open-source AR488 firmware running on an Arduino Nano microcontroller. HP-IB is a short-range, 8-bit parallel, multi-master digital interface bus used for remote control and data acquisition between laboratory instruments and controllers. In this work, the HP 3582A spectrum analyzer serves as a case study.*

The developed system converts data from the GPIB bus to USB serial communication. A graphical user interface (GUI) application was designed in the MATLAB App Designer environment. The application utilizes HP-IB commands to enable instrument connection, parameter configuration, data acquisition, graphic spectrum display, and export of the measured data in ASCII format.

The proposed solution demonstrates how the operational lifespan of legacy laboratory instruments can be successfully extended while allowing their seamless integration and automation in modern laboratory environments. The obtained results confirm reliable communication, accurate data transmission, and a substantial expansion of the HP 3582A's functionality under contemporary laboratory conditions.

1. INTRODUCTION

The rapid advancement of modern measurement instrumentation has rendered many legacy laboratory devices obsolete, despite their continued technical reliability and high performance. The HP 3582A, a dual-channel dynamic signal analyzer from the late 1970s, exemplifies such equipment [1]. Based on the Fast Fourier Transform (FFT) algorithm, it offers excellent low-frequency spectral analysis capabilities and remains valuable for applications in audio engineering, vibration analysis, and acoustics [2]. However, the lack of native integration with contemporary computers and automated test systems limits its usability in modern laboratory environments. The primary barrier is the obsolescence of the Hewlett-Packard Interface Bus (HP-IB), later standardized as the General Purpose Interface Bus (GPIB) interface under IEEE 488 standard, which, although robust and widely adopted in the past, is no longer natively supported by current personal computers.

This paper presents a low-cost implementation of HP-IB interface based on the open-source AR488 [3] firmware running on an Arduino Nano microcontroller. The developed system enables bidirectional communication between the HP 3582A spectrum analyzer and a personal computer via USB, converting HP-IB commands and data into serial communication. A user-friendly graphical user interface (GUI) application was developed in MATLAB App Designer to facilitate instrument control, parameter configuration, spectrum visualization, and data export in ASCII format. By demonstrating reliable communication and extended functionality of legacy instrumentation, this work contributes to the preservation and modernization of valuable laboratory equipment at minimal cost, offering a practical solution for educational institutions and research laboratories.

2. GPIB (IEEE 488)

One of the longest-standing standards for instrument

Corresponding author: S. Gundelj;
E-mail: gundelj@yahoo.com
DOI: 10.5937/OTEH26149M

interconnection is the GPIB (IEEE 488) [4], [5]. Originally developed by Hewlett-Packard in the late 1960s under the name HP-IB. The GPIB standard was formalized in 1975 and subsequently updated as IEEE 488.1 (electrical and mechanical specifications) and IEEE 488.2 (command and data formats). GPIB (IEEE 488) is an 8-bit parallel bus with a maximum theoretical data rate of 1 MB/s, supporting up to 15 devices over short distances (typically up to 20 m with proper cabling). Its robust handshake mechanism and multi-master capability made it the de facto standard in automated test and measurement systems for decades [3]. Figure 1 illustrates the standard GPIB (IEEE 488) connector pinout.

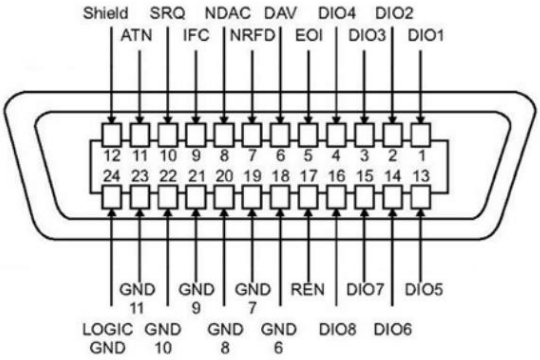

Figure 1. GPIB (IEEE 488) Fimale Connector Pinout [3]

Bus operation is based on dedicated control and handshake lines. The Attention (ATN) line differentiates between command and data modes, while the End Or Identify (EOI) line signals the end of data transfer or enables parallel polling. System control is maintained through Interface Clear (IFC) and Remote Enable (REN) lines, managed exclusively by the system controller. Asynchronous service requests are handled via the Service Request (SRQ) line. Data transfer is synchronized using the three-wire handshake protocol consisting of Data Valid (DAV), Not Ready for Data (NRFD), and Not Data Accepted (NDAC) lines, providing reliable communication even with devices of varying speeds [4], [5]. Figure 2 illustrates the functional grouping of the GPIB (IEEE 488) lines.

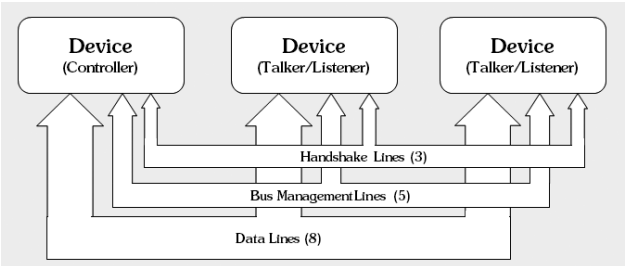

Figure 2. GPIB (IEEE 488) Functional Line Groups [6]

Devices on the bus assume one of three primary roles: Controller, Talker, or Listener. The Controller (usually a computer) manages bus arbitration, addressing, and overall system operation. Multiple controllers are supported, with clear distinction between the System Controller and the active Controller-in-Charge. Addressing is performed using primary addresses from 0 to 30, with Talk and Listen commands derived by adding fixed offsets to the device address. This flexible architecture, supporting configurations from simple point-to-point transfers to complex multi-controller systems, ensures deterministic behavior and remains highly relevant for the modernization of legacy laboratory equipment, as demonstrated in this work.

3. HP 3582A SPECTRUM ANALYZER

The HP 3582A is a classic dual-channel dynamic signal analyzer developed by Hewlett-Packard in the late 1970s. It is based on the Fast Fourier Transform (FFT) algorithm and provides high-resolution spectral analysis in the low-frequency range from 0.02 Hz to 25.5 kHz. Thanks to its advanced digital signal processing capabilities at the time, the instrument achieves a frequency resolution of up to 0.02 Hz with real-time spectrum display, making it particularly suitable for applications in audio engineering, vibration analysis, acoustics, and sub-audio measurements [1], [2]. Figure 3 shows the external appearance of the instrument.

Figure 3. HP 3582A Spectrum Analyzer

Within the HP-IB bus, the HP 3582A offers extensive remote control capabilities. Virtually all front-panel functions are programmable, and the instrument supports full read/write access to its internal memory, including time records, amplitude and phase spectra, transfer functions, coherence functions, and alphanumeric CRT display data [1]. Figure 4 presents a typical display of the analyzer during operation. These features enable efficient integration into automated measurement systems, where data can be systematically acquired, stored, post-processed, and compared with reference values.

From the signal processing perspective, the HP 3582A implements digital heterodyne processing followed by the FFT algorithm, allowing band-selectable analysis with exceptionally high frequency resolution. The instrument supports multiple window functions (rectangular, Hanning, and flat-top) to optimize the trade-off between spectral leakage and amplitude accuracy. Additionally, the built-in sine wave and pseudo-random noise generator (periodic and random) enables standalone testing and calibration of the measurement chain. The dual-channel configuration further supports advanced analyses such as transfer function and coherence measurements — key parameters for system identification and linearity assessment [2]. Due to these characteristics, the HP 3582A serves not only as a measurement instrument but

also as an excellent platform for studying dynamic systems in the frequency domain.

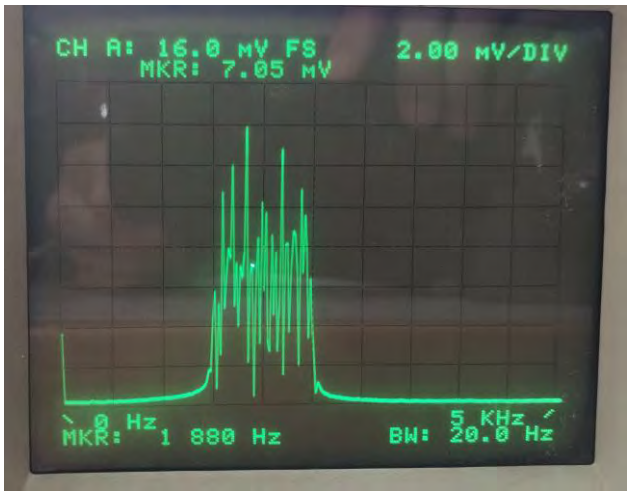

Figure 4. HP 3582A Display Example

4. AR488

The AR488 is an open-source Arduino-based GPIB (IEEE 488) controller developed by Twilight Logic [3], which provides a low-cost alternative to commercial GPIB (IEEE 488) interfaces. The firmware has been developed and tested on various Arduino boards, including the Uno, Nano, Mega 2560, Micro, and Leonardo, with additional support for certain ATmega and ESP32 variants [3]. It emulates Prologix command syntax (with minor exceptions) and enables seamless USB-to-GPIB communication.

The AR488 firmware supports SN75160 and SN75161 GPIB (IEEE 488) transceiver integrated circuits. These ICs provide a buffer between the Arduino and the GPIB (IEEE 488) bus and allow the full 48 mA drive current for a GPIB (IEEE 488) device. In addition, when powered down, these devices present a high impedance to the GPIB (IEEE 488) bus so that the connected device does not interfere with the operation of the bus. [3] In this proposed solution, the SN75160 and SN75161 integrated circuits were not used, as the HP 3582A demonstrated reliable operation in a configuration with one computer. However, for devices requiring higher current drive or full IEEE 488.1 compliance, the use of these IC's is recommended.

Configuration is performed by editing the AR488_Config.h header file, while firmware updates are done through the Arduino IDE. The interface was assembled by soldering short wires from an GPIB (IEEE 488) male connector directly to the Arduino Nano pins, as illustrated in Figure 5. The complete assembly was then placed in a custom 3D-printed enclosure (Figure 6) for mechanical protection and practical use.

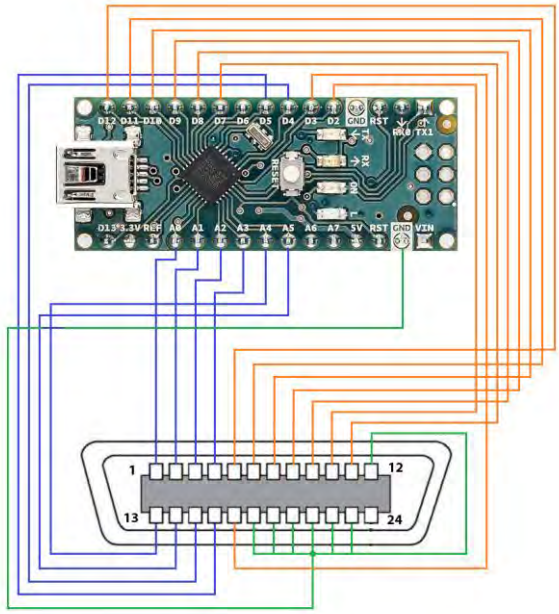

Figure 5. Wiring diagram (male connector)

Testing of the interface was performed using the CoolTerm terminal emulator. The controller version was first verified by issuing the command ++ver, which elicited the response AR488 GPIB controller, ver. 0.53.33, 12/12/2025. Verbose mode was subsequently enabled with the command ++verbose, resulting in the confirmation Verbose: ON.

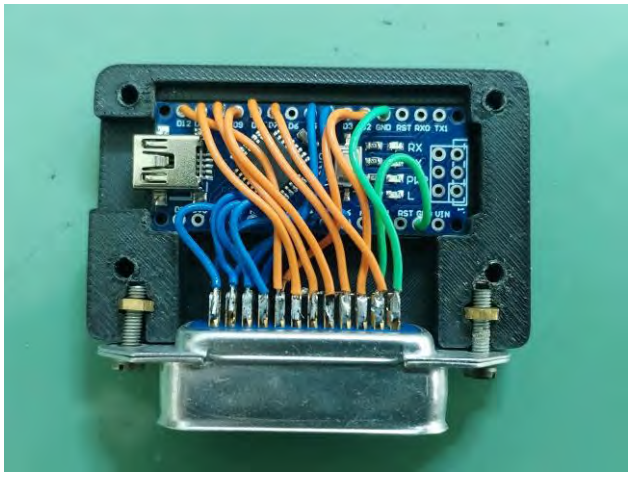

Figure 6. The complete assembly (male connector)

The minimum set of commands required to configure the controller and enable communication with the HP 3582A spectrum analyzer was then applied. The command ++mode 1 configured the AR488 to operate as Controller-in-Charge (CIC) on the HP-IB bus. This was followed by ++auto 1, enabling automatic reading of responses from the instrument, and ++addr 11, which set the HP-IB address of the HP 3582A to its factory default value of 11 (octal). Measured data were subsequently acquired from the spectrum analyzer by issuing the command LDS (Low Data Strobe), which returned a sequence of 256 values. The complete testing procedure is presented in Figure 7.

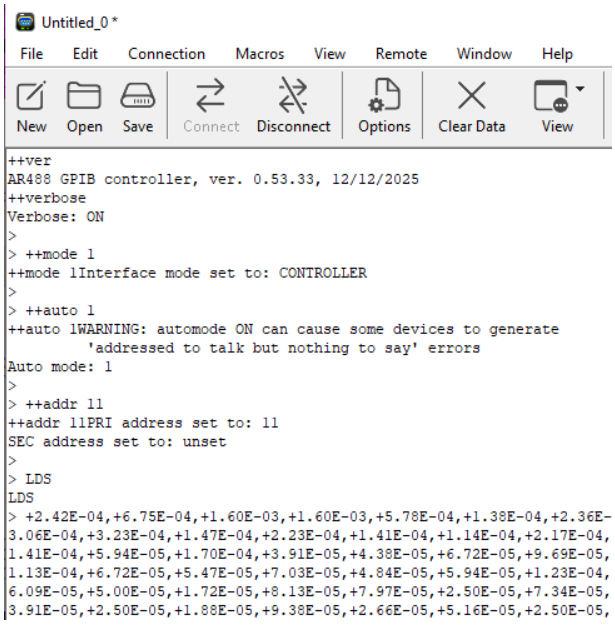

Figure 7. CoolTerm view

This low-cost and compact solution demonstrates the practicality of open-source hardware for extending the usability of legacy GPIB (IEEE 488) instruments.

5. MATLAB GRAPHICAL USER INTERFACE

Prior to developing the full graphical user interface, reliable communication between the AR488 GPIB adapter and the HP 3582A spectrum analyzer was established and tested using MATLAB's serialport interface. The AR488 serves as a USB-to-GPIB bridge, allowing transmission of HP-IB commands over a virtual serial port.

Figure 8 illustrates the initial MATLAB command window test sequence used to configure the adapter and retrieve measurement data.

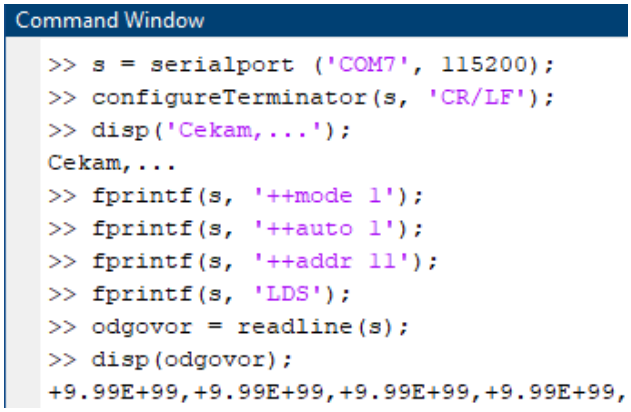

Figure 8. Matlab Command Window

After successful verification of low-level communication, the graphical user interface was designed in MATLAB R2023b App Designer using a modular layout. The main window is divided into three primary sections: (1) a connection and control panel at the top, (2) a central visualization area with axes for spectrum plotting, and (3) a status and data management panel at the bottom. This structure provides an intuitive workflow. Standard App Designer components (drop-down menus, buttons, labels, and axes) were used, with all functionality implemented through callback functions. Figure 9 presents the main window of the developed HP 3582A Control Application (version 1.2).

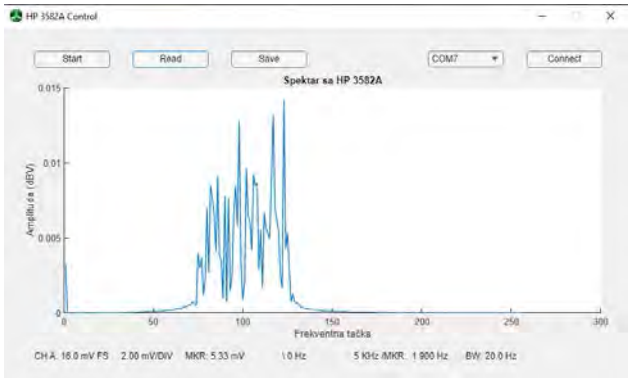

Figure 9. HP 3582A Application V1.2

The core operations are realized as follows. Instrument connection is handled by the ConnectButtonPushed callback function, as illustrated in Figure 10.

```
% Button pushed function: ConnectButton
function ConnectButtonPushed(app, event)
    try
        port = app.COMDropDown.Value;
        app.SerialPort = serialport(port, 115200);  % Baud iz AR488 default
        configureTerminator(app.SerialPort, 'CR/LF');  % ++eos 0 = CR+LF
        app.StatusLabel.Text = 'Čekam inicijalizaciju AR488 (3 sekunde)';
        pause(3.0);
        fprintf(app.SerialPort, '++ver');
        pause(1.0);
        app.StatusLabel.Text = readline(app.SerialPort);
        pause(3.0);
        app.StatusLabel.Text = ['Povezano na ' port '- AR488 inicijalizovan.'];
    catch e
        app.StatusLabel.Text = ['Greška pri povezivanju: ' e.message];
    end
end
```

Figure 10. 'ConnectButtonPushed' function

Upon pressing the Connect button, the application opens the selected COM port at 115200 baud, sets the appropriate terminator, and initializes the AR488 adapter. Comprehensive error handling using try-catch blocks ensures robust operation.

Configuration of the HP 3582A is performed in the StartButtonPushed function, which sequentially sends the necessary commands (++mode 1, ++auto 1, ++addr 11) with appropriate delays (Figure 11).

```
% Button pushed function: StartButton
function StartButtonPushed(app, event)
    try
        app.StatusLabel.Text = 'Setujem HP 3582A (9 sekundi).';
        fprintf(app.SerialPort, '++mode 1');
        app.StatusLabel.Text = 'Setujem Controller mode';
        pause(3.0);
        fprintf(app.SerialPort, '++auto 1');
        app.StatusLabel.Text = 'Setujem auto mode';
        pause(3.0);
        fprintf(app.SerialPort, '++addr 11');
        app.StatusLabel.Text = 'Setujem adresu 11';
        pause(3.0);
        app.StatusLabel.Text = 'Setovanje završeno.';
    catch
        app.StatusLabel.Text = 'Greška pri pokretanju setovanja.';
    end
end
```

Figure 11. 'StartButtonPushed' function

Measurement acquisition and visualization are implemented in the ReadButtonPushed function. When the Read button is activated, the application sends the LDS command, reads the returned data string, converts it into a numeric array using str2double and strsplit, and stores it in the application property SpectrumData. The spectrum is immediately plotted on the designated axes with appropriate labels and title. Additionally, the LAN command is sent afterward to return the instrument to local mode.

Finally, the SaveButtonPushed function enables data export. If spectral data is available, the user is prompted via uiputfile to select a save location. The data is saved as a .txt file in ASCII format with a descriptive header containing timestamp and metadata, ensuring traceability and ease of further processing.

The integration of these callback functions with the graphical components resulted in a robust, user-friendly application that significantly simplifies control of the HP 3582A spectrum analyzer while maintaining full transparency and reproducibility of the measurement process.

During repeated testing sessions, the system exhibited stable operation with consistent spectral data acquisition and no observed transmission errors. The MATLAB GUI provided intuitive and responsive control, noticeably simplifying the measurement workflow compared to manual operation of the HP 3582A.

6. CONCLUSION

This paper successfully demonstrated a low-cost HP-IB (GPIB, IEEE 488) interface based on the open-source AR488 firmware and Arduino Nano microcontroller, coupled with a custom MATLAB GUI application for controlling the HP 3582A spectrum analyzer. The developed system enables reliable bidirectional communication, remote parameter configuration, spectrum acquisition and visualization, as well as data export in ASCII format. By utilizing inexpensive and widely available components, the proposed solution significantly extends the operational life of legacy laboratory instrumentation while seamlessly integrating it into modern computer-controlled measurement environments. The obtained results confirm stable operation and accurate data transmission, validating the practical value of the approach for educational and research purposes.

The presented work opens several avenues for further development. The MATLAB application can be expanded to support virtually all HP-IB commands available on the HP 3582A, enabling more comprehensive automation. Additionally, integration with MATLAB and Simulink environments [7] would allow advanced post-processing of acquired data, such as enhanced filtering, statistical analysis, or system identification techniques not natively supported by the instrument itself. Future research may also explore alternative microcontrollers (e.g., ESP32) to overcome the speed limitations of the Arduino Nano, although the current platform proved fully sufficient for the intended low-frequency applications. Overall, this low-cost modernization strategy contributes to more sustainable and accessible laboratory infrastructure.

Abstract: *This paper presents a quasi-dynamic experimental investigation of the tracer path of a 12.7 × 108 mm projectile, as well as the processing of collected signals using a developed supporting methodology and procedure.*

The aim of the presented methodology and accompanying procedure is to enable reliable, rapid, and safe verification of the quality of the tracer composition within the projectile, using a suitable device, without the need for an open firing range with a long firing line. The experimental procedure described allows for routine and swift factory quality control of tracer projectiles, reducing testing time and cost, improving data acquisition quality and overall test safety compared to conventional field tests, while achieving the desired repeatability of measurement conditions.

The developed methodology, along with the accompanying procedure and device, enables the simulation of real flight conditions of a projectile along its trajectory. The experimental setup allows projectile rotation exceeding 100,000 rpm on the projectile carrier and includes an air-guiding system, a non-contact ignition system for combustion initiation, a spectrophotometer for light emission acquisition, and a PLC for experiment control and monitoring. The results confirm the potential of the developed experimental approach for application in the quality control and development processes of tracer ammunition across various calibers This work relates to the improvements of methods for testing pyrotechnic compositions that make up small arms ammunition tracers, as well as the tracer itself, to the development of contemporary experimental configurations for tracer functional tests, and to an attempt to establish quasi-dynamic testing conditions as an alternative to long-range firing range testing.

Keywords: *small arms ammunition, tracer rounds, tracer testing, pyrotechnic compositions, quality control.*

1. INTRODUCTION AND OBJECTIVES

The manufacturing of cal. 12.7 tracer bullets in the small arms ammunition factory Belom, Požega has been established two years ago. Tracer charge, placed in the container at the bullet's bottom, comprises three different sub-charges, stacked by pressing in sequential order in this container - igniter charge, transfer charge and tracing visible coloured flame producing charge. Corresponding pyrotechnic compositions have been developed and put in production by the factory's resources. Tuning of pyrotechnic compositions, quality control of made batches and lots of loaded tracers include, among the other things, functional tests — emitted colour quality (trace signature quality), burning time, tracing integrity against exposed combined stress in the different phases of bullet firing and motion, and tracer performances at prescribed distances on the bullet trajectory. These tests are principally based on firing tracing rounds, and monitoring and ranking of appearance and colour flame quality by human observers, deployed along the bullet trajectory at assigned distances. Operating procedures and requirements for testing and evaluating of tracer round performances are part of related manuals and standards [1-4]. Tracing signature inspection for every ammunition lot includes shooting 50 to 100 rounds (with double sample repeating in the case of failure), usually at night, and asked for large surface dangerous area because observation posts commonly are distributed in the range at least 1000 m from firing point in the shooting direction and no less than 70 m laterally from the shooting direction. Skilled observers are required for right classification of detected trace signature.

Manufacturing of pyrotechnic compositions, which made tracer charge, is based on the small quantity batches, due to the work safety requirements posed for the high risk

DOI: 10.5937/OTEH26150B

processing of pyrotechnic materials. Numerous batches of the same pyrotechnic compositions make corresponding lot. Several lots of the each involved pyrotechnic compositions, i.e. the several tracer lots are necessary for the single tracer ammunition lot. Inspection of each tracer lot are mandatory before assembling in the related ammunition lot. Moreover, pyrotechnic composition lots shall be passed acceptance test before being loaded in to the tracer. Functional testing of tracer is the inherent part of these stepwise quality control process. High volume production of tracer rounds multiplies the amount of this tests, as well as diagnostic of tracer failure mode, if any.

The required long range proving ground is not the part of the Belom factory, therefore scheduling and renting available distant certified proving ground on time represent production organisation and supporting logistic burden.

The existing acceptance test of pyrotechnic lots includes static testing of the burning time and spectral characteristics of the flame emitted by the tracer. Static test method of tracers is proven as not enough efficient in qualifying the effectiveness of the pyrotechnic lots in question and applied process parameters during tracer charge manufacturing. There is real uncertainty about the acceptance tests result of tracer ammunition by shooting, regardless of successful static tracer tests. Complex stress on the tracer charge, and quick changes of combustion conditions during firing and tracer bullet flight (high gradient pressurisation of tracer charge ignition, sharp initial load of inertial force, stress due to imposed high spin, sudden depressurisation on the muzzle exit, vacuum area on the tracer combustion front during bullet flying and shock waves around the bullet due supersonic flow at the tracer acting part of trajectory), can result with the tracer signature or burning time failure due to tracer charge cracking or break-up, de-lamination between tracer sub-charges, and de-bonding from the tracer container.

Acceptance or rejection of tracer lots based on proving ground ballistic tests represents reliable and efficient testing method. However, considering large yearly number of tracer signature testing, testing timeline that corresponding production process, and occasional accessibility to the suitable long range proving ground, have been imposed need for introducing reliable method of testing tracers for burn time prior to proving ground ballistic tests. Moreover, it was attempt to establish alternative acceptance method of tracers in combination with firing tests (EPVAT, precision, function and casualty), which is inherent part of ammunition inspection at the manufacturer site.

There are numerous test fixtures that combined described in the relevant literature [5-7], which combine tracer burn time measurements under simulated bullet's spin as the most influential factor on the tracer burning time. Application of spectrometers for formulation and inspection of the colour flame producing compositions by measuring the spectrum of light from the composition flame is widely used measurement method [8-11], usually applied in a dark environment with evacuation of produced smoke (photometric tunnel).

The skid for testing of tracer signature has been designed by the Belom factory, as an alternative to acceptance and surveillance tests of pyrotechnic compositions that made tracer charge. This measuring skid provides measurement of tracer burn time and emitted spectral characteristics, under the high angular velocities. Additionally, the skid enables evaluation of the possible tracer charge failure mode due to imposed spin. The measuring skid comprises tracer spinning device, ignition source, process controller and spectrometer arranged in to the compact, portable photometric tunnel.

Diagnostic evaluation of tracer failure modes due to rapid pressurisation and depressurisation environment acting on the tracer bullet during barrel motion and at the muzzle exit, is treated as part of regular ballistic testing (EPVAT test, precision test) in the long closed proving range, as well as tracer behaviour during flight up to 100 m from the barrel muzzle. Observations are based on analysing of the video captured by the high speed camera.

The lot of reference tracer bullets has been established by entirely verification of tracer signature and burning time according to the prescribed procedures based on ballistic firing at long range proving ground. After that tracer bullets sample from this reference lot, have been tested by alternative way in order to establish baseline for evaluation of results obtained by testing tracer lot in question. Also, reference lot is using for checking of measuring equipment prior alternative tests are going on.

Combination of these two test methods provide that functioning of the tracer on ballistic flight is properly simulated insofar as is practical and necessary. This complete in-house testing of the tracer functioning represents an alternative to acceptance and surveillance tests of tracer by rounds firing at the long range proving ground.

2. EXPERIMENTAL WORK

The measuring skid (Figure 1) comprises tracer spinner assembly, smoke evacuation fan, optical fibre port, ignition opening and camera for recording, all boxed in to the cube-like container, and external devices attached on the container – laser system for tracer ignition, spectrometer for separation of visible light emitted by tracer to components and measuring them intensities, display for monitoring of ignition and burning process in to container, PLC for ignition and spinning control, electrical box, air compressor, and oil heating and recirculation unit.

Tracer spinner assembly (Figure 2) includes compressed air driven turbine, holders for tracer at turbine rotating shaft, oil lubrication port, and rotational speed indicator.

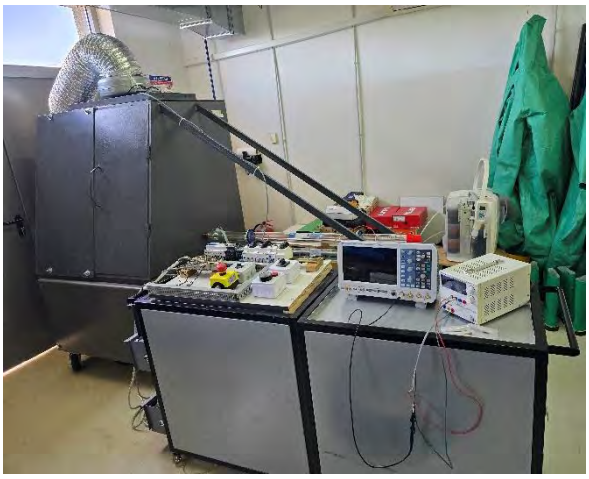

Figure 1. Tracer signature and burning time measuring skid

Turbine has been balanced together with attached tracer up to rotational speed of 200,000 rpm. The rotational speed is adjustable, i.e. applied spin during tracer signature measurement is 128,000 rpm, which corresponding to the rotation rate of 12.7x108 APIT bullet at the barrel muzzle.

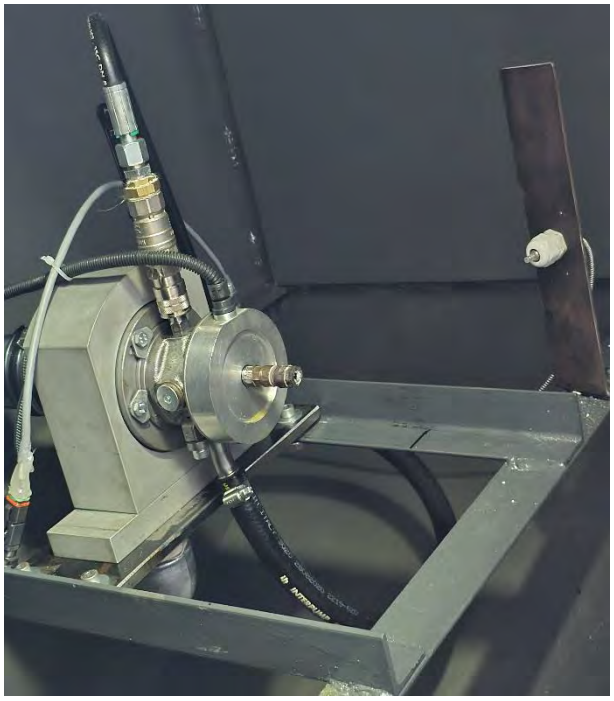

Figure 2. Tracer assembly spinner

The tracer is inserting the core of the rotor and ignited after the desired rotational speed is reached. Ignition has been accomplished by 100W CO2 laser with the laser beam focal spot dimeter of 4 mm (Figure 3).

The laser power is variable, so that the tracer ignition takes place with the minimum energy and exposure time required for stable ignition and combustion of the tracer charge.

The light given off by the burning tracer was picked up by a micro spectrometer with 342 – 820 nm wavelength range, 2048 pixels linear CMOS detector, 16-bit 2 MHz AD converter. The light from tracer signature is transmitted by the optic fibre (Figure 2) to the SMA905 optical input interface on the spectrometer.

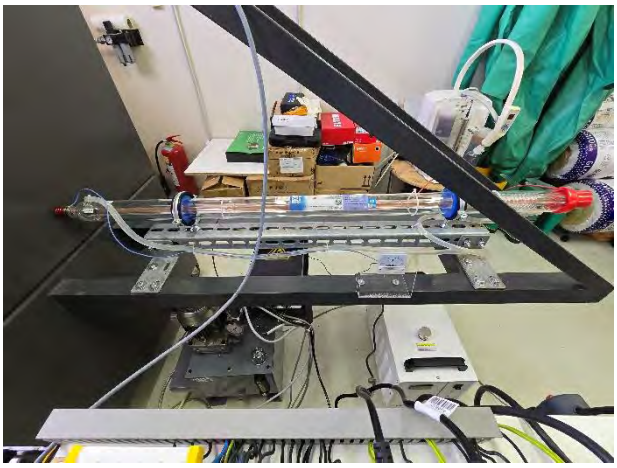

Figure 3. Laser ignition system

When desired laser power is reached tracer charge is ignited and spectral acquisition of emitted light is started. Burning process is monitoring on the external display. Burning time is acquired by the video captured by the camera inside the photometric box. Chronological sequence of tracer burning is given in the Figure 4.

Figure 4. Sequences of tracer burning in photometric box

Acquired spectral data of tracer samples taken for the lot acceptance test, are given in the Figure 5. Calculated tracer colour purity of the red colour is 82.0 to 83.4% (requirement is 75% minimum). Detected burning times are in the range 3.18 – 3.36 s (requirement is 2.6 s minimum).

The test result of pyrotechnic compositions (applied in to the tracer charge) batches, regarding to the spectral characteristics (composition checking, colour purity of tracing composition, burning time measuring) is given in Figure 6.

Observations made from testing of tracer lot under combined stress existing during firing and tracer bullet flight are given in the Figure 7, as series of captured frames, which indicated of proper tracer function.

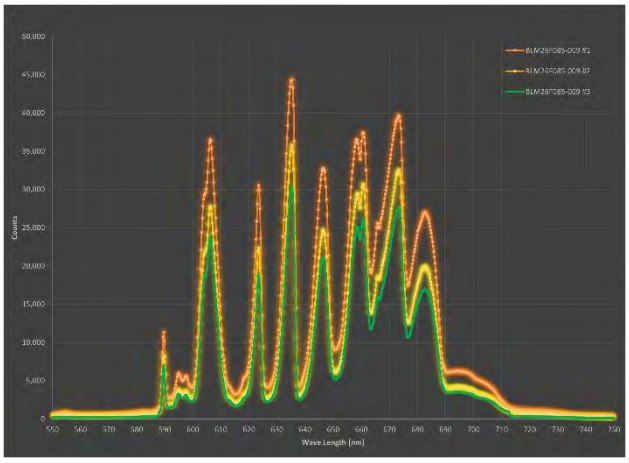

Figure 5. Spectral data for samples from the same tracer lot (acceptance test)

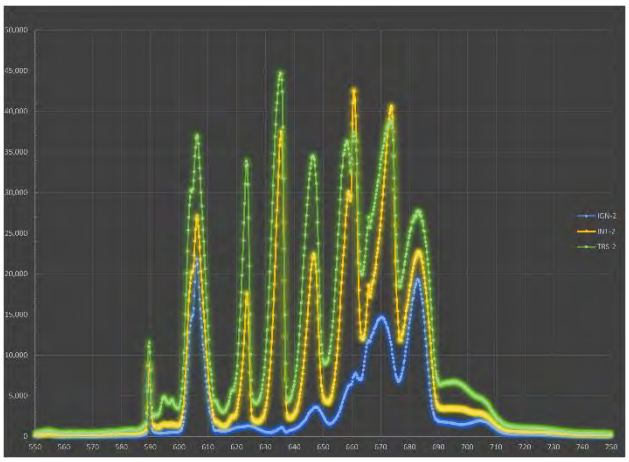

Figure 6. Spectral data for pyro compositions (igniter – blue, transfer – yellow, and tracing – green) which make tracer charge (acceptance test)

Figure 7. Tracer function testing by firing (part of the acceptance test)

The spectrometry offers simply, quick and reliable determination of differences between tracers loaded with sub-charges of different or unknown compositions (Figure 8), with indications of appearance of chemical species in the tracer flame.

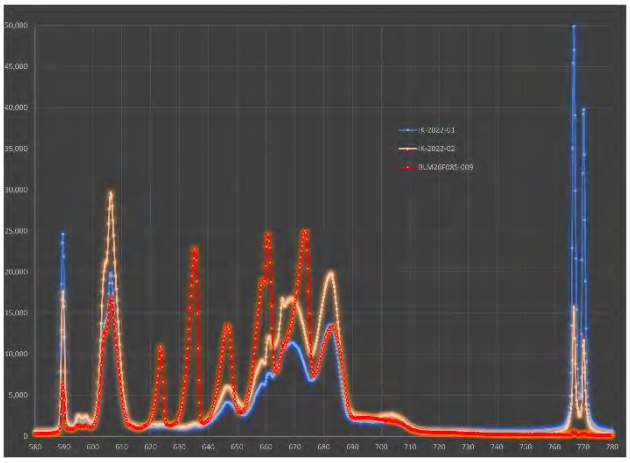

Figure 8. Spectral data for two tracers type regarding to the loaded pyrotechnic compositions (IK and BLM type), but with same tracer configuration (12.7x108 BZT-44 bullet). It is noted absence of SrCl spectra (625, 637, 661, 675 nm), as desired species for red signature in the flame of the IK tracer type, but with strong incandescent emission by the MgO in the flame (760-780 nm), which is undesired because deteriorates color quality of the tracer.

3. CONCLUSIONS

The quasi-dynamic method of tracer signature and burning time measurement has been investigated as an alternative to the firing of tracer bullets at long distances with human observations of the tracer functioning and descriptive evaluation of the flame colour quality.

This method is based on photometric test of tracer flame by the spectrometer, during tracer functioning at spin given by turbine, and corresponding to one imposed by the firing of tracer bullets. Ignition is done remotely by the laser, when assigned spin has been obtained. The related burning time is obtained by the camera. All of these devices are embedded in the portable, compact box.

Firing tracer bullets at short range in-door shooting range supply quasi-dynamic test data with tracer charge structural strength results. It is found that these combined tests represent a real possibility for simple, reliable and timely manner tracer testing at ammunition manufacturer site.

The quasi-dynamic test with ‘reference’ tracers (ones that is tested by the firing procedures at long range proving ground) provides requirements for acceptance test of tracer lot, and for measuring devices calibration and verification.

There is also a useful purpose for this quasi-dynamic test to check the composition and quality of produced batches of pyrotechnic compositions that are included in the composition of the tracer charge.

The spectral data of the tracer signature, obtained by this quasi-dynamic test are valuable in the process of tracer charge formulation, identification and comparative analysis.

Abstract: *This paper analyzes radioactive waste as a long-term security challenge through the prism of international protection principles and the national normative framework of the Republic of Serbia. Radioactive waste management encompasses a series of administrative and technical activities aimed at ensuring the long-term protection of people and the environment. Of particular importance are the standards of the International Atomic Energy Agency (IAEA), which introduce a graded approach based on risk assessment; therefore, safety and security requirements differ depending on the radioactive waste category and include administrative measures, physical protection, and institutional oversight, alongside the application of multiple engineered and natural barriers. The paper further examines the fundamental IAEA safety principles, such as responsibility, the role of the state, optimization of protection, and the protection of future generations, which constitute the basis for the sustainable management of radioactive waste. In normative terms, the legal framework of the Republic of Serbia is based on a specific legislative regime governing this area, supported by a number of bylaws and implementing regulations. However, challenges have been identified with regard to institutional coordination, strategic planning, and the integration of safety and security aspects. This paper points to the need for improving a comprehensive and long-term sustainable radioactive waste management system.*

Keywords: *radioactive waste, security, risk management.*

1. INTRODUCTION

Modern energy and technological developments have renewed focus on the question of nuclear energy's role in ensuring stable, low-carbon, and sustainable national energy systems. Alongside its potential benefits, the use of nuclear energy raises a range of complex safety, regulatory, and ethical issues, with radioactive waste management occupying a central place among them. Unlike many other types of industrial waste, radioactive waste poses a long-term potential risk to human health and the environment, necessitating a systemic approach based on long-term planning, institutional responsibility, and internationally harmonized protection standards.

In this context, IAEA has developed a set of fundamental safety principles [1] that form the basis of the global nuclear safety and security architecture. These principles encompass not only technical protection aspects but also establish a broader framework integrating responsibility for safety and security, the role of the state, risk management, the protection of present and future generations, and the need for transparency and public involvement in decision-making processes. Their application enables states to develop sustainable and reliable radioactive waste management systems that are resilient to technical, safety, security, and societal challenges.

A particular complexity is added to this issue by the fact that radioactive waste management extends beyond the timeframe of a single generation, thereby opening the way for considerations regarding intergenerational responsibility, long-term safety, and environmental protection [2]. In this regard, the safety and security approach to this problem entails not only preventing accidents and controlling radiation exposure but also establishing systems that remain reliable and functional over extended periods. This approach also involves addressing potential security threats, such as unauthorized access to radioactive materials or their misuse, thereby further underscoring the need to integrate safety and security aspects.

In the Republic of Serbia, the issue of radioactive waste management is gaining importance in light of recent strategic and regulatory changes, including the recognition of the importance of nuclear energy in the

Corresponding author: P. Božović;
E-mail: bozovic@vin.bg.ac.rs
DOI: 10.5937/OTEH26151C

Energy Development Strategy [3], the abolition of the Moratorium on the construction of nuclear power plants [4] with the adoption of amendments to the Law on Energy [5] and the preparation of a Preliminary Technical Study on the Peacetime Application of Nuclear Energy [6]. Although the regulatory framework in the field of radiation and nuclear safety and security is established, certain aspects of radioactive waste management remain fragmented, especially in relation to the general system of waste management and emergency situations. This situation indicates the need for further improvement of the normative and institutional framework, with the aim of harmonizing with international standards and ensuring a comprehensive approach to this issue.

Based on the above, the aim of this paper is to analyze the basic principles of radioactive waste management defined by the IAEA, as well as to consider their application and challenges in the context of the Republic of Serbia. Special emphasis is placed on the security aspects of this issue, including long-term risks, institutional responsibility and the need for an integrated approach that links regulatory, technical and social aspects of radioactive waste management.

2. INTERNATIONAL PRINCIPLES OF PROTECTION IN RADIOACTIVE WASTE MANAGEMENT

Radioactive waste management includes all administrative and operational activities related to the handling, pretreatment, treatment, conditioning, transport, storage and final disposal of radioactive waste, with the aim of ensuring long-term protection of people and the environment. In order to achieve this, it is necessary for radioactive waste to be adequately characterized, processed and disposed of in a scientifically based and ethically responsible manner [7].

According to IAEA standards, the safety of radioactive waste is implemented using a graded approach, where the level of physical protection (detection, delay and response) is based on potential hazards and the category of radioactive waste. The danger mentioned as potential is based on the D value of the radioactive material contained in the radioactive waste and is defined for each radioisotope individually. These values are shown in the IAEA Categorization of Radioactive Sources [8]. They represent a specific activity for which a given radioisotope can cause a severe deterministic effect if radioactive source is not under control. Based on this value and activity, sources are categorized from 1 to 5, where 1 is the highest category.

Based on the categorization of sources, according to the IAEA document [9], the safety requirements are defined through three levels A, B and C with the correlation of source category 1 - level A, source category 2 - level B and categories 3 to 5 - level C. On the other hand, the classification of radioactive waste basically serves to determine the required depth and type of disposal according to the time during which the material is considered radioactive. According to the IAEA document [10], the following classification of radioactive waste was adopted: Exempt waste (EW), Very Short-Lived Waste (VSLW), Very Low-Level Waste (VLLW), Low Level Waste (LLW), Intermediate Level Waste (ILW) and High-Level Waste (HLW). For waste categories up to VSLW, security measures include mainly administrative controls to prevent the unauthorized removal of material that is still considered to be radioactive. LLW and ILW require both physical protection (detection and delay system) to prevent malicious acts and unauthorized access during storage and institutional control measures based on active monitoring and regulatory oversight. The most stringent requirements in terms of security measures are required by HLWs that form an integrated safety and security system and a long-term storage strategy.

When both aspects are looked at in the end (classification of radioactive waste and D values of the radioactive materials that make up that waste) the safety requirements can be summarized as follows through Tables 1 and 2.

Table 1. Determination of safety levels based on the type of radioisotopes in radioactive waste and the classification of radioactive waste.

Used description quantity		D value	Classification of radioactive waste
Input parameters for analysis	Primary purpose	Safety and response in the event of an emergency	Disposal and long-term management
	Quantities used	Activity and D-value ratio	Activity concentration and half-life
	Categories	1 - 5 (1 – highest)	1 - 6 (HLW – highest)
Output parameters of analysis	Result/implication	Dictates requirements for physical protection	Dictates requirements for protective barriers and disposal depth

Ensuring the long-term stability and sustainability of the disposal system involves the application of multiple engineering and natural barriers, designed to prevent the release of radionuclides into the environment. These barriers work complementary, enabling passive security and reducing dependence on active surveillance over time. In addition, establishing institutional controls, maintaining comprehensive documentation, and implementing long-term management strategies are key elements in maintaining oversight and accountability over a long period of time.

Equally important are public participation and

transparency in decision-making processes, which contribute to building trust, strengthening social acceptability and respect for ethical aspects. All activities related to the disposal of radioactive waste must be synchronized with relevant national regulations and international legal instruments, thus ensuring a harmonized and responsible approach at the global level. Finally, the minimization of radioactive waste generation and the integration of waste management issues into all phases of the nuclear cycle - from production and use to final disposal - are the basic prerequisites for achieving long-term sustainability and efficiency.

Table 2. Technical security requirements depending on the security level

Radioactive source category	Security level	Primary goal	Security equipment requiremts - examples
1	A	Prevention of unauthorized removal	Detection: alarm system, CCTV, real-time monitoring, PTS Delay: high-security vaults, containers with heavy-duty protective barriers, multiple barriers Response: immediate tactical response to interrupt the act Security equipment requirements
2	B	Minimization of the probability of removal	Detection: alarm system Delay: access control (keys, ID cards, and biometrics) Response: rapid assessment and response that does not necessarily entail interrupting the act
3	C	Reduction of the probability of removal	Detection: daily checks and a simple sensor system Delay: basic physical barriers Response: notification of competent authorities upon confirming the loss of the source
4	C	Maintaining administrative control	Equipment: secure storage, periodic inventory checks, basic locking system to prevent access
5	C	Maintaining administrative control	Equipment: secure storage, periodic inventory checks, basic locking system to prevent access

In this regard, the fundamental safety principles developed by the IAEA constitute an internationally recognized basis for the safe management and disposal of radioactive waste. These principles [1], briefly outlined below, form the foundation for ensuring the long-term protection of human health and the environment, as well as the sustainability and transparency of radioactive waste management practices.

A. Responsibility for safety

Primary responsibility for safety rests with the license holder, that is, the natural or legal person authorized to conduct the activity or operate the facility involving radiation risks. This responsibility applies throughout the entire lifecycle of the facility or activity, regardless of the involvement of other actors. From a safety perspective, clearly defined and indivisible responsibility forms the basis for preventing institutional gaps and the shifting of responsibility during crisis situations.

B. Role of the State

The State is responsible for establishing and maintaining an effective legal and institutional framework for safety. This entails the formation of an independent regulatory body, as well as the establishment of mechanisms for oversight, emergency preparedness, and the control of all radiation sources and radioactive waste disposal. An effective state role is crucial for establishing a comprehensive system capable of addressing complex safety challenges and managing risks at the national level.

C. Leadership and management for safety

Organizations conducting activities involving radiation risks are required to establish effective leadership and an integrated management system that prioritizes safety, fosters a strong safety culture, and ensures continuous performance improvement and the application of lessons learned, in order to prevent safety from being compromised by competing demands.

D. Justification of facilities and activities

The justification of facilities and activities involving radiation exposure is based on the principle that the overall benefits must outweigh the potential radiation risks, taking into account all relevant health, economic, social, and environmental factors. Decisions regarding justification are often made at the highest level of government, particularly in the context of strategic decisions such as the introduction of a nuclear program, whereas in individual cases, the regulatory body plays a key role in assessing the acceptability of specific activities.

E. Optimization of protection

Protection measures must be optimized to achieve the highest reasonably achievable level of safety throughout the entire lifecycle of a facility or activity. A graded approach is applied, encompassing normal, abnormal, and

accident conditions, while taking into account the interdependencies between various phases, groups of exposed persons, and the different stages of radioactive waste management.

F. Limitation of individual risk

Radiation risk management must incorporate clearly defined dose and risk limits to ensure that no individual is exposed to an unacceptable level of harm. These limits represent an upper permissible value and must be complemented by the continuous optimization of protection. Establishing clear risk limits is crucial not only for protecting individuals but also for maintaining public trust in the institutions of the system.

G. Protection of present and future generations

Protection must encompass both people and the environment, in the present and the future, while taking into account long-term and trans boundary risks. Radioactive waste management must be conducted in a manner that does not impose an undue burden on future generations, through the implementation of safe, feasible, and environmentally acceptable solutions. This principle introduces the concept of intergenerational safety as a key element of strategic planning in the field of nuclear policy.

H. Accident prevention

All practical measures must be taken to prevent and mitigate nuclear and radiological accidents, with particular attention paid to preventing the loss of control over a nuclear reactor, a chain reaction, or a radiation source. A key principle in this area is "defense-in-depth," achieved through a combination of multiple successive and independent levels of protection, technical, organizational, and operational, such that a failure or error at one level does not lead to harmful consequences. This principle encompasses high-quality design and engineering solutions, the use of reliable control and monitoring systems, a strong safety culture, rigorous operational procedures, and pre-defined accident management plans. This approach ensures that no single technical, human, or organizational failure can cause significant damage, while combinations of failures that could lead to serious consequences remain extremely rare; this significantly enhances system resilience and reduces the likelihood of accident escalation.

I. Emergency Preparedness and Response

Organizations and competent authorities must establish and maintain effective mechanisms for preparedness and response to nuclear and radiological emergencies at local, regional, national, and, where agreed upon, international levels. The aim of these preparations is to minimize radiation risks associated with foreseeable incidents and, in the event of an accident, to implement practical measures to protect human life, health, and the environment. Plans include criteria for implementing protective measures, capabilities for protecting and informing personnel and the public, and periodic exercises to verify the effectiveness and readiness of the relevant institutions. In emergency situations, subject to informed consent, emergency response personnel may receive doses exceeding standard occupational limits, but only up to a pre-defined level.

J. Protective measures for existing or unregulated risks

Protective measures aimed at reducing existing or unregulated radiation risks must be justified and optimized. Such risks may arise in situations outside the oversight of regulatory bodies, including natural radiation sources (e.g., radon exposure in dwellings and workplaces), legacies of past human activities that were not adequately regulated (such as residual radioactive materials from mining operations), or the consequences of uncontrolled radionuclide releases into the environment. Every protective measure entails economic, social, and environmental costs, and sometimes risks to the individuals implementing them. A measure is considered justified only if the benefits significantly outweigh the potential risks and other negative consequences, while optimization seeks to achieve the greatest possible benefit relative to the resources invested.

In addition to the basic principles defined in the aforementioned IAEA Fundamental Safety Principles, radioactive waste management is further elaborated through specific standards defining operational and technical requirements. Notable among these is *Predisposal Management of Radioactive Waste* [11], which covers all steps in radioactive waste management from generation to disposal, including pre-treatment, treatment, conditioning, storage, and transport. Such waste can be generated during the commissioning, operation, and decommissioning of nuclear facilities; the use of radionuclides in medicine, industry, agriculture, research, and education; the processing of materials containing naturally occurring radionuclides; and processes for the remediation of contaminated areas. At the European level, radioactive waste management is governed by Directive 2011/70/Euratom [12], which obliges Member States to establish national programs for the safe management of radioactive waste and spent nuclear fuel. The aim of this regulation is to ensure the long-term protection of people and the environment in accordance with international standards, while harmonizing practices among Member States and ensuring transparent planning for all stages of the radioactive material lifecycle.

3. NORMATIVE AND INSTITUTIONAL FRAMEWORK IN THE REPUBLIC OF SERBIA

The regulatory framework for radioactive waste management in the Republic of Serbia is based on a clearly defined legal structure comprising primary and secondary legislation. Although the general waste management system is governed by the Law on Waste Management [13], its provisions do not explicitly apply to radioactive waste; this distinguishes the area as a separate and specific category requiring a dedicated regulatory approach.

Radioactive waste management is governed by the Law on Radiation and Nuclear Safety and Security [14], which serves as the fundamental legal act in this field and

establishes key obligations and operational principles. Pursuant to this Law, the Rulebook on Radioactive Waste and Spent Nuclear Fuel Management ("Official Gazette of the RS", No. 127/2021) was adopted, providing detailed regulations on the operational and technical aspects of management [15]. This rulebook prescribes mandatory measures that include avoiding the generation of radioactive waste or minimizing it to the greatest extent possible, preventing criticality, preventing unauthorized access and handling, ensuring controlled storage and disposal, maintaining records, and establishing an emergency response plan. At the same time, it mandates that all management procedures must prevent environmental contamination, harmful impacts on flora and fauna, and adverse effects of ionizing radiation on employees and the general public. It is particularly significant that the rulebook recognizes the need for an integrated approach when radioactive waste also possesses the properties of other hazardous materials, thereby requiring compliance with regulations governing hazardous waste management as well.

Although the Regulation on Security Measures for Nuclear Facilities and Nuclear Materials [16], adopted pursuant to Article 61, Paragraph 3 of the Law on Protection against Ionizing Radiation and on Nuclear Safety ("Official Gazette of the RS," Nos. 36/09 and 93/12), defines technical, physical, and organizational security measures, its legal framework is limited in certain respects compared to the current Law on Radiation and Nuclear Safety and Security. The Regulation applies to the security of radioactive material storage, including technical and organizational aspects, yet it does not fully encompass the broader regulatory framework and strategic provisions of the current law. The current law, which incorporates insights from international standards and harmonizes national regulations with IAEA guidelines, expands the competencies of regulatory bodies, brings a wider range of activities under supervision, and emphasizes inter-institutional coordination. In this context, the aforementioned regulation remains relevant for operational and technical procedures but does not fully cover the law's new provisions regarding strategic oversight, long-term nuclear material management, and systemic security policies.

Similarly, the Decree on Establishing the Nuclear Safety and Security Program [17], adopted pursuant to Article 4, Paragraph 1 of the Law on Protection against Ionizing Radiation and Nuclear Safety ("Official Gazette of the RS", Nos. 36/09 and 93/12), governs long-term plans and objectives regarding nuclear activities, including the system of control and physical protection of nuclear facilities and nuclear materials, in accordance with the standards of international organizations and assumed international obligations. The Decree serves as an operational and strategic framework for implementing the nuclear safety and security program and constitutes an integral part of the regulatory system defined by law. However, compared to the current law, the Decree remains primarily focused on defining the Program and plans, while failing to cover the detailed provisions of the new law regarding oversight, the coordination of regulatory bodies, and the comprehensive management of nuclear materials throughout the entire lifecycle of facilities. This highlights the need for the continuous adjustment of subordinate legislation to ensure full alignment with modern principles of nuclear safety and security and international standards.

Despite the existence of a regulatory framework, certain structural and functional gaps are evident that may pose a challenge to the development of a comprehensive radioactive waste management system in the Republic of Serbia. Above all, separating radioactive waste from the general waste management system, while justified given its specific nature, can lead to fragmentation of the regulatory framework and insufficient integration with broader environmental protection policies.

Coordination among various competent authorities poses a significant challenge, particularly in areas where competencies overlap, such as environmental protection, hazardous materials management, and emergency response. The Law on Disaster Risk Reduction and Emergency Management [18] regulates disaster risk reduction, prevention, the strengthening of resilience and preparedness among individuals and communities, the protection and rescue of people and material and cultural assets, the rights and obligations of citizens, legal entities, and state and local government bodies, as well as emergency management, civil protection operations, early warning systems, and international cooperation. The Law also provides for inspection oversight and regulates other matters relevant to the effective functioning of the disaster risk reduction system. It is specifically emphasized that protection against accidents involving radioactive and nuclear materials is subject to special regulations.

Specifically, business entities and other legal persons that use hazardous substances in their operations, or may come into contact with them, are required to take all necessary measures to prevent accidents and limit their consequences for human life and health, the economy, the environment, and social stability. This includes drafting an accident protection plan and submitting it to the Ministry for approval, as well as implementing the measures defined therein. Particular attention is paid to facilities for the exploitation of mineral resources and those where radioactive and nuclear materials are used, stored, or disposed of, as the consequences of technical or technological accidents at such sites can severely impact human life and health, economic and environmental systems, and social stability. In such cases, legal persons are obliged to organize and carry out protection and rescue operations for people, property, and the environment in accordance with specific regulations. Consequently, it is essential to further improve cooperation and information-sharing mechanisms among institutions, given that various laws stipulate different obligations and involve different institutions responsible for taking action. Such a coordinated approach would enable more effective implementation of preventive measures, better preparedness for potential incidents, and an overall strengthening of the system's safety and resilience.

Furthermore, although the law and accompanying bylaws regulate the technical and operational aspects of management in detail, the strategic dimension—encompassing long-term planning, the selection of permanent solutions for radioactive waste disposal, and a clearly defined national policy in this area—is less pronounced. This is particularly significant given current deliberations regarding the potential development of a nuclear program in the Republic of Serbia.

From a security and safety perspective, while regulations acknowledge the need for protection against unauthorized access and the definition of emergency measures, there is still room to further develop an integrated approach that fully links safety and security components, especially regarding the protection of radioactive materials against misuse. These gaps highlight the need to further develop an integrated, strategically oriented, and cross-sector aligned radioactive waste management system that is fully adapted to the potential future requirements of a nuclear program in the Republic of Serbia.

4. CONCLUSION

Radioactive waste management represents one of the most complex issues in modern safety and environmental policy, given its long-term nature, potential risks, and the need for sustainable solutions that extend beyond the timeframe of a single generation. Analysis shows that international standards, primarily those developed by the IAEA, provide a clear and comprehensive framework based on the principles of a graded approach, optimization of protection, responsibility, and the protection of future generations. These principles enable the establishment of a system that integrates technical, organizational, and institutional measures to minimize risk and ensure long-term safety and security.

The Republic of Serbia's regulatory framework in this area is built on a solid foundation, comprising a dedicated law and accompanying bylaws that recognize radioactive waste as a distinct category requiring a specialized regulatory approach. However, certain weaknesses have been identified, including system fragmentation, insufficient coordination among competent institutions, and an underdeveloped strategic management dimension, particularly regarding long-term disposal and planning in the context of a potential nuclear program. There is also room for further improvement in the integration of safety and security aspects.

Accordingly, the further development of the radioactive waste management system in the Republic of Serbia should focus on strengthening inter-institutional cooperation, enhancing the regulatory framework in line with the latest international standards, and developing long-term strategies that encompass the entire lifecycle of radioactive material. Enhancing transparency and involving the public in decision-making processes is of particular importance, as this contributes to building trust and social acceptance. Only an integrated, strategically oriented, and sustainable approach can ensure the effective management of radioactive waste while safeguarding human health, protecting the environment, and maintaining the long-term stability of the system.

SRĐAN ŽIVKOVIĆ
Military Technical Institute, Belgrade, srdjan.zivkovic@mod.gov.rs

Abstract: *The accelerated progress and digitization of defense technologies imposes the need for a deeper understanding of the interaction of man and technology within the military profession. The paper sets up a conceptual framework for analyzing how organizational culture acts as a guarantor of consistent application of military standards and building trust in technical assets. Organizational culture is viewed as a set of internalized values and behavioral patterns that shape the attitude of system members towards technology, risk and prescribed procedures. Relying on the sociotechnical theory, the concept of highly reliable organizations and the theory of trust, the paper distinguishes key dimensions: perceived technical reliability, safety culture, the relationship between formal procedures and informal practices, as well as the impact of automation on the sense of control and decision-making. Special attention is paid to the role of technical systems and standards as active factors that shape work practice. In this way, it is indicated that the exploitation of military assets is not exclusively a technical, but also a sociocultural issue. The work is conceived as a theoretical analysis, with a proposal of a model of operationalization through examples of questions and questionnaires that have an illustrative function and indicate possible directions for future empirical research.*

Keywords: *exploitation, armament & military equipment, standards (technical & military), organizational culture.*

1. INTRODUCTION

The rapid advancement of modern technologies is witnessed on a daily basis. In recent decades, technological development in the defense sector has been characterized by accelerated digitalization, the introduction of complex sensor, information, and automated systems, as well as the networking of weapon platforms into unified systems. Recent and ongoing conflicts in Nagorno-Karabakh, Ukraine, and the Middle East have demonstrated that without rapid digitalization, the implementation of artificial intelligence (AI), and automated systems, effective deterrence of aggressors and the conduction of conflicts are no longer viable or economically sustainable.

The Serbian Armed Forces and the Ministry of Defence are rapidly embarking on the "Digital Army" project [1], which will significantly strengthen the defense posture of the Republic of Serbia while further propelling the entire system, organizational units, and enterprises operating within the defense sector. These structures, which encompass specialized military-technical institutions and defense industry factories, form the core of the Defence Technological and Industrial Base of Serbia (OTIBS), whose capacities in research, development, testing, quality control, and metrology hold strategic importance for national security and the system's response to contemporary threats [10]. The integration of advanced technologies, such as artificial intelligence, virtual, and augmented reality, into the military system does not merely constitute a technical and engineering modernization, but represents a reality, a necessity, and an imperative for the efficient functioning and survival of the organization in a contemporary information society [20]. This trend dictates the need to evaluate the functioning of defense systems not solely through engineering and technical parameters, but also through the manner in which members of the armed forces-soldiers, officers, engineers, and workers-interact with this technology on a daily basis. The exploitation of weapons and military equipment, understood in its broadest sense as the use, handling, and maintenance of technical assets in accordance with prescribed procedures, represents the convergence point of two vital aspects. One is technical, grounded in design and engineering solutions, while the other is social, built upon the norms, experience, skills, and behavioral patterns of the organization's members. In the sociological theory of organizations, it has long been recognized that the influence of culture on organizational behavior operates at a deep, subconscious level, generating thought patterns that are treated within the system as entirely natural.

When advanced technologies or external standards are introduced into military technical systems, it must be taken into account that the subconscious assumptions and values of the actors themselves exert a decisive influence

Corresponding author: L. Bjelica;
E-mail: lazar.bjelica@mod.gov.rs
DOI: 10.5937/OTEH26152B

on the formulation and selection of practical solutions to operational problems. Neglecting this aspect poses a risk of parochialism, wherein the universal applicability of technical concepts is assumed without sufficient awareness of the specific local and organizational context in which the technology will be exploited [22].

The baseline assumption of this paper is that the consistent application of military and technical standards, as well as the trust users place in technical assets, are not solely a product of the quality of the technology itself, but significantly depend on the organizational culture in which that technology is implemented. Organizational culture is understood as a system of assumptions, beliefs, values, and behavioral norms developed and adopted by the members of an organization through shared experience, manifested through symbols, and guiding their thoughts and actions [2]. It is a relatively stable and clearly defined set of core values, beliefs, shared knowledge, norms, and customs that shapes organizational behavior, cognitive frameworks, and directs all activities of individuals and groups within the organization.

The objective of this paper is to offer a conceptual framework for analyzing the relationship between organizational culture, trust in technology, and the application of standards within a military environment. To this end, the study draws upon three theoretical sources: primarily socio-technical theory, as well as the concept of high-reliability organizations and trust theory. Based on these sources, four analytical dimensions are identified: (i) perceived technical reliability, (ii) safety culture, (iii) the relationship between formal procedures and informal practices, and (iv) the impact of automation on the sense of control and decision-making. Their interconnectedness allows the exploitation of weaponry to be viewed as a socio-technical phenomenon rather than the mere execution of technically defined procedures.

This paper is theoretical and analytical in nature. In the final section, a framework for the operationalization of the presented dimensions is developed, complete with illustrative questions and a draft questionnaire. Its purpose is to indicate potential directions for future empirical research within the defense system and enterprises engaged in the production and exploitation of weapons and hardware, without claiming to represent a definitive or validated measurement instrument.

2. ORGANIZATIONAL CULTURE IN A MILITARY ENVIRONMENT

As previously noted, organizational culture is most frequently defined in the literature as a system of shared assumptions, values, and norms that organization members share and use to interpret their own experience, which are transmitted to new members as the correct way to perceive, think, and feel in relation to the problems the organization faces. Although definitions of this concept vary across authors, they share a common distinction between visible cultural elements—symbols, rituals, language, formal regulations—and deeper, often unspoken assumptions from which these visible elements emerge [4]. The author refines this division through three clearly defined levels: artifacts (visible organizational structures and processes), espoused values (official strategies, goals, and norms), and basic underlying assumptions (unconscious, deeply ingrained beliefs that actually guide behavior) [4]. In military-technical systems, formal standards and operational procedures primarily emerge as artifacts and espoused values. However, to truly guarantee safety, they must be cognitively transformed through practice and collective experience into the basic assumptions of the users themselves. In doing so, the standard ceases to be merely an external obligation and becomes an integral part of professional identity.

Organizational culture is a dynamic process that continuously evolves, is nurtured, and is internalized by transmitting established norms and standards of behavior from more experienced to junior colleagues. It is grounded in community and symbols through which employees share and interweave their values within the collective. Due to its transmissible nature, this culture evolves into a stable tradition of the enterprise or organization, while simultaneously maintaining the flexibility required to adapt quickly and easily to current trends and environmental needs.

In the context of contemporary organizational transformations, particularly driven by rapid technological development, the traditional bureaucratic model characteristic of military systems is undergoing structural changes. Classical bureaucratic structures that strictly rely on formal procedures and hierarchy exhibit severe limitations in dynamic environments. Consequently, there is a growing need to develop more flexible, decentralized forms that influence internal culture and the adoption of technological innovations [23].

Such a cultural framework exerts a decisive influence on the daily behavior of individuals, their productivity, as well as general job and organizational satisfaction. When values are clearly established, they serve as a powerful internal driver and motivator for employees, directing their daily efforts, engagement, and energy toward achieving the shared strategic goals and priorities of the organization [5]. In the context of complex military-industrial systems, the success of implementing a broader development vision directly correlates with the degree to which employees understand the organizational strategy; without this understanding, individuals cannot adequately link their daily operations and equipment handling to strategic outcomes [10]. The military organization represents a highly specific environment for the development and operation of organizational culture. A pronounced hierarchy, emphasized discipline, formalized procedures, and the existence of thoroughly prescribed standards, technical manuals, and operational regulations might create the impression that the behavior of personnel is entirely dictated by formal rules. However, formal procedures never fully encompass the complexity of real-world work scenarios. The space "between" regulations and reality is filled by informal behavioral patterns,

established habits, tacit rules, the ways experience is passed from senior to junior personnel, and the minor shortcuts developed during daily work. It is precisely these patterns that largely determine whether a prescribed standard will be consistently applied in a concrete situation.

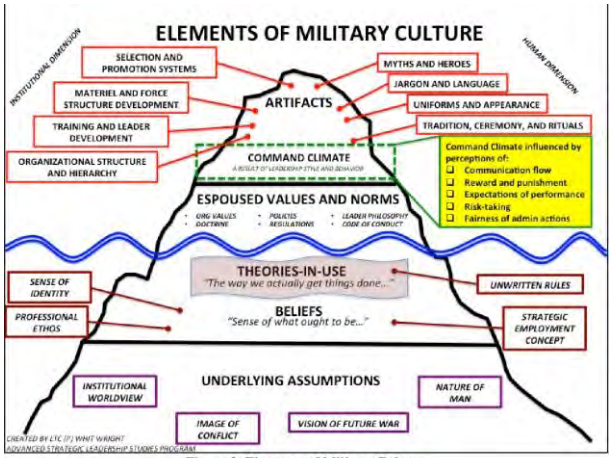

Figure 3. Elements of Military Culture

Figure 1. Elements of Military Culture [9].

For this reason, organizational culture is not treated in this paper as a secondary or less significant variable in relation to technology; rather, it is regarded as a factor that actively mediates between prescribed standards and the actual behavior of all users of technical equipment. In this way, culture becomes a mechanism that can either strengthen or undermine system reliability to an equal extent, regardless of the objective quality of the technology itself.

3. THEORETICAL FOUNDATIONS

The sociotechnical systems theory of organization, the foundations of which were established in the mid-twentieth century through studies of miners in British coal mines [6], posits that an organization's technical and social subsystems must be optimized jointly rather than in isolation. The introduction of a new technological solution inevitably alters the division of labor, communication flows, and power dynamics within work groups; consequently, a technically "optimal" solution may yield poor results in practice if it disrupts established social patterns of cooperation and trust. When applied to a military context, this perspective implies that the deployment of new weaponry is not solely a technical matter of procurement and training. Instead, it requires alignment with the existing unit structure, the division of responsibilities, and the established operational routines of the crew or team operating the system.

The concept of high reliability organizations (HROs) was developed through the study of systems operating under conditions of extreme complexity and potentially catastrophic consequences-such as nuclear power plants and operations on military aircraft carriers-which, despite these hazards, record a surprisingly low number of serious incidents [7]. This finding also served as a response to earlier, more pessimistic perspectives regarding the inevitability of severe accidents in complex, tightly coupled technical systems [8]. Researchers have identified five interrelated characteristics inherent to high reliability organizations:

- a persistent preoccupation with failure and a refusal to dismiss minor signs of disruption as insignificant;
- a reluctance to oversimplify complex events;
- a pronounced sensitivity to operations and the actual state of affairs "on the ground";
- a commitment to resilience, ensuring the system can recover rapidly following an error; and
- a deference to expertise, valuing the input of those closest to the source of risk regardless of their formal rank or stature [11].

Military units that handle complex and potentially hazardous weaponry belong, by the very nature of their mission, to this type of organization; thus, the question of how these characteristics are developed, nurtured, or, conversely, eroded through daily practice emerges as a legitimate research question.

In organizational theory, trust is most frequently examined through interpersonal relationships, where the assessment of the other party's ability, benevolence, and integrity stands out as key factors [12]. When it comes to trust in technology, one must also account for the fact that a technical asset possesses neither intent nor a moral component, yet the user nevertheless develops a specific type of "trust" in the system. Trust is of particular importance in situations where the complexity of an automated system is such that the user is unable to fully comprehend all of its processes and algorithms. Under such circumstances, trust serves as a mechanism that enables decision-making and reliance on the technical system under conditions of uncertainty [13]. It is the conviction that the system will behave in a predictable and reliable manner within the boundaries of its designed capabilities. Research in the field of automation indicates that the user's relationship with technology oscillates between two unfavorable extremes: over trust, where control and verification procedures are neglected because the system is deemed infallible, and under trust, where reliable technology is avoided or bypassed due to user skepticism [13]. Building "calibrated" trust, aligned with the actual capabilities and limitations of the system [13], represents a particularly sensitive issue in the military context, where both over trust and under trust in weaponry and equipment can have severe consequences for safety and successful mission execution.

Trust in automated systems within complex organizations is recognized as a multidimensional construct that, in addition to perceptions of reliability and competence, encompasses affective and experiential components. Recent empirical research on human-autonomy interaction demonstrates that user trust is not based solely on successful task execution or technical accuracy, but primarily on the quality of the interaction process and the manner in which the system manages uncertainty [19].

Safety culture encompasses shared beliefs and practices that determine how seriously risk will be treated in daily operations, independent of the moments when formal

control or inspection takes place. Key elements of a safety culture include a willingness to report minor deviations and occurrences without fear of punishment, the practice of learning from incidents rather than merely assigning accountability, and consistency between organizational rhetoric on safety and actual daily practices [14]. This logic closely mirrors the distinction between an approach that equates safety with the absence of negative outcomes and an approach that conceptualizes safety as an active capacity of the system to function correctly under most conditions, thereby requiring learning from examples of successful operations rather than exclusively from failures [15].

High-Reliability Organizations maintain their performance precisely through this type of collective safety and systematic learning [16]. In a military environment, where hierarchy and discipline are intricately intertwined with safety issues, it is particularly vital that the error-reporting culture does not conflict with the demands of discipline and adherence to the chain of command—specifically, a clear distinction must be made between negligent non-compliance with procedures and the honest admission of an oversight aimed at preventing future incidents.

When the previously outlined dimensions are viewed collectively, it becomes clear that the consistent and safe operation of weaponry and military equipment depends not solely on the technical serviceability of the asset and the formal completeness of regulations, but to a significant degree on how the organizational culture aligns the perception of reliability, safety practices, attitudes toward procedures, and responses to automation. The exact same technology, embedded within different organizational cultures, may in one instance be utilized precisely in accordance with the designer's intent and designated risk parameters, while in another, it may lead to severe deviations without a single formal modification to the weapon system itself. This supports the assertion that enhancing reliability and safety in the operation of military assets cannot be viewed exclusively through the prism of acquiring more advanced technology or enacting increasingly detailed regulations; rather, it demands parallel attention devoted to developing an organizational culture that supports the rigorous application of standards, appropriately calibrated trust in technology, and a sustainable balance between automation and human control.

Based on the presented theoretical framework, it can be hypothesized that organizational culture serves as a mediating factor between military standards, trust in technical systems, and operational safety. It is posited that organizations possessing a well-developed safety culture, consistent procedural compliance, and trust in technical systems achieve a higher degree of operational reliability and a lower risk of errors driven by the human factor. By integrating the specificities of the domestic defense environment into this theoretical framework, it becomes evident that strategic leadership must define an appropriate model for organizational culture change within the Serbian Armed Forces, aiming to create the necessary conditions for the development of operational capabilities and the efficient employment of forces in a dynamic and rapidly changing environment [21].

4. FUTURE EMPIRICAL RESEARCH

Although the paper is conceived as a theoretical-analytical study, the presented conceptual model opens up avenues for future empirical research within the defense system. Grounded in the identified theoretical constructs, it is possible to develop a standardized survey questionnaire to investigate the relationship between organizational culture, the application of military and technical standards, trust in technical systems, and the operational safety of weaponry and military equipment.

The prospective research is quantitative in nature and relies on an anonymous survey of defense system personnel directly involved in the design, testing, metrology, maintenance, operation, and management of technical assets. Respondents comprise military and/or civilian personnel, including engineers, researchers, and technical staff participating in these processes within military institutions (such as VTI, TOC, TRZ...) or defense industry factories.

The introductory section of the questionnaire covers the sociodemographic and professional characteristics of the respondents, such as gender, age, defense system status, field of work, and years of service. These data enable the analysis of potential attitudinal variations among different professional groups and levels of work experience. This approach to sample segmentation is scientifically grounded in existing studies of military systems, which demonstrate statistically significant differences in safety perception and readiness to modify practices across different service branches (e.g., more pronounced safety improvement practices in the air force compared to the army). This variance is attributed to the specific operational environments where errors in technical utilization carry immediate, catastrophic consequences [17].

The core section of the questionnaire is organized into several thematic blocks designed in alignment with the theoretical framework developed in this paper. Each of these blocks comprises items directly linked to key concepts and research objectives, ensuring the systematic collection of relevant data and facilitating subsequent analysis in accordance with the established theoretical premises.

The first domain addresses attitudes toward military and technical standards, metrology, and maintenance procedures. The objective is to examine the extent to which personnel accept standards as an essential element of the safety and reliability of technical systems. One of the items reads: "*During the operation or maintenance of an asset, I consistently rely on official technical manuals and prescribed procedures*."

The second thematic area explores trust in technology, digitalization, and automation. This segment focuses on assessing trust in modern technical systems, the adoption

of digital technologies, and the impact of automation on decision-making. An illustrative item states: *"The introduction of new technologies contributes to increasing occupational safety."*

The third domain encompasses organizational culture and safety culture, specifically focusing on procedural compliance, the role of leadership, the treatment of errors, and the transfer of professional knowledge. For instance: "*Operational errors are analyzed systematically, with the aim of learning rather than individual punishment*." These and similar questionnaire items allow for an assessment of the degree to which the organization exhibits the characteristics of High-Reliability Organizations. This segment builds directly upon modern methodological modifications of military surveys, according to which reflection on the impact of regulations on operations and the utilization of incident reporting are treated as primary tools for improving safety procedures at the tactical unit level [17]. Developing these items tests the openness of the military environment to feedback loops, which are critical for adaptive command and control in complex sociotechnical systems [17]. Within this domain, it is justified to introduce specific items measuring the safety leadership capacity of superiors. Validation for this addition lies in the fact that, within military structures, command personnel (officers and non-commissioned officers) typically manifest a significantly higher level of safety knowledge and safety communication compared to enlisted soldiers. Leadership in a military context thus represents the primary channel through which formal procedures and technical operation standards are translated into the conscious behavior of subordinates [3].

The fourth thematic area relates to the perception of technical reliability and risk. It examines how employees assess the risk of working with technical equipment, the extent to which they trust the outcomes of technical inspections, and how they react when results deviate from expectations. One such item is: "*Trust in prescribed procedures reduces my fear of asset malfunction or failure*." Evaluating this dimension is of particular importance for reference military-technical centers engaged in weapons testing, where maintaining objective independence in decision-making regarding test results constitutes a critical prerequisite for building end-user trust in the reliability of military assets [10].

The fifth domain concerns ethics and professional responsibility. The intention is to determine the degree to which metrology, technical serviceability, and compliance with procedures are internalized as a part of professional responsibility, rather than viewed merely as a formal obligation. An example item is: "*How would your confidence in crisis situations be affected by the knowledge that the asset had not undergone regular metrological inspection*?"

In addition to closed-ended questions utilizing a five-point Likert scale, the questionnaire would contain a small number of multiple-choice categorical questions, as well as several open-ended questions allowing respondents to share their own observations regarding the factors that influence trust in technical assets, the greatest operational challenges, and opportunities for enhancing the maintenance and quality control systems.

In this manner, the assumptions set forth in this paper are empirically tested, and the interrelationships among organizational culture, the application of standards, trust in technical systems, and the operational safety of weaponry and military equipment are analyzed. The obtained results serve as a foundation for improving the training system, developing organizational culture, revising maintenance procedures, and further advancing the digitization process within the defense system.

5. CONCLUSION

This paper proceeds from the premise that the operation of weaponry and military equipment constitutes a complex sociotechnical process in which the technical characteristics of assets, human behavior, and organizational conditions are mutually interdependent. Theoretical analysis indicates that the consistent application of military and technical standards, as well as the cultivation of adequate trust in technical systems, do not depend solely on the quality of technology or formally prescribed procedures, but to a significant degree on the organizational culture within which these assets are utilized. Drawing upon sociotechnical theory, the framework of High-Reliability Organizations, trust theory, and the concept of safety culture, this study proposes a conceptual framework that facilitates an integrated examination of the relationship between humans, technology, and organization within the military environment. Crucially, it is highlighted that organizational culture acts as a mediating factor influencing the consistency of procedural compliance, the adoption of new technologies, risk response mechanisms, and the development of trust in technical systems.

The proposed model for future empirical research does not constitute a definitive measurement instrument; rather, it demonstrates how the outlined theoretical concepts can be operationalized and empirically validated. Research based on this model would enable the determination of the interrelationships among organizational culture, the application of standards, trust in technology, and operational safety, while also identifying areas where organizational and technical improvements can be achieved. The scientific contribution of this paper lies in bridging concepts that are traditionally examined in isolation within the literature, and in demonstrating that the operation of weaponry and military equipment cannot be viewed exclusively as an engineering process. Instead, it must be understood as the product of interaction between technical systems, organizational values, and the professional behavior of their users.

Contemporary trends and security challenges necessitate a transition toward more flexible and operationally integrated workflow management systems. This implies a reliance on smaller organizational units comprised of highly qualified individuals, a reduction in management

layers, and the realization of an authentic, organic convergence between the technical and social subsystems within the defense system [18]. Furthermore, synthesizing social aspects and applying them to technical disciplines would yield a significant contribution, fostering enhanced collaboration between the social and technical sciences, particularly within the military context. Concurrently, this paper serves as a baseline for future empirical investigations that could contribute to optimizing training systems, cultivating organizational culture, rigorously applying standards, and further advancing digitization processes within the defense system. Organizational culture integrates technical standards into the military ethos and professional identity. Thus, armament exploitation ceases to be a mere routine and becomes a direct expression of responsibility in the modern military profession.

Abstract: *Cavitation is a very common phenomenon in mechanical systems involving the interaction between a solid body and a fluid acting either as a working medium or as a lubricant. Under certain operating conditions, the occurrence of cavitation leads to cavitation erosion, i.e., material degradation. Numerous experimental studies have demonstrated that cavitation erosion affects the mechanical properties of material. However, an even more pronounced effect is observed in the alteration of surface roughness.This phenomenon is not necessarily detrimental, as it has been reported in the literature that cavitation can be effectively utilized for polishing geometrically complex components, which are often produced using additive manufacturing technologies.In this study, the influence of cavitation on the surface roughness of samples fabricated by laser sintering of MS1 steel was investigated. Cavitation was experimentally induced under laboratory conditions according to ASTM G32 standard.. The samples were also subjected to post-processing treatments, including heat treatment (aging) and mechanical strengthening (shot peening), enabling an analysis of the effects of different strengthening methods and their combinations on surface roughness evolution. The measurements were performed at multiple time intervals in order to monitor the progression of cavitation effects over time.*

Keywords: *cavitation, cavitation erosion, surface roughness, MS1, additive manufacturing*

1. INTRODUCTION

Cavitation is a phenomenon that occurs in fluids when the pressure drops below the saturation pressure or when the temperature rises above the evaporation temperature. In mechanical systems, cavitation is primarily caused by pressure variations, which may result from local drops due to changes in geometry and fluid flow velocity (hydrodynamic cavitation), or from pressure fluctuations induced by vibrations (acoustic cavitation). [1–4] These two mechanisms are often coupled, since changes in geometry and vibrations are common in mechanical systems, leading to hydrodynamic–acoustic cavitation (HAC). [5]

Cavitation bubbles implode, generating strong shock waves in the case of homogeneous nucleation, or microjets in the case of heterogeneous nucleation, which damage material surfaces. The implosion (condensation) process occurs within an extremely short time frame, while the number of bubbles is large, so this type of material damage can be considered a dynamic load from the perspective of load-bearing capacity studies. The resulting damage, known as cavitation erosion, affects the properties of the material's surface layers, as demonstrated by numerous studies conducted on different materials. [6, 7] Above all, cavitation has a significant impact on surface roughness, which is a crucial surface parameter and directly affects the functionality of machine parts.

This phenomenon is often neglected in vital machine parts, and there is very little research on the impact of cavitation erosion on their operational capacity. Furthermore, this is a very common occurrence in vital machine elements such as bearings, gears, seals, etc. In the calculation standards for these elements, cavitation erosion is listed as a mode of destruction, but it is deemed to have no effect on operational capacity. Although it is not a dominant phenomenon compared to primary damages, material particles suspended in oil can secondarily cause abrasive wear; in systems whose operating parameters are such that cavitation is pronounced, this can significantly affect operational capacity and reliability. [8]

Since hydrodynamic cavitation is more common, optimization of geometry is possible in order to reduce cavitation, but such optimization must be carried out in accordance with other potential damage mechanisms in mechanical components. Recently, mainly for techno-economic reasons, mechanical parts are increasingly being manufactured using additive technologies. These technologies enable the rapid production of components directly from 3D models and successfully overcome the challenges associated with manufacturing parts of

E-mail: pljubojevic@mas.bg.ac.rs
DOI: 10.5937/OTEH26153L

complex geometry. For this reason, it is essential to determine the behavior of 3D-printed materials under cavitation erosion conditions. In this study, the influence of cavitation erosion on the surface roughness of MS1 steel samples produced by Direct Metal Laser Sintering (DMLS) technology was investigated, with and without subsequent thermal and mechanical surface treatments.

2. MATERIAL AND TECHNOLOGY

The test samples were produced from MS1 steel powder, which corresponds to tool steel grade with European classification 1.2709, the American 18% Ni Maraging 300, and the German X3NiCoMoTi 18-9-5. According to the powder manufacturer's specification (EOS GmbH), the chemical composition of the steel is presented in the following table. [9]

Table 1. Chemical composition of MS1 powder

Element	%	Element	%
Ni	17 - 19	Cu	0.5
Co	8.5 – 9.5	C	0.03
Mo	4.5 – 5.2	Mn	0.1
Ti	0.6 – 0.8	Si	0.1
Al	0.05 – 0.15	P	0.01
Cr	max. 0.5	S	0.01
Fe		Balance	

The particle size of the powder ranges from 15 to 65 µm and the density of the manufactured part 8 g/cm³ The test samples are cylindrical in shape, with a height of 5 mm and a diameter of 10 mm.

The test samples were manufactured using Direct Metal Laser Sintering (DMLS) technology, which belongs to the Powder Bed Fusion (PBF) process category. Fabrication of the test samples was carried out on an M280 DMLS system. The chamber is equipped with a build plate measuring 250 × 250 mm, allowing a maximum build height of 325 mm. The printing was performed in the vertical direction, directly on the plate without the use of support structures. Each layer was deposited at a thickness of 40 µm. The laser operates at a power of 200 W, emitting infrared radiation with a wavelength of 1064 nm. Prior to the start of the process, the build plate was preheated to 40 °C to ensure stable processing conditions. [10, 11]

One group of the test samples was tested in the as-built condition, without any subsequent thermal or mechanical treatments. Since the manufacturer recommends aging of this steel to improve mechanical properties, particularly strength, another set of samples was subjected to aging according to the manufacturer's guidelines. To achieve the maximum guaranteed hardness of 54 HRC, the aging process was carried out for 6 hours at 490 ±10 °C, followed by air cooling. One of the objectives of this study was to compare the influence of aging and shot peening on the cavitation resistance of the samples. Therefore, one group of test samples was shot peened. In addition, an analysis of surface roughness was performed on specimens that were first aged and subsequently shot peened.

3. EXPERIMENTAL PROCEDURE

The experiment was conducted in accordance with ASTM G32. At defined time intervals, the specimens were exposed to cavitation, subsequently dried, and evaluated for mass loss and surface roughness. Since the focus of this study is exclusively on changes in roughness, mass loss measurements are not discussed. The ultrasonic cavitation device used is shown in Figure 1. The test sample was immersed in a water bath, positioned 0.5 mm below the horn tip. The water temperature was 25ºC. The horn, excited by mechanical vibrations generated through a piezoelectric element converting electrical energy, oscillated with an amplitude of 5 µm at a frequency of 20 kHz. These vibrations induced pressure fluctuations in the water layer between the horn and the specimen, leading to bubble formation and cavitation erosion. [12]

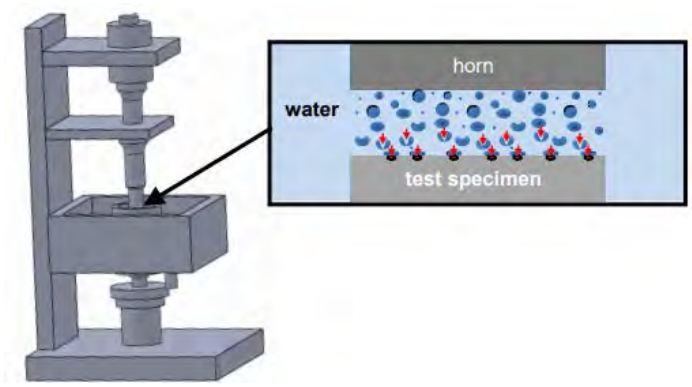

Figure 1. Device for ultrasonic cavitation testing

At specific measurement intervals, the surface roughness of the specimens was evaluated alongside mass measurements. For the as-built and aged specimens, roughness was assessed after 60, 120, and 240 minutes of cavitation exposure, whereas for the shot-peened and aged + shot-peened specimens, roughness was measured only after 240 minutes. Prior to cavitation testing, the initial roughness of each test sample was recorded. Roughness measurements were performed using a MarSurf SD26 device (Figure 2), which employs a diamond-tipped stylus. The stylus was positioned so that its tip lightly contacted the specimen surface. A cutoff length of 0.8 mm was applied, with a traversing length of 5.6 mm, and evaluation length of 4mm.

Figure 3 shows the surface roughness of the aged specimen after 240 min of cavitation erosion testing as an example of the measurement results. However, this study will not discuss the entire measured roughness profile; instead, the focus will be placed on the parameter Arithmetic Mean Height of the Assessed Profile, i.e., Arithmetic Mean Roughness – R_a. The change in the R_a parameter directly affects the operating capability of mechanical components exposed to cavitation, particularly gears, where surface roughness plays an important role in defining contact conditions and represents one of the parameters considered in the

correction factors for critical stress evaluation.

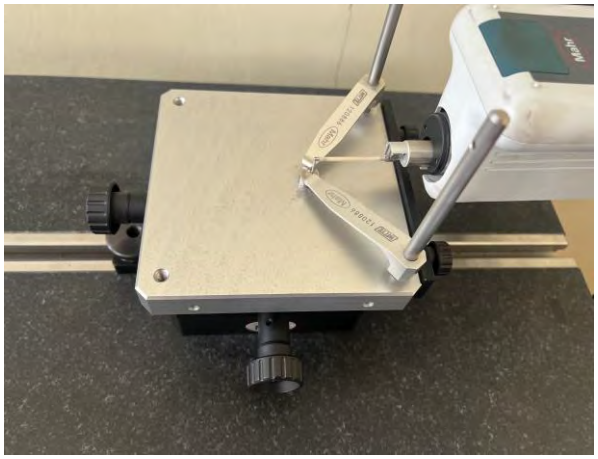

Figure 2. Measurement of test sample surface roughness

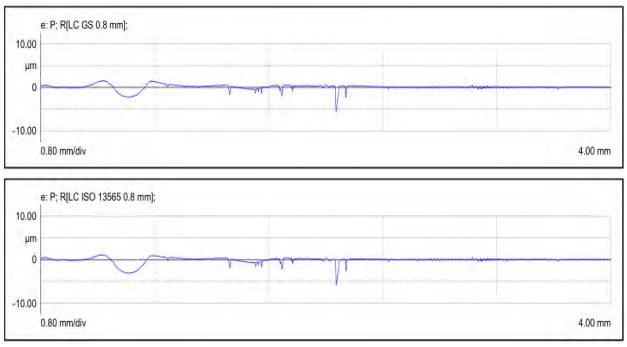

Figure 3. Surface roughness of aged MS1 steel after 240 min of cavitation exposure

4. RESULTS

Based on the measured surface roughness values for the as-built and aged samples, together with the initial roughness values, the dependence shown in Figure 4 is obtained.

One of the key parameters for the analysis of cavitation erosion is the Mean Depth of Erosion (*MDE*), which represents the average erosion depth over time and is calculated according to the following equation:

$$MDE_{\Sigma_i} = \sum_{i=0}^{n=8} \Delta MDE_i \sum_{i=0}^{n=8} \frac{4\Delta m_i}{\rho \pi d^2} 10^3 [\mu m] \quad (1)$$

Where: i is a testing period, ρ is a density, Δm_i is a mass loss measured in mg, and d is a test sample diameter.

The values of *MDE* were measured and obtained for the as built samples, as presented in the study [13]. Since both *MDE* and R_a represent averaged values, and experimental analyses have shown that the best approximation of *MDE* is achieved using the least squares method, in this work the values of R_a were also approximated using the least squares method. In the case of the aged samples, the mean squared error (MSE) is negligible, whereas for the as-built samples, it is comparatively higher.

Based on the obtained results for MDE, a straight line of the following form is derived with negligible error (R^2 = 0.9886):

$$MDE = 0.0105t - 0.0368 \quad (2)$$

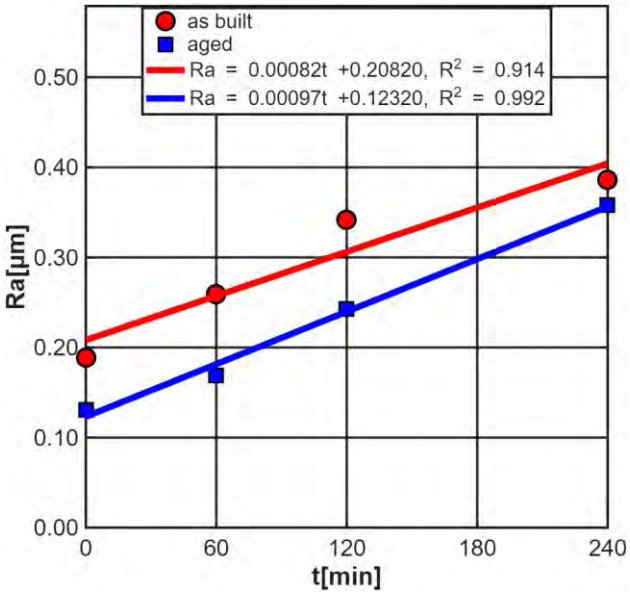

Figure 4. Surface roughness vs. time for as-built and aged MS1 steel

From the slope of the linear trends for R_a and *MDE*, it is evident that *MDE* changes at a considerably faster rate than R_a. A possible correlation between these two parameters could be established by comparing the lines without intercepts on the y-axis. In such a case, the variation of R_a could be predicted solely from its initial value and the time-dependent change of *MDE*. To define this relationship, a series of experiments would be required to determine the ratio between the slopes of the *MDE* and R_a curves. This ratio could then be expressed as a coefficient, enabling the prediction of one parameter based on the evolution of the other. Verification of this assumption would necessitate further experimental work and potentially the development of a mathematical model describing surface damage and roughness evolution. The obtained results also indicate that both *MDE* and R_a can be represented as linear functions of time. In that case, R_a could be calculated as follows:

$$Ra\,(t) = Ra\,(t = 0) + \frac{k_{MDE}}{C}\, t \quad (3)$$

Where C is the ratio of k for *MDE* and R_a. In this case of as-built MS1 steel, that ratio is 12.8.

For the test samples subjected to shot peening and combined aging + shot peening, surface roughness was measured at the beginning of the test and after 240 minutes of cavitation exposure. The results are presented in Figure 5. "Due to having only two measurement points, no linear regression approximation can be used, so the results are presented in the form of bars. The initial R_a values are significantly higher than in the case of these samples.

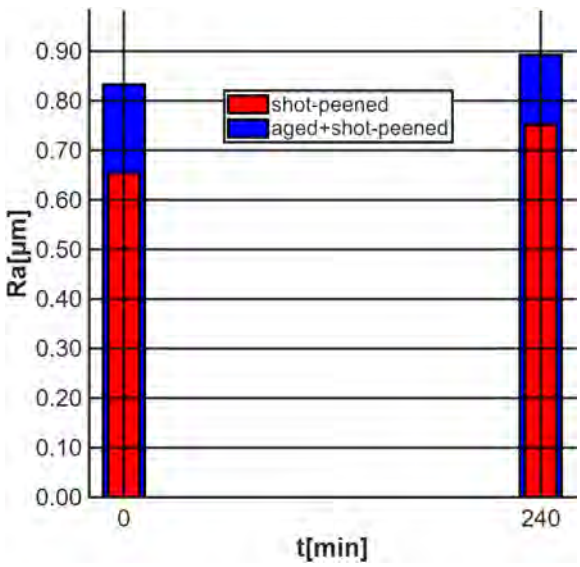

Figure 5. Surface roughness vs. time for shot peened and aged + shot peened MS1 steel

5. CONCLUSIONS

Based on the obtain results it can be concluded:

MS1 steel, characterized by excellent properties as a high-hardness steel, demonstrates very good performance in terms of surface roughness evolution. It exhibits only a minimal increase in R_a over time. Since R_a represents the average surface roughness, by analogy with MDE, which is the average depth of erosion, it can be approximated using the least squares method. The slope of this line is one of the indicators of the material's sensitivity to changes in surface roughness. These slopes are very small: 0.00082 for the as-built condition, 0.00097 for the aged condition, 0.00041 for the shot-peened condition, and 0.00025 for the aged + shot-peened condition (if a straight line were drawn through these two points), which indicates a very minor change in the R_a parameter over time.

For the MS1 as-built samples, analysis of the time-dependent changes in *MDE* and R_a indicates that *MDE* is a significantly more sensitive parameter than R_a, as its slope is nearly 13 times greater. By conducting a large number of experiments, it would be possible to establish a correlation between the time-dependent variations of *MDE* and R_a, enabling the prediction of one parameter based on the evolution of the other. For the as built and aged test samples, the slope of the line is higher than for the shot-peened and aged+shot-peened samples. One possible reason is the significantly lower initial roughness of the as built and aged samples, which were polished prior to testing and are very similar (as built – R_a = 0.189 µm, aged – R_a = 0.131 µm). An inconsistency observed is that the slope of the line approximating Ra for the aged samples is somewhat higher than for the as built samples, which should not be the case since aged samples exhibit greater cavitation resistance due to the higher surface hardness. However, the considerably larger approximation error in the as built samples likely influences this phenomenon. The initial roughness of the shot-peened and aged+shot-peened samples is significantly higher (shot-peened – R_a = 0.654 µm and aged+shot-peened – R_a = 0.833 µm), which is explained by the subsequent mechanical surface treatment (shot peening) that increases roughness. In addition to the strengthened surface, the initial roughness contributes to the gentler slope of the approximating curves in this case. Accordingly, as expected, the aged+shot-peened test samples exhibit the lowest slope of the line due to the highest surface resistance resulting from both thermal and mechanical treatment. In the case of the shot-peened and aged+shot-peened samples, only the initial and final roughness values were measured. Therefore, future experiments should include measurements at additional intermediate points to achieve a more precise determination of the slope of the approximating line.

Abstract: *The Velika Morava represents the largest river basin in the Republic of Serbia, with a total area of 37,444 km², of which 36,163 km² belongs to Serbia, accounting for 42.38 % of its total territory. In its lower course, it is a typical lowland river that frequently changes the geometry of its riverbed under the influence of natural and anthropogenic factors, which poses a major problem for the establishment of river navigation. River navigation on this river was established at the beginning of the 19th century, when the first steamboat arrived in Stalać, and during that period it was used exclusively for tourism purposes. Today, only the last 15 km of its course are navigable for the vessels of the River Flotilla in the execution of assigned tasks. However, the river flow itself and its hydraulic connection with groundwater formed in the alluvium of this river are of exceptional importance for the water supply of the population and industry, for agricultural purposes (irrigation), as well as for the extraction of sand and gravel from the riverbanks and the riverbed itself. The paper will present an analysis of natural and anthropogenic factors using statistical methods, as well as an assessment of their impact on the geometry of the river course, the regime of surface and groundwater, and, in this regard, the utilization of this natural resource for various purposes.*

Keywords: *water regime, river navigation, water supply, sand and gravel exploitation, Velika Morava*

1. INTRODUCTION

From the very beginning to the present day, human civilization and settlements have been tied to riverbanks and river courses themselves. The river was their source of everything needed for survival. Rivers provided sufficient amounts of water for water supply, irrigation of crops, and livestock watering. They also served as routes for river transport, sources of high-quality food (fishing), renewable sources of building materials (clay, gravel, and sand), and the like. However, it was also necessary to defend against rivers. This was particularly crucial during high water levels and the onset of flood waves. For this reason, historical records were initially kept indicating which areas the river flooded (the inundation area). Buildings were relocated and constructed beyond the influence of recorded flood waves, while digging wells in areas with settlements allowed the population to have accessible water for their own needs right where their living quarters were located.

Later, monitoring was established—initially for surface waters and subsequently for groundwater. One of the first instruments for tracking changes in river levels was the nilometer, used by the ancient Egyptians to monitor the Nile River. Much later, official services and institutions began to form. They established observation networks and conducted observations and measurements, initially of quantitative parameters (water levels and discharges) and later of qualitative parameters when that became necessary. By establishing a sufficiently long observation

Corresponding author: M. Kresojević;
E-mail: milan.kresojevic@va.mod.gov.rs

DOI: 10.5937/OTEH26154K

series of a quantitative parameter, it became possible to discern changes in their regimes resulting from both natural factors (climate change) and anthropogenic factors (dam construction and the formation of surface reservoirs, gravel and sand extraction, riverbed relocation for infrastructure projects like roads, or for expanding the extraction areas of existing or new mines, etc.). Many authors have analyzed the impact of natural and anthropogenic factors on changes in surface water regimes in their papers. For example, Wrzesiński & Sobkowiak [1] conducted a detailed analysis of the impact of natural and anthropogenic factors on changes in the water regime of the Vistula River (Poland), aiming to establish better water resource management and hydrological forecasting. A group of Ethiopian co-authors [2] addressed a similar topic, using the regime of the Gumara River (Ethiopia) as an example. Rempel & Church [3], focusing on the Fraser River (Canada), presented the impact of anthropogenic factors (gravel extraction) on the river course itself, as well as its overall environmental impact.

Since the banks and beds of larger rivers contain significant (mostly renewable) reserves of sand and gravel, extraction fields used for harvesting these building materials are often located on their banks. This paper presents how illegal and uncontrolled sand and gravel extraction from the banks of the Velika Morava River near the Ljubičevo Bridge affected the water resource of the Velika Morava itself, as well as the groundwater within the river's alluvium. During the 1990s, in the section near the Ljubičevo Bridge, this extraction led to the deepening of the Velika Morava riverbed by about 4 m, which reduced groundwater reserves in this area and degraded their quality. As a consequence, due to increased nitrate concentrations in the groundwater, the "Ključ" water source had to be disconnected from Požarevac's water supply system in 2006 [4], while the Trnovče water source (supplying Velika Plana and Smederevska Palanka) operates at a reduced extraction capacity [5].

In terms of basin size (37,966 km²) and length of its course, the Velika Morava is one of our largest rivers. Together with the Južna and Zapadna Morava, it drains just under 50% of Serbia's territory. The maximum discharge of the Velika Morava is 2,350 m³/s, the lowest recorded discharge is 25 m³/s, while the mean annual discharge stands at 257 m³/s [5]. This is a typical lowland river, featuring numerous meanders, oxbow lakes, and abandoned channels. From an agricultural production perspective, the alluvial plain of the Velika Morava represents high-quality soil suitable for cultivating grains, vegetables, industrial crops, and more. This has also influenced population density, though settlements are mostly located along the edges and less frequently on the alluvial plain itself.

On the other hand, river deposits of sand and gravel in the Velika Morava alluvium are among the most important construction materials and carry the character and significance of a natural resource. In addition to illegal gravel and sand extraction from the riverbed itself or its banks, it is a frequent occurrence for agricultural land to be purchased from owners, after which extraction begins on that very plot. The topsoil is mostly sold as high-quality earth, while the deeper layers are excavated for gravel and sand. This extraction has a major negative impact on neighboring agricultural lands, which are also quickly abandoned as extraction progresses, ultimately falling into the hands of those involved in gravel and sand extraction. This results in the permanent devastation of prime agricultural land [5].

Regarding navigability and river traffic, the Velika Morava was navigable along almost its entire length in the 19th century, from its confluence with the Danube to Stalać (the steamboat "Morava" sailed to Ćuprija and Stalać in 1867) [6]. Today, the Velika Morava is not navigable due to the dimensions of the waterway—primarily the depth, which has changed compared to the 19th century. This is the result of intensive erosion along its constituent rivers and main tributaries, primarily the Južna Morava, as well as the deposition of the mobilized material in the downstream sections of the Velika Morava. The aforementioned gravel and sand extraction, which led to the 4 m deepening of the riverbed downstream near the Ljubičevo Bridge, also caused an increase in the hydraulic gradient of the water table. Increased gradients drive more pronounced headward (regressive) erosion in certain upstream sections of the Velika Morava, causing further riverbed deepening upstream. Consequently, the Velika Morava is navigable for naval fleet vessels for only 15 km upstream from its confluence into the Danube River, as established by the Decree on International and Interstate Waterways [7].

2. METHODOLOGY

For the purpose of researching the impact of natural and anthropogenic factors (gravel and sand extraction from the banks and the riverbed itself) on the regime of surface and groundwater, all historical data on the water table elevations of the Velika Morava River at the Ljubičevo Bridge profile were collected, covering the period since monitoring was established (1923). Additionally, data on groundwater levels observed in piezometers placed perpendicular to the Velika Morava riverbed were gathered. Monitoring of the Velika Morava water levels was conducted daily (from 1923 to 1960 using a staff gauge, and from 1960 to the present day using a water level recorder/limnigraph). The groundwater regime is monitored using water level meters every 5 or 10 days. Groundwater monitoring in this section was established in 1977 and 1978. Subsequently, in 1987 and 1988, the existing network of observation facilities (piezometers) was densified, while during 2002, automatic water level loggers were installed for continuous groundwater monitoring. Figures 1 and 2 present comparative diagrams of the absolute water level elevations of the Velika Morava at the Ljubičevo Bridge gauging station and the groundwater level elevations recorded in the accompanying piezometers, covering the observation period from 1977 to 2018 (the period from the inception of groundwater monitoring up to 2018). Figure 1 refers to the right bank, and Figure 2 to the left bank [8].

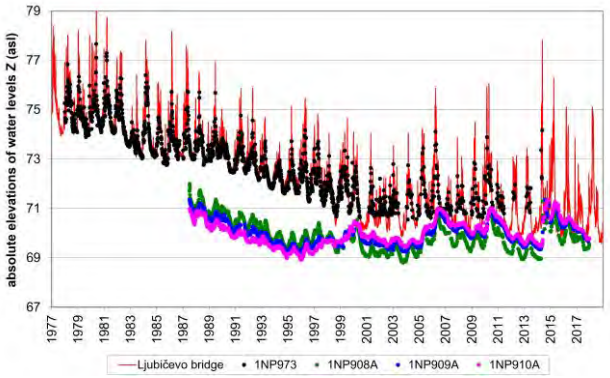

Figure 1. Comparative diagrams of the absolute water level elevations of the Velika Morava at the Ljubičevo Bridge gauging station and the groundwater levels observed in piezometers, observation period from 1977 to 2018 (right bank) [8]

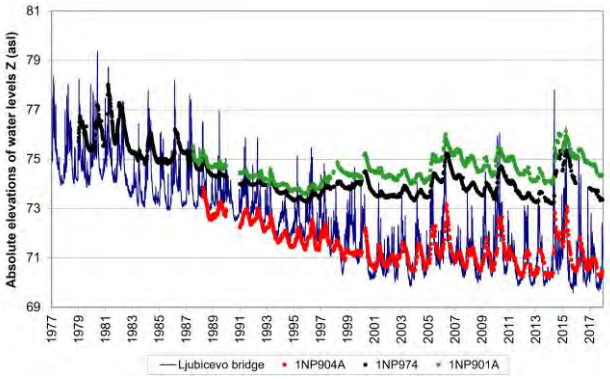

Figure 2. Comparative diagrams of the absolute water level elevations of the Velika Morava at the Ljubičevo Bridge gauging station and the groundwater levels observed in piezometers, observation period from 1977 to 2018 (left bank) [8]

It is clearly visible from diagrams 1 and 2 that the deepening of the Velika Morava riverbed affected both the water table elevations of the Morava and the groundwater levels. What is clearly evident from both Figure 1 and Figure 2 is that in piezometers 1NP973 and 1NP904A, which are located at the shortest distances from the Velika Morava riverbed itself, during the period from 1977 to 2000, the groundwater elevations were generally hypsometrically lower throughout the entire year; meaning that during this period, groundwater recharge occurred at the expense of the Velika Morava waters. After 2000, it is clearly visible that during low water levels, as well as during medium water levels, the groundwater elevations are at a higher elevation than the water levels of the Velika Morava. In other words, a change in the direction of groundwater flow occurred, so during these periods, the river is recharged at the expense of the groundwater.

To determine whether the aforementioned deepening of the riverbed affected the homogeneity of the water level series, homogeneity tests were applied. These tests showed that the examined samples extracted for the considered periods (before the riverbed deepening - the period before 1990, and after - the period after 1990) of the Velika Morava River level elevations observed at the Ljubičevo Bridge profile do not belong to the same population. More precisely, the extracted series are not homogeneous [9].

For the purpose of determining the homogeneity of the total discharge series, Student's t-test was also utilized, in which the criterion for evaluating the mean values is obtained using the following expression [10]:

$$t = \sqrt{\frac{n_1 \cdot n_2 \cdot (n_1 + n_2 - 2)}{n_1 + n_2}} \cdot \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{n_1 \cdot \sigma_{X_1}^2 + n_2 \cdot \sigma_{X_2}^2}} \quad (1)$$

where: n_1 and n_2 are the sample sizes of time series 1 and 2, $\overline{X}_1$ and $\overline{X}_2$ are the mean values of time series 1 and 2, σ_{X_1} and σ_{X_2} are the standard deviations of time series 1 and 2.

The variable t follows a Student's distribution with $n_1 + n_2 - 2$ degrees of freedom. In this regard, the null hypothesis is accepted—meaning the series is homogeneous—if:

$$t_{\frac{\alpha}{2}} < t < t_{1-\frac{\alpha}{2}} \quad (2)$$

where α is the significance level, and in this specific case, a value of $\alpha = 0.05$ was chosen.

Furthermore, the paper places an emphasis on separating direct runoff and baseflow, with the aim of determining whether a change has occurred in any of the components of total runoff.

Baseflow is formed at the expense of groundwater located within the basin. The intensity of groundwater recharge decreases over time depending on the basin characteristics, geological composition of the terrain, and hydrogeological conditions—namely, the types of aquifers. This is of great importance because the terrain's capacity to retain water that has fallen on the basin underground, and subsequently return it to the river course, represents one of the more crucial basin characteristics, which largely defines the runoff regime during dry periods. Rivers whose basins are primarily composed of fractured aquifers or provisionally arid terrains frequently dry up during prolonged dry periods. Therefore, during these periods, the aquifer exhausts all of its dynamic reserves on recharging the surface course. After that, the river channel remains dry because the aquifer runs out of dynamic reserves. Consequently, during low and mostly medium water levels, the water in the riverbed is sustained by groundwater.

Since the observed (total) discharge consists of direct runoff—which is a consequence of precipitation—and baseflow—which is formed through the recharge of the surface course by groundwater—this paper first performed the separation of direct runoff from baseflow. For this purpose, the BFI+ software [11] was applied, utilizing the Local Minimum method [12]. This method identifies days with the lowest flow within a defined time interval—half of the observed period minus one day before and after the analyzed day. If the flow on that day

is the lowest, it is designated as a local minimum and connected to neighboring minima using straight lines. The baseflow between these points is estimated via linear interpolation, thereby connecting the lowest values on the hydrograph into a simplified curve [13].

After calculating the direct runoff and baseflow and applying the homogeneity test to the formed series, the Baseflow Index (BFI) was also calculated. This index represents a quantitative indicator of the share of baseflow in the total river discharge at a specific profile. Essentially, the BFI represents the ratio between the volume of baseflow, V_B and the total volume of discharged water, V_T :

$$BFI = \frac{V_B}{V_{uk}} \tag{3}$$

where:

$$V_T = \overline{Q} \cdot T \tag{4}$$

and where $\overline{Q}$ represents the mean multi-year discharge, while T represents a one-year period expressed in seconds.

Depending on the geological composition of the terrain, namely the capacity of the subsurface to accumulate and release water, the BFI value varies within very wide limits, ranging from 0.15 to 0.90 [10].

3. RESULTS

By applying the aforementioned methodology, baseflow and direct runoff were calculated. Figures 3 and 4 present the hydrographs of total and baseflow runoff, specifically in Figure 3 for the first 10 years of the calculated series (1948–1957) and in Figure 4 for the last 10 years of the observation series (2009–2018). The hydrograph characterizing the entire observation period is not shown in the figure due to the length of the considered timeframe.

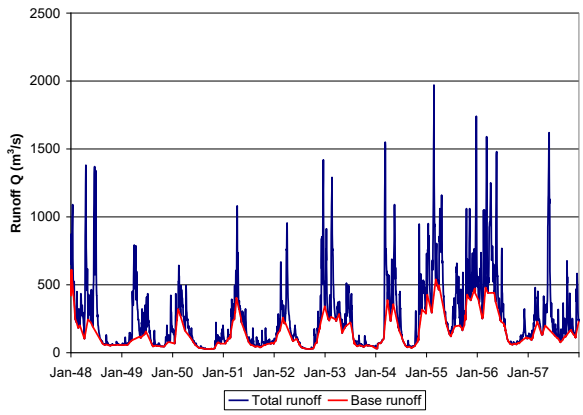

Figure 3. Hydrograph of total and baseflow runoff of the Velika Morava, Ljubičevo Bridge gauging station, period 1948–1957

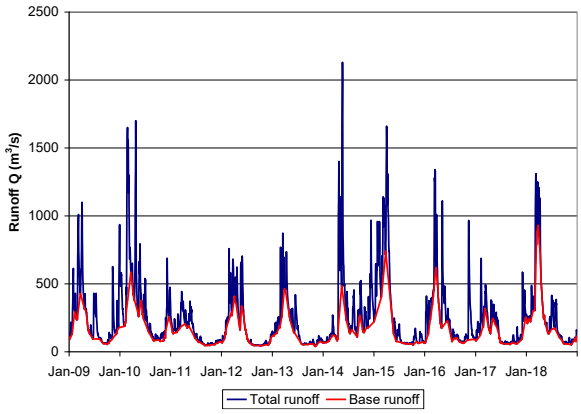

Figure 4. Hydrograph of total and baseflow (runoff) of the Velika Morava, Ljubičevo Bridge gauging station, period 2009–2018

After calculating the baseflow and direct runoff, and with the aim of applying the homogeneity test to the obtained series (total, direct, and baseflow runoff), Table 1 presents the statistics (mean value and standard deviation) for the separated periods (the first period 1948–1989 and the second period 1990–2018). Table 2 presents the calculated statistics as well as the conditions for accepting the null hypothesis.

Table 1. Mean values and standard deviations of total, direct, and baseflow runoff (m³/s)

	Q_t		Q_b		Q_d	
	I period	II period	I period	II period	I period	II period
Q_{av}	244.7	221.1	158.4	153.8	86.28	67.32
σ	70.511	72.813	43.056	45.940	35.738	32.186

Table 2. Calculated t-statistics and conditions for accepting the null hypothesis, i.e., the hypothesis that the series are homogeneous

	t	$t_{\alpha/2}$	$t_{1-\alpha/2}$	homogeneity
Q_t	1.346	-2.00	2.00	yes
Q_b	0.425	-2.00	2.00	yes
Q_d	2.254	-2.00	2.00	no

Based on the obtained values and t-statistics, it can be concluded that the 4 m deepening of the Velika Morava riverbed did not have a statistically significant impact on the change in total and baseflow runoff, while a certain change appeared in the direct runoff. In addition to the anthropogenic impact, climate change—specifically the increasing frequency of intense precipitation or its absence—certainly had a certain influence on such a result.

Furthermore, based on the obtained baseflow values, the base flow index (BFI) was calculated using equation (3). Figure 5 presents the diagram of the BFI change over time. The same diagram also displays the trend line, as well as the mean BFI values for the period before 1990 and after 1990.

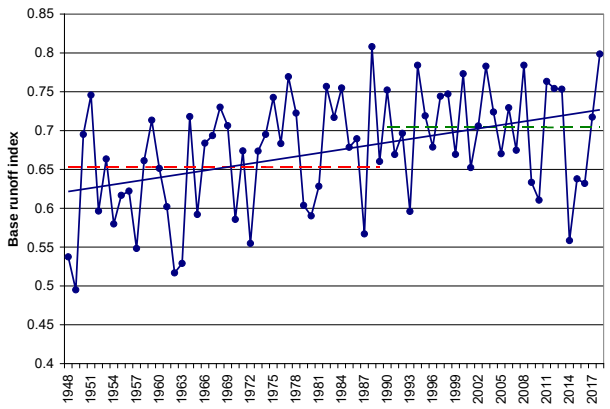

Figure 5. Diagram of the base flow (runoff) index change in the period from 1948 to 2018, featuring the trend line and multi-year mean values calculated for the separated periods (before and after 1990)

4. DISCUSION WITH CONCLUSION

Based on Diagram 5, it can be concluded that, on average, the base flow index values in the period from 1948 to 1989 are 0.05 lower than those characteristic of the period from 1990 to 2018. The BFI trend is positive, and its multi-year mean value for the period before 1990 is 0.653, while for the period from 1990 to 2018, it stands at 0.704. The lowest BFI values are associated with exceptionally rainy years, when direct runoff, formed as a result of intense precipitation, plays a more significant role in the Velika Morava riverbed. In contrast to rainy years, the BFI reaches its highest values during dry periods. In the first period, the absolute minimum BFI was calculated for the year 1949, amounting to 0.495, while the absolute maximum was recorded in 1988, reaching 0.808. During the period after 1990, an absolute minimum BFI of 0.558 was obtained for 2014—the year when record-breaking May rainfall caused by Cyclone Tamara led to severe flooding in western and central Serbia. The absolute maximum (BFI = 0.798) was recorded in 2018.

Based on the presented data, it can be concluded that there has been an increase in the proportion of groundwater forming the total runoff of the Velika Morava. This is certainly partly a consequence of the change in the direction of groundwater flow during low and medium water periods; meaning that for most of the year now, the first aquifer discharges to recharge the Morava River. The surface watercourse recharges the aquifer only during high water periods.

The lowering of the Morava River level due to the deepening of its riverbed (as previously discussed) consequently led to a drop in the groundwater levels of the first aquifer formed within the river's alluvium. Together with the change in the direction of groundwater flow—namely, the depletion of groundwater reserves to recharge the Morava River—these factors have driven the significant reduction in groundwater reserves currently observed. According to some calculations, based on an average groundwater level decline of about 1.5 m in the alluvial plain area of the Velika Morava (within the section belonging to the sheet of the Basic Hydrogeological Map of Požarevac, 1:100,000, and relative to the 1975–1985 period), the calculated volume of "lost" groundwater amounts to approximately 150.5 x 10^6 m³ (16.5%), out of the total estimated permanent reserves of 756 x 10^6 m³ of water [14]. As a result of diminished groundwater reserves, their quality degraded. Specifically, due to the use of artificial and natural fertilizers (manure), combined with the reduced groundwater reserves, nitrate concentrations exceeded the maximum allowable limit of 50 mg/dm³ after the 1990s. For this reason, for example, the "Ključ" water source, whose waters are used for the water supply of Požarevac, was taken out of service in 2006. The problem in this area was resolved by constructing infiltration basins, which helped lower the concentration of nitrate ions in the water source zone. Thus, in addition to reducing groundwater quantities, the deepening of the Velika Morava riverbed near the Ljubičevo Bridge consequently impacted the quality of these waters as well.

In addition to the aforementioned issues, there is also the problem of intense riverbed clogging (clogging/clogging of the riverbed) in certain sections, caused by an increased content of suspended material resulting from sand and gravel extraction. The result of riverbed clogging is a lowering of the water level in the alluvial aquifer due to a reduction in the contact area between the aquifer and the riverbed. This directly results in a decrease in the volume of water that infiltrates into the subsurface to be used for public water supply. The ultimate outcome is, once again, reduced groundwater reserves in this area.

Because of this, in the area of the "Trnovče" regional water source, whose waters are used for the water supply of Velika Plana and Smederevska Palanka, highly yield-abundant groundwater localities are not located in the immediate vicinity of the riverbed, but rather in the zone of a fossil river channel (meander) that has remained in direct hydraulic connection with the Velika Morava River. Thus, at a distance of about 100 m from the riverbank, vertical water intakes can capture maximum groundwater quantities of only Q = 3–6 l/s, whereas moving deeper toward the hinterland, wells of the same type can yield quantities of Q = 10–25 l/s [15].

The lowering of groundwater levels has caused many shallow dug wells, whose waters were used for irrigating agricultural crops, to run dry during arid periods (when irrigation is most necessary). Consequently, problems with irrigating agricultural areas have also emerged.

Another highly critical impact is on the navigability of the river itself. The natural course of the Morava River in its lower section is meandering in character; therefore, the riverbed shifts through natural processes, which in this area are now also driven by the extraction of construction materials from the banks and the riverbed itself. This extraction affects the displacement of the thalweg (the main current line), which, for example, can shift from the central section toward one of the banks where extraction is taking place, thereby accelerating bank erosion. In this manner, riverbanks collapse, the river meanders more intensely, and the bed depth changes frequently, which greatly complicates the establishment of navigability on

the Velika Morava.

However, by expanding its waterways, the Republic of Serbia could potentially realize major economic benefits, primarily by increasing the transport corridor of the cheapest and most environmentally sustainable mode of transport within its territory. Integrating the Velika Morava into the system of navigable rivers in the Republic of Serbia would certainly be a massive undertaking. Furthermore, it would be of immeasurable importance from the perspective of national defense, both regarding military threats and in the event of natural disasters. Expanding the waterway network would provide River Flotilla (RF) units with an increased scope for operational deployment, while a potential enemy advance would be hindered. From a national defense standpoint, a dense network of waterways and canals intersecting flat, easily accessible terrains impedes the operational advancement of enemy forces.

We must remain cognizant of these facts in order to change the irresponsible attitude toward water resources, and to reduce gravel extraction within the riparian zone and bed of the Velika Morava River to a reasonable level—one that will not negatively impact the development of existing water sources, all with the ultimate goal of improving public water supply in the future.

Abstract: *The paper presents the comparative analysis of projectile velocity measurement results obtained using different types of measuring equipment in ballistic testing. The considered velocity measurement systems include infrared barriers and various types of radar systems, with the aim of assessing their applicability, accuracy, reliability, and limitations under different test conditions. In addition to the comparative analysis of experimentally obtained results, the paper also provides an overview of different types of measuring equipment, their structural design, operating principles, and basic technical characteristics relevant to their application in ballistic testing. The tests were carried out using a ballistic barrel receiver, a test barrel, and accompanying measuring equipment, for several different calibers within the category of small-arms ammunition. The comparison of the measured projectile velocity values obtained by different measuring systems was performed, together with the analysis of the influence of the type of measuring equipment, measuring position, test configuration, and test conditions on the obtained results. Particular attention was given to the analysis of the estimation of measurement uncertainty in order to evaluate the validity and repeatability of the obtained data. Based on the obtained results, the assessment of the applicability of different measuring systems in ballistic testing of small arms was given.*

Keywords: *Projectile Velocity, Ballistic Testing, Measuring Equipment, Ammunition.*

1. INTRODUCTION

In the field of ballistics, measuring projectile velocity is one of the most important tasks. Projectile velocity directly determines kinetic energy, stability, and terminal effectiveness. Without precise velocity data, it is impossible to develop modern weapons, control the quality of gunpowder and ammunition, or test the resistance of ballistic protective equipment.

In the past, mechanical and electrical methods, such as the ballistic pendulum or wire grids, were used to measure projectile velocity. With older systems, the projectile had to physically hit the pendulum or cut wires at a precisely defined distance to calculate the projectile's velocity. The procedure was complicated to set up, required constant replacement of destroyed wires, and often yielded inaccurate results. Today, technology has completely changed this process and shifted to non-contact measurement. Modern devices allow the projectile to pass through the measurement point without any physical contact, while electronic measurement stations instantaneously read data on the screen with extremely high precision [5, 6, 8, 9].

In this study, two such modern but technologically completely different measuring systems were used: a ballistic chronograph based on infrared barriers *Top Trend V2.205* (Figure 1), and a portable Doppler radar *Garmin Xero C1 Pro* (Figure 2). The ballistic chronograph based on IR barriers (hereinafter referred to as the optical chronograph) operates on an optical principle – it measures the time required for a projectile to pass between two invisible IR light beams [3, 6, 9]. On the other hand, the Garmin (hereinafter referred to as the radar chronograph) utilizes radar technology, where the device emits radio waves that bounce off the flying

DOI: 10.5937/OTEH26155A

projectile, thereby continuously tracking its velocity.

To compare the performance of the aforementioned measuring systems, three calibers were selected for this research, covering a wide range of applications.

Figure 1 Ballistic chronograph based on infrared barriers, Top Trend V2.205 (optical chronograph)

Figure 2 Garmin Xero C1 Pro

The calibers used during the ballistic testing are as follows:

- 9 mm Luger (Figure 3a)
- 7.62x39 mm (Figure 3b)
- .308 Winchester (7.62x51 mm) (Figure 3c)

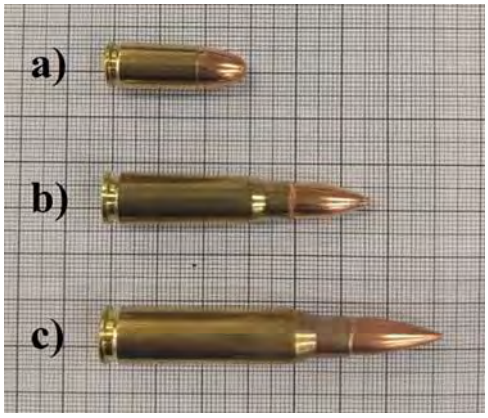

Figure 3 Ammunition: a) 9 mm Luger; b) 7.62x39 mm; c) .308 Winchester (7.62x51 mm)

Figure 4 shows the test barrels used for the testing.

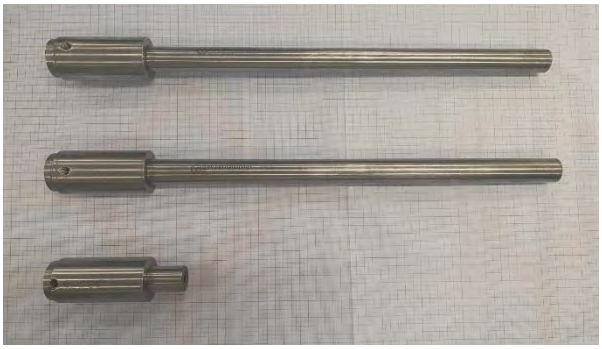

Figure 4 Test barrels (in order): 7.62x39 mm; .308 Winchester; 9 mm Luger

This study aims to perform a comparative analysis of the measuring systems through experimental testing. Through statistical processing of the measured velocity values for the specified three calibers, the paper aims to determine the level of measurement uncertainty for both systems, identify their operational advantages and limitations, and provide recommendations for their optimal application in research, development, and testing ballistic processes.

2. EXPERIMENTAL PERFORMANCE TESTING

This chapter details the method of executing the test, the spatial layout of the measuring components in the ballistic tunnel, as well as the basic physical principles on which the operation of the applied measuring systems is based.

For the purpose of measuring the muzzle projectile velocities of the selected calibers (9 mm Luger, 7.62x39 mm and .308 Winchester), specialized ballistic barrels were used. These barrels were manufactured, mounted, and calibrated in strict accordance with the international C.I.P. standard (*Commission internationale permanente pour l'épreuve des armes à feu portatives*). According to the C.I.P. standard, projectile velocity is measured at a distance of 2.5 m from the muzzle, with the chronograph positioned to determine the projectile velocity at that reference distance [1].

The use of standardized barrels in ballistic testing is crucial because they eliminate the influence of mechanical tolerances, wear and gas losses characteristic of service weapons. This ensures controlled, maximally repeatable initial conditions and allows the generated pressures and projectile velocities to be solely a function of the propellant charge characteristics and the geometry of the cartridge itself.

Ammunition conditioning was also performed in a temperature control chamber to prevent external environmental factors from negatively affecting the test. The temperature inside the chamber was 21°C, while the air humidity was 65%. The ammunition was stored in the chamber for 24 hours prior to the test itself. Table 1 shows the characteristics of the tested ammunition.

Table 1 Characteristics of the ammunition used for testing

Caliber	Projectile type	Bullet mass (gr)	Projectile mass (g)	Nominal muzzle velocity (m/s)
9 mm Luger	FMJ	124	8,00	~340
7,62x39	FMJ	123	8,00	~715
.308 Win	FMJ BT	145	9,40	~850

Before starting the test, the measuring devices were placed in specific positions to ensure simultaneous recording of the velocity of the same projectile during a single firing. Figure 5 shows the spatial configuration of the measuring systems, with the optical chronograph positioned on the right side, while the radar chronograph is positioned on the left side. They are located at a distance of 2.5 m ± 5 cm from the muzzle.

Figure 5 Spatial configuration of measuring systems: infrared barrier (right) and Garmin Xero C1 Pro (left)

The applied measuring devices represent two fundamentally different technological solutions in the field of experimental kinematics. The optical chronograph (Figure 1) functions as a passive-active optoelectronic discrete system for measuring passage time. Its operation is based on forming a continuous light curtain in the infrared spectrum within a rigid metal frame. When an opaque body (projectile) cuts through the first light plane, an instantaneous change in light intensity occurs at the photodetectors, which electronically activates a high-resolution time counter (timer). Passage through the second light plane, located on a factory-calibrated measuring base, generates a second pulse that stops the counting. The projectile velocity is subsequently interpreted as the average velocity over that fixed distance [3, 6, 9]. Table 2 provides the technical specifications of the optical chronograph.

Table 2 Technical specifications of ballistic chronograph based on infrared barriers, *Top Trend V2.205[3]*

Effective measuring area	1000x1000 mm
Caliber	4 – 40 mm
Velocity measurement range	30 – 3000 m/s
Fixed mesurement base	2000 mm
Measurement error	±0,1%
Spectral range	790 – 1050 mm (IC – A)
Detection maximum	940 nm
Output signal: square wave pulse	≤5V DC
Operating range	-10°C do +50°C
Power supply	230 V AC, 50 – 60 Hz
Weight	35 kg

The radar chronograph (Figure 2) functions as an active continuous-wave high-frequency radar system. The device continuously emits electromagnetic waves of a defined frequency in the direction of the projectile's movement. When the emitted wave encounters a projectile in flight, it reflects and returns to the device's receiving antenna. Given that the projectile moves at a velocity significant relative to the wave propagation velocity, the frequency of the reflected signal shifts proportionally to the body's velocity (Doppler shift). The system performs real-time frequency analysis (FFT) of the received signal, transforming the measured frequency shift directly into the instantaneous velocity of the projectile [2, 5, 8]. Table 3 provides the technical specifications of this measuring system.

Table 3 Technical specifications of the Garmin Xero C1 Pro [2]

Measuring range	30 do 1600 m/s
Dimension	77 x 60,5 x 34,44 mm
Weight	105,6 g
Water rating	IPX7
Display type	Sunlight-visible, monochrome
Display size	133 x 44 mm, diagonal 55 mm
Battery type	Internal rechargeable lithium-ion battery; non replaceable

Battery life	Up to 2000 shots or up to 6 hours
Operating range	-10°C to +55°C (14°F to 131°F)
Memory/history	50 sessions at max 100 shots per round before a Xero Core app sync is required to save data to phone
Interface	USB-C

3. RESULTS AND DISCUSSION

After setting up the measurement configuration, testing was conducted for each caliber individually. For each caliber, 20 shots were fired in a single group, during which the results provided by the optical chronograph were read alongside the muzzle velocity value measured by the radar chronograph. The tables presented below, in addition to the muzzle velocity values of each individual projectile, contain the average measured velocity value, maximum velocity, minimum velocity, spread of values (extreme spread) and standard deviation.

The first test was conducted for the 9 mm Luger caliber, and the obtained values read from the measuring systems are compared in Table 4.

Table 4 Muzzle velocity of the 9 mm Luger projectile measured by two different measuring systems

9 mm Luger		
No.	Optical chronograph	Radar chronograph
1.	387,60	388,40
2.	391,54	392,80
3.	381,97	380,40
4.	388,73	386,10
5.	384,76	383,00
6.	384,17	384,20
7.	386,03	386,60
8.	387,22	387,90
9.	383,29	384,60
10.	375,38	377,00
11.	377,71	376,00
12.	387,37	387,90
13.	381,61	380,40
14.	389,11	390,30
15.	380,01	381,00
16.	381,90	379,20
17.	381,61	382,60
18.	388,50	390,70
19.	385,73	387,80
20.	373,13	373,80
Avg.val.	383,87	384,04
Max:	391,54	392,80
Min:	373,13	373,80
Spread:	18,41	19,00
St. dev.	4,79	5,21

Based on the 20 performed measurements, it was determined that the average measured velocity for the optical chronograph is 383.87 m/s, while for the radar chronograph it is 384.03 m/s. The difference between the average values is only 0.16 m/s, indicating very good agreement between the results.

The spread of measured values for the optical chronograph is 18.41 m/s, and for the radar chronograph it is 19 m/s, which shows that both devices record almost identical velocity variations. The standard deviation for the optical chronograph is 4.79 m/s, while for the radar it is 5.21 m/s, implying low dispersion of results and good measurement repeatability for both systems.

The obtained results show that the radar chronograph yields almost identical results to those provided by the optical chronograph. The small difference in average values, as well as the similar values for spread and standard deviation, indicate that the radar chronograph provides reliable and stable measurements of the muzzle velocity for the 9 mm Luger projectile.

Following the 9 mm Luger caliber, the muzzle velocity measurement was performed for the 7.62x39 mm caliber. Table 5 presents the measurement results.

Table 5 Muzzle velocity of the 7.62x39 mm projectile measured by two different measuring systems

Min:	725,16	725,40
Spread:	20,55	20,70
St. dev.	4,04	4,20

Based on the 20 performed measurements, it was determined that the average measured velocity for the optical chronograph is 737.23 m/s, while for the radar it is 737.60 m/s. The difference between the average values is

only 0.38 m/s, indicating very good agreement between the results obtained by both measuring systems.

The spread of measured values for the optical chronograph is 20.55 m/s, and for the radar it is 20.70 m/s, which shows that both devices record almost identical velocity variations. The standard deviation for the optical chronograph is 4.04 m/s, while for the radar chronograph it is 4.20 m/s, implying low dispersion of results and good measurement repeatability for both systems.

The obtained results show that the radar chronograph yields almost identical results to those provided by the optical chronograph. The small difference in average values, as well as the similar values for spread and standard deviation, indicate that the radar chronograph provides reliable and stable measurements of the muzzle velocity for the 7.62x39 mm projectile.

The next measurement was performed for the .308 Winchester (7.62x51 mm) caliber.

19.	849,98	850,10
20.	857,63	855,70
Avg.val.	858,13	857,83
Max:	868,43	871,80
Min:	847,10	838,70
Spread:	21,33	33,10
St. dev.	6,15	7,65

Based on the 20 performed measurements, it was determined that the average measured velocity for the optical chronograph is 858.13 m/s, while for the radar chronograph it is 857.83 m/s. The difference between the average values is only 0.30 m/s, indicating very good agreement between the results obtained by applying both measuring systems.

The spread of measured values for the optical chronograph is 21.33 m/s, while for the radar chronograph it is 33.10 m/s. The standard deviation for the optical chronograph is 6.15 m/s, and for the radar it is 7.65 m/s, indicating less dispersion of results and slightly better measurement repeatability for the optical chronograph compared to the radar chronograph during this test.
Although a slightly larger spread of measured values and a larger standard deviation were recorded for the radar chronograph, the average values obtained by both devices are practically identical. Based on the obtained results, it can be concluded that the radar chronograph provides reliable and stable measurements of the muzzle velocity for the 7.62x51 mm projectile, with the results agreeing very well with those obtained using the optical chronograph.

4. RESULTS ANALYSIS

Following the testing and the obtained data, it is necessary to analyze the results, which is done in this chapter. An analysis of the results obtained from the measurements of the optical chronograph and the radar chronograph was conducted. The aim of the analysis is to compare the results obtained with the two measuring systems, evaluate their mutual agreement, and examine the repeatability and reliability of the measurements. The analysis is based on a comparison of average velocity values, spreads of measured values, standard deviations, percentage deviations, and measurement uncertainty for all three tested ammunition calibers.

4.1 Analysis of average values

Figure 5 shows a comparative diagram of the average velocity values for all three calibers (both measurement systems).

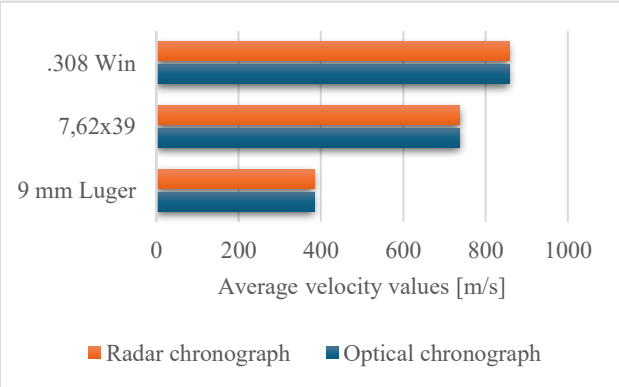

Figure 5 Comparative presentation of the obtained average velocity values using different measuring systems for three different calibers

The diagram clearly shows that the average velocity values of both measuring systems are almost identical, indicating consistency between the two systems.

4.2 Analysis of measurement repeatability

Figure 6 shows the comparative values of the standard deviation obtained by measuring with both systems for three different calibers.

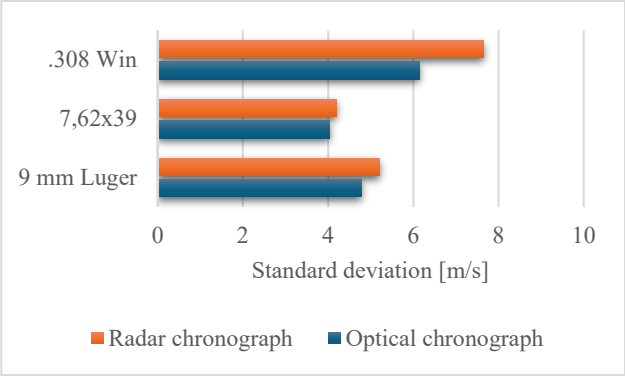

Figure 6 Comparative presentation of the obtained standard deviations

A smaller standard deviation value indicates higher measurement repeatability. For all three calibers, it was observed that the standard deviation obtained by measuring with the optical chronograph is smaller. The minimal difference between the two systems is noticed for the 7.62x39 caliber, while the largest difference between the standard deviation values was obtained during the testing of the .308 Winchester caliber.

4.3 Percentage deviation

To show the percentage deviation, the following formula was used:

$$\delta = \frac{\left|V_{avr(optical)} - V_{avr(radar)}\right|}{V_{avr(radar)}} * 100\%$$

Based on the tables from Chapter 3, the following percentage deviations were obtained:

- 9 mm Luger: 0.04%
- 7.62x39 mm: 0.05%
- .308 Winchester: 0.04%

The percentage deviations for all three calibers are approximately equal, indicating very small deviations between the measurement results.

4.4 Measurement uncertainty

Measurement uncertainty is calculated based on the obtained standard deviation[4, 7]. First, it is necessary to calculate the standard uncertainty:

$$u = \frac{Standard\ deviation\ value}{\sqrt{n}}$$

where *n* represents the total number of shots.

After calculating the standard uncertainty, the expanded uncertainty is calculated as follows:

$$U = 2u$$

Based on the aforementioned relations, the obtained results for the expanded measurement uncertainty are presented in the diagram in Figure 7.

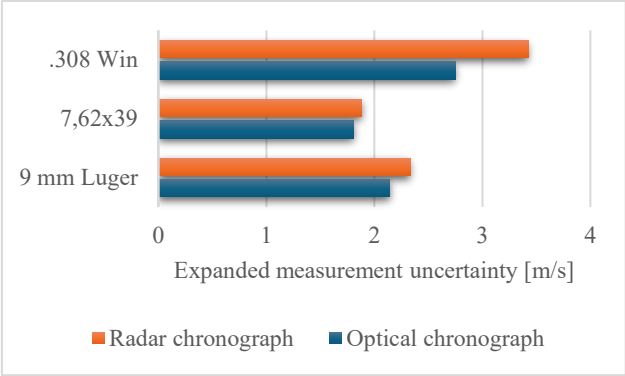

Figure 7 Comparative presentation of expanded measurement uncertainty

4.5 General analysis

Based on all performed measurements, it can be concluded that the optical and radar chronographs provide reliable, stable, and repeatable measurements of muzzle projectile velocity. The analysis of average values, spread, standard deviation, expanded measurement uncertainty, and percentage deviation showed a high degree of consistency between the results obtained by applying both ballistic chronographs for all three tested calibers. The observed differences are small and within the expected measurement uncertainty, indicating that the radar chronograph can be successfully used as an alternative to the optical chronograph for measuring muzzle projectile velocity [5, 8].

CONCLUSION

The aim of this study was to test the measuring systems to see if approximate results are obtained using two different systems. Tests were performed for three different ammunition calibers: 9 mm Luger, 7.62x39 mm, and .308 Winchester, with 20 individual measurements realized for each caliber.

An analysis of the obtained results determined that the average values of the measured velocities are very similar for both measuring systems. Also, the analysis of spread, standard deviation, expanded measurement uncertainty, and percentage deviation showed that the differences between the results are small and within the expected measurement uncertainty. The percentage deviations for all three calibers amounted to approximately 0.04-0.05%, indicating a high degree of agreement between the results.

The calculated values of spread, standard deviation, and measurement uncertainty show that both measuring systems have good measurement repeatability. The obtained results confirm that the optical and radar chronographs can be successfully used to measure initial projectile velocity in laboratory and testing conditions.

The results of this work represent a basis for further research, which may include a larger number of different ammunition types, testing under different environmental conditions, and the analysis of additional factors affecting measurement accuracy. Such research would enable an

even more complete evaluation of the measurement characteristics of the optical chronograph as well as the radar chronograph and their application in ballistic testing.

Based on all conducted tests, it can be concluded that the optical and radar chronographs represent reliable and practical solutions for measuring muzzle projectile velocity, and the obtained results confirm that their application can satisfy the requirements of experimental ballistic testing.

Abstract: *Special vehicles frequently encounter numerous challenges to achive and maintain adequate thermal comfort in the passenger compartmen, such as high external temperatures and sun radiation, significant heat generation from onboard equipment and engine, limited space, problems with disposition of supply and exhaust vents, etc. In this paper, a CFD-based numerical simulation of airflow and thermal processes in the passenger compartment of a special vehicle is presented. A three-dimensional model of the enclosed space is developed, which includes internal heat sources from occupants and onboard equipment, as well as external thermal loads introduced via appropriately calculated heat flux boundary conditions. Thermal conditions within enclosed compartments of vehicles for special purpose are governed by complex interactions between airflow, heat transfer and surface radiation. Approach based on CFD can offer detailed insights into airflow dynamics and temperature distribution, which helps address varying thermal comfort levels in enclosed spaces (evaluated using the Predicted Mean Vote (PMV) and Predicted Percentage of Dissatisfied (PPD) indices). Numerical model presented in the paper is validated against experimental data of PPD and PMV values and average cabin temperature. The temperature and velocity distributions obtained through CFD simulation demonstrate the capability of this method to serve as a valuable tool for evaluating thermal comfort, as it enables detailed analysis at any surface, plane or point of interest within the domain. From the other side, CFD introduces the challenge of determining whether a simplified model can simultaneously ensure computational efficiency with reliable predictive capability for the specific HVAC systems in special purpose vehicle, on which some conclusions are given.*

Keywords: *thermal comfort, PMV, PPD, vehicle HVAC system, CFD.*

1. INTRODUCTION

In special-purpose vehicles (such as military, emergency response, security vehicles, etc.) maintaining appropriate thermal conditions presents significantly greater challenges than in conventional passenger cars. These vehicles frequently operate under severe environmental conditions combined with geometric parameters, such as: compact cabin layouts and enhanced structural protection that adds load by means of heat accumulation of the structure (higher thermal mass). Furthermore, high internal heat loads can be generated by electronic equipment along with prolonged mission durations. Occupants frequently wear protective clothing and equipment, which influences heat exchange between the human body and the surrounding environment.

In the commercial automotive sector, the quality of the climate control system is often regarded as an important factor influencing customer satisfaction and vehicle competitiveness. Consequently, considerable effort is devoted to analyzing, optimizing, sizing and validating HVAC systems to achieve high levels of thermal comfort and energy efficiency. The situation is relatively different for special and military vehicles in which operational capability, reliability and crew protection are primary, rather than thermal comfort [1]. As a result, air-conditioning systems have traditionally received less attention during the initial design stages and are frequently incorporated using empirical practices or simplified design procedures. Considering military and urgent systems, already stressful service is enhanced by working in hot environment.

The distribution of temperature, airflow velocity and pressure within an enclosed vehicle compartment is governed by complex fluid flow and heat transfer phenomena. Because of the nature of this interacting mechanisms, predicting the thermal performance of a passenger compartment only through experimental testing

Corresponding author: M. Ivanović;

DOI: 10.5937/OTEH26156I

is often time-consuming, expensive and limited to a relatively small number of operating conditions. Under these conditions, conventional methods for HVAC sizing and control are no longer sufficient.

The application of CFD (Computational Fluid Dynamics) analysis in the initial stage of design and afterwards for the evaluation of system work, enables engineers to evaluate multiple design configurations without extensive and expensive experimental testing. Numerical simulations enable investigation of the air temperature influence of supply air diffuser location, airflow, ventilation, radiation and cabin geometry on the resulting thermal and flow field. Additionaly, CFD simulation facilitates the identification of recirculation zones, dead-air regions and temperature non-uniformities that may reduce occupant comfort or impair equipment reliability. Such analyses support engineering decisions during the development and optimization of vehicle HVAC system.

The objective of this paper is to perform a CFD-based numerical simulation of the thermal processes and airflow within the passenger compartment of a special-purpose vehicle, with the aim of validating a simplified geometric and numerical model against experimental data of PMV and PPD value and average cabin temperature. This approach naturally raises the question of the extent to which such a model can be both computationally efficient, cost-effective and accurate.

The investigation focuses on predicting the three-dimensional distributions of air velocity and temperature under representative operating conditions.

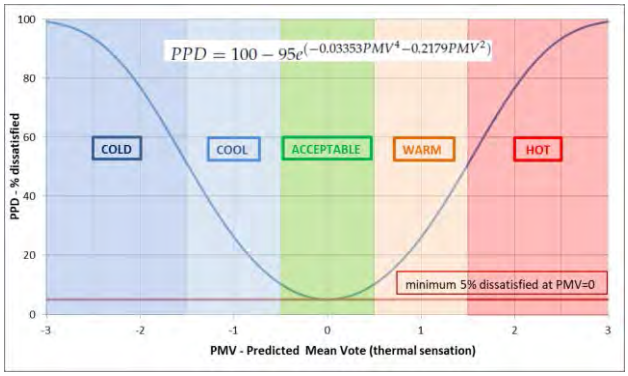
1.1. PPD/PMV indices and standards

Predicted Percentage of Dissatisfied (PPD) is a comfort index that quantifies the expected proportion of occupants dissatisfied with their thermal environment. It is derived directly from the Predicted Mean Vote (PMV) index, which expresses the average thermal sensation of a group on a seven-point thermal sensation scale. This indices are standardized in ISO 7730 standard (Serbian SRPS EN ISO 7730:2008: Ergonomics of the thermal environment - Analytical determination and interpretation of thermal comfort using calculation of the PMV and PPD indices and local thermal comfort criteria. Along with this standard, ANSI/ASHRAE Standard 55: Thermal Environmental Conditions for Human Occupancy, also rely on PMV/PPD model. ASHRAE 55 defines the acceptable comfort zone as a PMV between -0.5 and +0.5 (meaning ≥ 80% of occupants are satisfied), while ISO 7730 splits this into strict categories (A, B, C) where Class B roughly mirrors ASHRAE's requirements. ISO 7730 also includes local discomfort criteria (radiant asymmetry, draft, floor temperature, thermal stratification).

Air speed has a large effect in warm conditions and is explicitly addressed in provisions of ASHRAE 55 standard. Understanding how these parameters interact helps designers create HVAC systems that achieve occupant satisfaction along with energy efficiency. ASHRAE Standard 55 features a highly adopted Adaptive Comfort Model, which sets dynamic indoor temperature targets based on outdoor climates, while ISO 7730 uses a more rigid approach based on the original Fanger PMV formulas.

The curve from Figure 1 shows PMV/PPD functional dependency with highlight that even under ideal thermal conditions (PMV = 0), at least 5% of people remain dissatisfied which is reflection of individual variation in comfort perception. That is why the PPD index ranges from 5% to 100%, with lower values representing higher comfort levels.

Figure 1. PPD — PMV diagram



The variables of importance to evaluate this indices are the function of design and environmental factors throughout a space:

- temperature (uneven thermal distribution increases discomfort),
- air velocity (low or high velocities can lead to stagnation spots or higher local cooling),
- occupant activity and clothing (metabolic rates (met) and clothing insulation (clo) affect PMV and PPD results),
- humidity (direct impact on evaporative cooling and related effects of perceived temperature),
- asymmetry in radiation (localized discomfort with warm and cold surfaces present).

1.2. Vehicle heat load

Sources of the heat that represent vehicle heat load are ambient and radiation load, engine load, metabolic load and exhaust. Loads can be separated based on the placement into two main groups: outer and internal gains. Outer heat gains are:

- direct Sun radiation,
- diffuse radiation (Sun atmospheric scattering),
- conduction load (ambient),
- ground reflected,
- exhaust heat of the vehicle (rejected by the engine and transferred in the vicinity of the cabin).

Internal heat gains are:

- engine heat (rejected by the engine and transferred into the cabin),
- metabolic heat of the occupants,
- onboard electronic equipment radiation.

3. NUMERICAL MODEL

The researched vehicle has an armored, air-conditioned

cabin and it allows the combat team to operate continuously in a hermetically sealed area protected from NBI (Nuclear-Biological-Chemical) threats. HVAC system completely works in air recirculation mode. Geometry of the simplified cabin model is given in Figure 2.

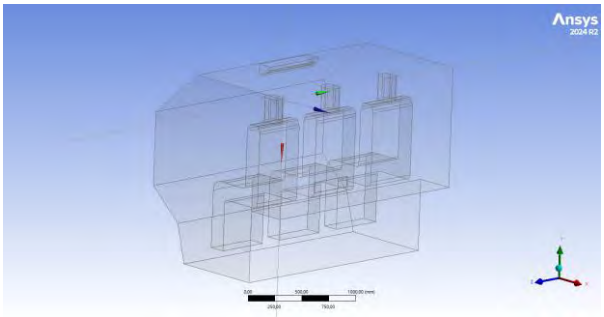


Figure 2. Geometry of the cabin model with occupants

Air circulation in air conditioning mode is carried out through the air distribution system located under the cabin roof and air distribution elements in the front, while exhaust is at the back side of the cabin, which is depicted in Figure 2.

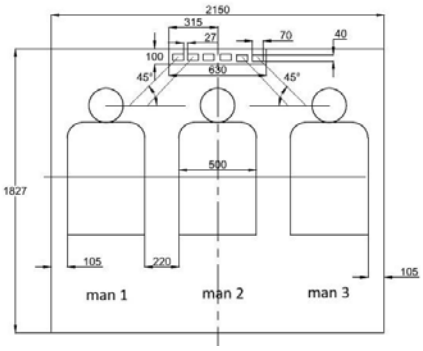

Figure 3. Disposition of supply vents and occupants

Since the simulation of special vehicle that accounts for all potential heat sources is computationally expensive, and moreover, there will be a lot of uncertanty in the final results due to the nature of multiple heat sources, the simplified model has been applied. That model accounts heat gains from the outside (radiation and convection) and electrical equipment radiation, as well as metabolic heat gains, all represented via total heat flux on the particular surfaces (W/m^2).

3.1. Boundary conditions

Experimental condition for air flow is 480 m^3/h, which calculated for the inlet geometry gives v=7,93 m/s. There are six section of the inlet, divided by two for every occupant. The mark of the occupant from the Figure 3 corresponds to the mark of the inlet section. In order to get airflow on every passenger, velocity inlet boundary conditions (BC) are given as components in *x-y-z* direction (Table 2). Turbulence intensity of 5%, and a turbulent-to-laminar viscosity ratio of 10 were set within inlet BC. Inlet temperature is set to 14°C to all sections. Pressure outlet BC was applied at the exit of computational domain. Under this formulation, all flow variables are assumed invariant along the outlet direction, with the exception of the velocity gradient normal to the exhaust plane, while the static pressure at the outlet is set equal to atmospheric pressure.

Table 1. Velocity inlet boundary condition

i	v_x	v_y	v_z
1	$v \cdot \sin(45^\circ) \cdot \cos(45^\circ)$	$-v \cdot \cos(45^\circ)$	$v \cdot \sin(45^\circ) \cdot \sin(45^\circ)$
2	$v \cdot \sin(45^\circ)$	$-v \cdot \cos(45^\circ)$	0
3	$v \cdot \sin(45^\circ) \cdot \cos(45^\circ)$	$-v \cdot \cos(45^\circ)$	$-v \cdot \sin(45^\circ) \cdot \sin(45^\circ)$

Heat flux boundary conditions applied to the vehicle cabin surfaces (except windshield) were determined using the sol-air temperature method (simplifying heat gain calculations by combining ambient air temperature, solar radiation and thermal radiation into a single equivalent outdoor temperature) for all surfaces except windshield. This condition is combined with one-dimensional steady-state conduction through the composite armored and insulatied wall. The daily solar insolation for is Belgrade in July is 6.4 kWh/m²/day (Global horizontal) [2], which converted to peak current flux gives 657 W/m². Considering more conservative approach of "clear-sky" peak values, which other autors used (930 W/m² in [3], 875 W/m² in [4], and 1120 W/m² in [5]), we decided to use I_{solar} = 900 W/m². The absorbed solar flux was calculated using a paint solar absorptivity of α = 0.85, derived from the absorbed-to-incident irradiance ratio reported in [5], which gives absorbed flux on the outer surface of 765 W/m². The external sol-air temperature ($T_{sol\text{-}air}$) is calculated using the ASHRAE Handbook heat balance relationship:

$$T_{sol-air} = T_o + \frac{\alpha \cdot I_t}{h_o} - \frac{\varepsilon \cdot \Delta R}{h_o} \tag{1}$$

With a safety margin for summer period the third member is omitted. The external convective heat transfer coefficient was calculated using the correlation from [1], yielding $h_{ext} \approx 29.5$ W/m²K at a vehicle speed of 30 km/h. The sol-air temperature was then used together with the thermal resistance of the 30 mm armor (λ = 15 W/m·K) [6] and 16 mm insulation (λ = 0.035 W/m·K) [7], to determine the interior wall heat flux driven by the difference between the sol-air temperature and the target cabin interior temperature of 26 °C. To account for reduced solar exposure, the effective irradiance on the sides and rear walls was assumed to be around 70% of the roof value.

The total incident solar heat flux on the tilted windshield (at a tilt angle of 40°) was determined by considering direct, diffuse, and reflected radiation components under peak summer conditions in Belgrade at 13:00 h. The direct radiation component was computed by modulating the Direct Normal Irradiation (DNI) with the cosine of the solar angle of incidence (θ), while the Diffuse Horizontal Irradiation (DHI) and Global Horizontal Irradiation (GHI) were scaled using the respective sky and ground view factors, incorporating a standard asphalt albedo of ρ_g = 0.15. To evaluate the actual thermal energy penetrating the cabin through the athermic glass, the calculated total

incident flux was coupled with a standard Solar Heat Gain Coefficient (SHGC=0.40).

Radiative heat transfer from onboard electronic equipment was estimated using the Stefan–Boltzmann relation with an emissivity of 0.9, surrounding temperature of 26 °C, and equipment surface temperatures of 50°C. Heat fluxes generated by the occupants are accounted according to the chosen one for estimating PMV/PPD values during experimental testing. Resulting heat fluxes and surface emissivities implemented as BC are given in the Table 2.

Table 2. Surface heat fluxes and emissivities

Section	Heat flux (W/m^2)	Emissivity
roof	90	0,9
windshield	180	0,9
rear	65	0,9
bottom	30	0,85
front (el.equipment)	150	0,9
sides	65	0,9
man 1	70	0,95
man 2	70	0,95
man 3	70	0,95

3.2. Mesh convergence

Discretization, flow and thermal calculations were performed using ANSYS Fluent [8][8]. A polyhedral mesh was formed with local sizing/refinement in the zones of the ventilation openings and on the occupants. Along the walls of the cabin and around bodies, 4 layers of the boundary layer with a growth factor of 1.2 were formed. The independence of the solution from the mesh density was confirmed with the analysis of three levels of mesh refinement (0.8, 1.2 and 2.2 million cells), where the difference in average cabin temperature was less than 0,3 % between medium and fine mesh (volume averaged temperatures in fluid domain were: 297,84 K, 299,31 K and 300,01K), so medium mesh was adopted for further simulations.

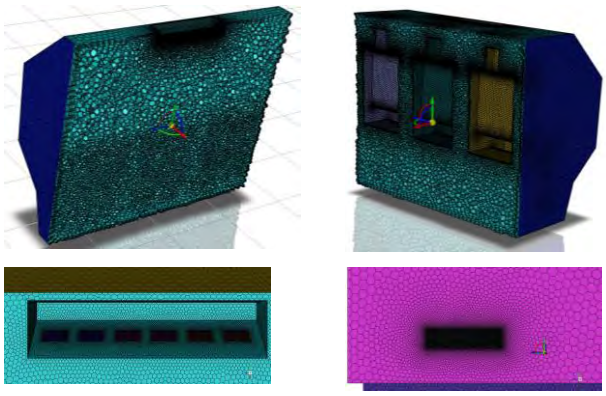

Figure 4. Details of the mesh

3.3. Methods

Radiative heat transfer from the heat sources was modeled using the Discrete Ordinates (DO) radiation model, whereas buoyancy-induced airflow arising only from density gradients within the cabin was accounted with Full buoyancy effects.

Turbulence closure was achieved through a modified two-equation Realizable k-ε model, along with Enhanced Wall Treatment and with Thermal Wall Function.

In the initial phase (first 300 iterations), the pressure-velocity coupling was managed via the SIMPLEC algorithm, combined with First-Order Upwind schemes for the momentum, energy and turbulence equations to establish a stable, non-oscillatory initial flow field. Pressure discretization was done with Body-force-weighted scheme.

For the secondary phase, the solution configuration was advanced to the Coupled algorithm to simultaneously solve the mass and momentum equations. In order to more accurately capture the buoyancy-induced flows driven by significant temperature gradients within the cabin, the pressure discretization was upgraded to the PRESTO! (PREssure STaggering Option) scheme, which is suited for natural convection with higher Rayleigh number. Spatial discretization for the remaining transport variables was elevated to the Second order upwind scheme.

Given the numerical instability inherent in coupled forced and natural convection regimes, the pseudo-transient formulation was included. The Time scale factor was systematically managed, initiating at lower bounds (1e-3) to damp transient numerical fluctuations during the transition to higher order discretization. The residuals stably converged below the thresholds of 1e-3 for continuity and 1e-6 for energy.

4. RESULTS

4.1. Experimental results

Experimenntal testing was conducted after system reached a steady-state thermal condition. Air temperature and velocity, relative humidity (RH), cabin pressure and radiant temperature were measured using sensors for each quantity, over a duration of 5 minutes with a sampling frequency of 1 s. The sensors were positioned at multiple points on different cabin segments (the height at which the sensors are placed is 1,1 m and 0,1 m from the floor of the vehicle as defined in the ISO 7730). This measurement protocol provided a sufficient number of time points (300 samples per sensor).

During the measurement, it was observed that the speed of air flow in the zone around the head is uneven. Unfortunately, technical possibilities and space dictate limitations. Those limitation cannot be changed.

Based on the measured values and using assumed values of metabolic rate, clothing thermal insulation (normal business wear; 0,154 m²K/W clo=0,57) and activity (sitting down, light activity; 70 W/m²; met=1,2), PMV and PPD indices were calculated according to Fanger's thermal comfort model, as defined in the ISO 7730 standard. The air speed was measured in front and was 2 m/s in the narrow zone where it was measured.

The results of average values, as well as extreme values are given in Table 3.

Table 3. Experimental data of temperatures and RH

	t_1, °C	t_2, °C	t_3, °C	%, RH
Average	26,8	25,8	27	36,1
Max.	27	26,1	27,1	39,4
Min.	26,5	25,2	26,6	35,2

Measured values resulted in values of PMV and PPD presented in Table 3.

Table 3. Obtained values of PMV and PPD

	PMV	PPD
Average	0,8	18,5
Maximum	1	22,1
Minimum	0,7	15,3

4.2. CFD results

For the purpose of simplification of the numerical model, relative humidity (RH) was not included in the CFD analysis. Experimental data of this variable showed only 4,2% difference between minimal and maximum value. For the calculation of PMV/PPD values, the average RH was used. Obtained value of average volume in fluid domain are 26,2 °C, while the temperatures at the surface of the passengers are given in Table 4. Surface averaged velocity for the plane created in front of the bodies (at the distance of 10 cm from the chest area) is 0,433 m/s.

Table 4. Numerical results for the body surface of the occupants

	Man 1	Man 2	Man 3
Surface averaged temperature, °C	33,32	33,19	33,44
Radiation temperature, °C	34,75	34,69	34,71
Total heat transfer rate, W	175,02	166,62	169,85

For the calculation of the PMV and PPV value the CBE Thermal Comfort Tool is used. That is web-based calculator developed by the Center for the Built Environment at UC Berkeley and is in compliance with a ASHRAE 55, ISO 7730 and EN 16798-1 standards.

Obtained PMV value is 0,83, while PPD is 20% according to EN 16798-1 standard.

The average temperatures on the passenger's body surface, obtained in the simulation, are in good agreement with the range considered physiologically neutral and comfortable for the human body in the literature (30-34°C) [9]. Given that the obtained average body surface temperatures in this simulation are within this recommended range, it can be concluded that the simulated ventilation conditions ensure a satisfactory thermal state of the passenger's body on average, although, as is shown at the Figure 5, local variations (especially in the head and lower extremities) may deviate from this neutral value.

The temperature distribution across the surfaces of the three occupants results reveal a clear vertical stratification of body-surface temperature, with the highest values at the head. This localized heating is consistent with the elevated temperatures identified on the interior roof surface, indicating that radiative heat transfer from the hot roof panel directly contributes to the thermal loading of the occupants head. In contrary, the back and upper torso region exhibits noticeably lower temperatures, in the range of approximately 29–35°C, which can be attributed to the direct impingement of the cold air jet discharged from the vents, as it can also be observed in the velocity contours from Figure 5. Moving further down the body, the lower torso and thigh region shows intermediate and elevated temperaturee, suggesting reduced local ventilation efficiency in this area and a corresponding accumulation of heat. Overall, this non-uniform thermal pattern across the body demonstrates that occupant thermal comfort cannot be adequately captured by a single average body temperature and supports the use of segment based approach in order to to properly characterize localized thermal sensation.

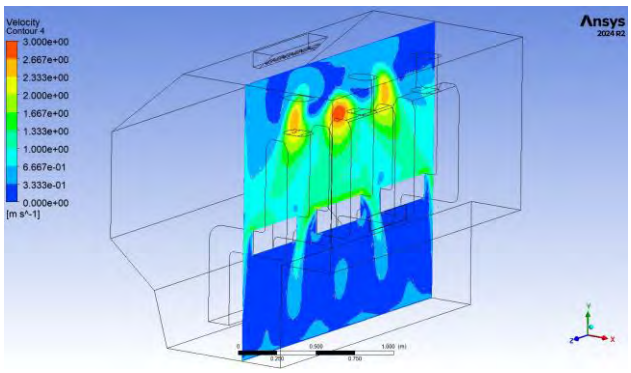

Figure 5. Velocity contours in the plane in front of the occupants

The temperature distribution on the interior surfaces of the cabin is shown in Figure 6. The results show pronounced spatial unevenness of the temperature field, with the highest values, up to 59.1°C, recorded on the windshield next to the cabin roof. These indicates that the windshield is the dominant source of radiant heat load inside the cabin, which is in line with physical expectations for a vehicle exposed to direct solar radiation. That suggests thermal insulation at the junction between the roof and the windshield, where thermal bridges are likely to be formed.

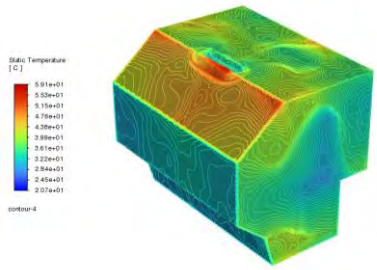

Figure 6. Temperature distribution on cabin interior surfaces (walls)

Considering the given conditions of speed angles, passengers can feel discomfort expressed in the form of uneven temperature on different parts of the body, primarily in the area of the legs and crown of the head. The applied heat flux has been increased on the safety side, so that in reality lower values are expected, and therefore less pronounced discomfort.

The distribution of air flow velocity in the longitudinal section of the cabin is shown by the vector field in Figure 7. The jet is directed downwards towards the central part of the cabin. After entering, the jet maintains a relatively high speed along a narrow vertical channel, after which it expands and gradually slows down due to mixing with the surrounding, much calmer air in the lower part of the cabin, where low flow speeds (below 2 m/s) dominate. This distribution is a direct consequence of the one-sided position of the inlet because entire airflow is supplied from one, upper side of the cabin, there is no symmetrical or multi-sided flow distribution along the longitudinal axis of the cabin, which leads to a pronounced velocity gradient between the central zone directly below the inlet and the front and rear of the cabin, where zones of lower velocity and potential stagnation are formed.

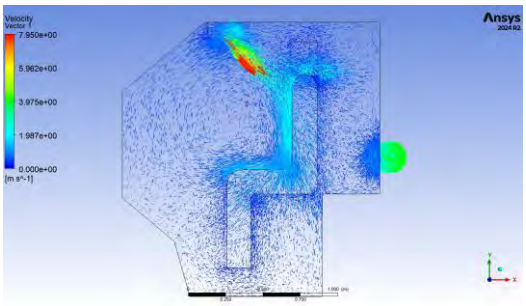

Figure 7. Velocity vector in cabin mid cross section

5. CONCLUSION

In this paper, a CFD analysis of thermal comfort and air flow in the cabin of a vehicle with three cabin crew members was carried out. The simulation included a cabin with a unique arrangement of air supply exclusively from the upper side of the cabin, which enabled a detailed analysis of the impact of spatially asymmetric configuration on the distribution of speed, temperature and thermal comfort indices of passengers.

The thermal comfort indices PMV and PPD calculated for the observed case were 0,83 and 20%, respectively, which is in good agreement with data obtained through experimental testing.

The results of this research indicate that the assessment of thermal comfort based solely on global, spatially averaged indices (PMV, PPD, average temperature) and simplified geometry does not fully include local variations of the thermal and velocity field inside the cabin, especially in the zones of direct interaction with air jets (head, chest) and solar heating zones (windshield and roof).

The obtained results contribute to a better understanding of airflow organization and heat transfer processes and provide a basis for future optimization of HVAC system performance, energy efficiency and occupant thermal comfort in special purpose vehicles.

Abstract: *Accurate determination of ground target coordinates is an important requirement in military, security and geospatial applications. Different target acquisition systems, such as electro-optical sensors, laser rangefinders, GNSS/INS units, total stations and photogrammetric platforms, can provide target coordinates, but their results are not directly comparable without a clearly defined testing methodology. This paper presents methods for assessing the accuracy of ground target coordinates determined by different acquisition systems. The proposed approach is based on the comparison of measured target coordinates with independently determined reference coordinates on a dedicated geodetic test field. In addition to direct coordinate comparison, repeated observations, relative geometric checks and operational scenario testing are considered. The paper also proposes statistical indicators for reporting results, including coordinate residuals, horizontal and three-dimensional position errors, RMSE values, systematic offsets and empirical percentiles. The presented methodology provides a basis for objective evaluation, verification and comparison of target acquisition systems under controlled and operational conditions.*

Keywords: *target acquisition; ground targets; coordinate accuracy; RMSE; test field.*

1. INTRODUCTION

Accurate determination of ground target coordinates is an important requirement in military, security, geospatial and reconnaissance applications. Target coordinates are used for surveillance, fire support, command and control, navigation and integration of sensor data into geospatial information systems. They can be determined by different acquisition systems, including electro-optical and infrared sensors, laser rangefinders, GNSS/INS units, digital compasses, total stations, photogrammetric systems, unmanned aerial platforms and integrated multi-sensor systems.

Although these systems may provide the same type of output, their accuracy may differ significantly. The final coordinate result depends not only on the nominal accuracy of individual sensors, but also on the complete measurement process. Important error sources include sensor position, orientation accuracy, distance and angular measurements, target identification, atmospheric conditions, coordinate transformation, time synchronization and operator influence.

The terms accuracy and precision are often used interchangeably, although they have different meanings. According to the ISO 5725 series, accuracy includes both trueness and precision, while precision refers to the closeness of repeated measurement results under specified conditions [1]. This distinction is important because a target acquisition system may produce highly repeatable coordinates that are still affected by systematic errors. In the military context, this problem is closely related to Target Location Error (TLE), which represents the difference between the actual target location and the location determined by the acquisition process [2].

A reliable assessment of target coordinate accuracy requires an independent reference framework. This can be achieved by establishing a geodetic test field with clearly defined target points whose coordinates are determined by higher-accuracy geodetic methods. The coordinates obtained by the tested acquisition systems can then be compared with reference coordinates. Similar principles are used in positional accuracy assessment of geospatial data, where independent checkpoints and RMSE indicators are commonly applied [3]. The interpretation of results should also consider measurement uncertainty, following general principles given in the Guide to the Expression of Uncertainty in Measurement [4].

The aim of this paper is to present a concise methodological framework for testing the accuracy of ground target coordinates determined by different acquisition systems. The paper discusses the concept of a

DOI: 10.5937/OTEH26157S

reference test field, main testing methods and statistical indicators required for objective evaluation, verification and comparison of acquisition systems under controlled and operational conditions.

2. TARGET ACQUISITION SYSTEMS AND ERROR SOURCES

Ground target coordinates can be determined using different types of acquisition systems. In general, these systems combine information about the position and orientation of the sensor with measurements directed towards the target. Depending on the system concept, target coordinates may be obtained from optical observation, laser distance measurement, angular measurements, GNSS/INS navigation data, photogrammetric processing or a combination of several sensors. Typical acquisition systems include handheld or tripod-mounted electro-optical devices with laser rangefinders, vehicle-mounted observation systems, airborne or UAV-based EO/IR platforms, GNSS/INS-based multi-sensor systems, total stations and photogrammetric systems. Some of the mentioned acquisition systems are shown in Figure 1. Although these systems differ in design and operational use, the final result is usually expressed as target coordinates in a selected coordinate reference system.

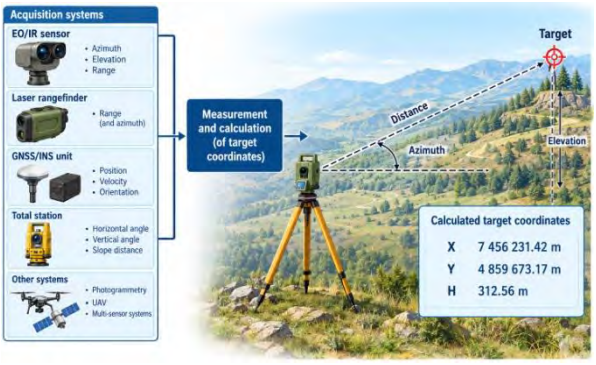

Figure 1. Target coordinate determination system

Studies dealing with target geo-location and acquisition systems show that the final coordinate accuracy is affected by the complete measurement chain, not only by individual sensor specifications. In airborne optoelectronic platforms, important error sources include sensor measurement errors, installation errors and transformations between different coordinate frames [5]. For systems based on laser rangefinders and inertial or attitude sensors, orientation error is often one of the dominant factors influencing the final target position [6]. Laser rangefinder-based airborne EO systems also show that platform position and distance measurement errors have a significant effect on target geo-location accuracy [7]. In image-based UAV systems, geolocation errors become more evident at longer distances and are strongly influenced by GNSS/INS accuracy, camera parameters and target elevation information [8].

The main error sources can be grouped into four categories. Sources of error in target coordinate detrmination are shown in Figure 2. The first category is related to the position of the acquisition system. Any error in sensor or platform coordinates is transferred directly to the computed target coordinates. This is especially important for mobile and airborne systems, where the sensor position is usually determined by GNSS or GNSS/INS integration.

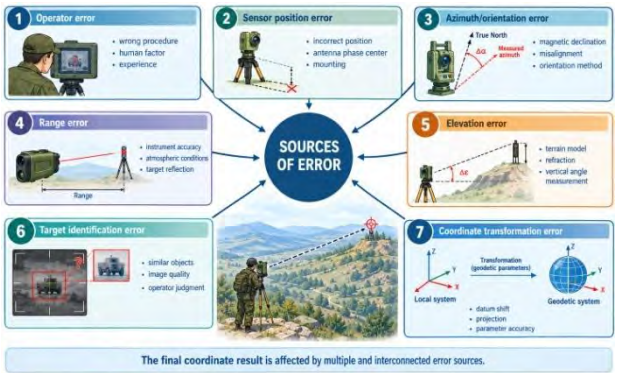

Figure 2. Sources of error in target coordinate detrmination

The second category includes orientation-related errors. Errors in azimuth, pitch, roll or sensor alignment may cause significant horizontal and vertical displacement of the target coordinates. Even a small angular error can produce a large transverse error at longer distances, which makes orientation accuracy one of the key factors in target coordinate determination.

The third category includes observation errors related to the target itself. These errors may originate from laser distance measurement, horizontal and vertical angle measurement, target identification, image resolution, camera calibration, atmospheric conditions, visibility and operator aiming. In image-based systems, additional errors may be caused by feature extraction, image matching and georeferencing.

The fourth category includes computational and reference system errors, such as coordinate transformation errors, incorrect geodetic datum parameters, height system inconsistencies and time synchronization errors. These errors are often difficult to detect during field use, but they may introduce systematic offsets in the final target coordinates.

For accuracy testing, it is therefore necessary to evaluate the complete acquisition process. The main error sources that influence ground target coordinate determination are summarized in Table 1.

Table 1: Main error sources in ground target coordinate determination

Category	Error source	Typical influence on target coordinates
Category 1 - position of the acquisition system	Sensor or platform position	Direct translation of the computed target coordinates
Category 2 - orientation-	Azimuth and orientation errors	Horizontal displacement

related errors		increasing with target distance
	Vertical angle and pitch errors	Height error and range-dependent position error
Category 3 - errors related to the target	Distance measurement error	Error mainly along the line of sight
	Target identification and aiming	Random or systematic targeting error
	Camera calibration and image processing	Image-based coordinate error
Category 4 - computational and reference system errors	Atmospheric and visibility conditions	Reduced observation quality and range accuracy
	Coordinate transformation error	Systematic coordinate offset
	Time synchronization error	Position error for moving platforms or targets
	Operator influence	Variations in aiming and measurement procedure

3. REFERENCE TEST FIELD CONCEPT

A reliable assessment of ground target coordinate accuracy requires a reference framework that is independent of the tested acquisition system. For this purpose, a dedicated geodetic test field can be established, consisting of clearly defined and stable target points with accurately determined reference coordinates. These coordinates should be obtained using higher-accuracy geodetic methods, such as static GNSS observations, total station measurements, precise levelling or a combination of independent techniques.

The concept of such a test field should be closer to a reconnaissance and target acquisition polygon than to a conventional firing range. Its primary purpose is not to test weapon effects, but to evaluate how accurately different systems can detect, identify and determine the coordinates of ground targets. Therefore, the field should combine geodetic accuracy requirements with operationally realistic observation conditions.

Publicly available examples relevant to this concept can be found in remote sensing calibration and validation sites, UAV target geolocation experiments and military sensor trials. The Baotou Comprehensive Calibration and Validation Site in China is equipped with artificial standard targets, including portable and permanent targets, and supports long-term calibration and validation of remote sensing sensors [9]. A UAV long-range oblique photography experiment presented by Liu et al. used three ground targets at slant ranges of approximately 48 km, 52 km and 49 km, while the ground-truth target coordinates were measured by a geodetic GNSS receiver with an error smaller than 0.1 m [8]. In Europe, the FGI Sjökulla Aerial Test Range in Finland includes permanent ground control points with precisely known coordinates, test-bar targets and reflectance panels for geometric and radiometric calibration of imaging systems [10]. Military sensor trials, such as NATO SET-250, also show the importance of observing military targets from different angles and configurations [11].

Based on these examples, a military-oriented reference test field should include open terrain for long-range line-of-sight observations, semi-urban or urban structures for complex backgrounds and partial occlusions, and areas suitable for tripod-mounted, vehicle-mounted and UAV-based acquisition systems. Targets should be distributed at different distances, azimuths and height differences relative to possible observation stations. This geometry makes it possible to evaluate how coordinate accuracy changes with range, viewing direction and vertical angle.

The test field should include several types of targets. Geodetic targets, such as marked points, prisms, retroreflectors and high-contrast panels, are suitable for reference coordinate determination and for testing visible-spectrum and laser-based systems. Photogrammetric targets, such as coded or cross-shaped ground control markers, are useful for UAV and image-based systems. For thermal imaging systems, thermally contrasted panels, heated plates, vehicle-size thermal targets and standard four-bar targets may be used. Four-bar targets are commonly used in thermal imager testing, especially for MRTD-based performance assessment [13]. Target acquisition performance for electro-optical and thermal systems can also be evaluated by field trials and models that consider detection, recognition and identification criteria [14], while thermal imager range performance depends on target characteristics, atmosphere, background, sensor parameters and selected perception criteria [15]. Proposed geodetic test field for accuracy assessment of target coordinates is shown on Figure 3.

Figure 3. Geodetic test field for accuracy assessment of target coordinates

In a reconnaissance-oriented test field, the target set should also include operationally representative objects, such as vehicle silhouettes, mock vehicles, shelters, observation posts, building corners, road intersections and personnel-size targets. These objects should not be treated only as visual targets, but as coordinate targets with precisely defined reference points, for example the centre

of a panel, the centre of a thermal target, a marked point on a vehicle silhouette or a selected structural corner. This is important because ambiguity in target definition may become a significant part of the final coordinate error.

A possible layout may include several observation stations with known coordinates and targets grouped into short, medium and long-range zones. Short-range targets, for example from 100 m to 500 m, are suitable for testing aiming, angular measurement and close-range coordinate determination. Medium-range targets, from about 1 km to 3 km, are suitable for handheld and vehicle-mounted EO/IR systems with laser rangefinders. Long-range targets, beyond 5 km, are useful for analysing the influence of orientation, ranging, atmospheric conditions and UAV-based observation geometry.

The main purpose of the reference test field is to provide targets whose coordinates are known with an uncertainty significantly smaller than the expected errors of the tested acquisition systems. The coordinates obtained by the tested systems can then be compared with reference coordinates. The same field can also be used for repeated observations, relative geometric checks and operational scenario testing. This type of configuration links geodetic traceability with operationally realistic target acquisition conditions.

4. TESTING METHODS

Several complementary methods can be used for testing the accuracy of ground target coordinates determined by different acquisition systems. The selection of methods depends on the type of system, observation distance, target type, required accuracy and operational conditions. Testing should include both comparison with reference coordinates and analysis of repeatability under defined conditions. A review of target geo-location algorithms for aerial remote sensing systems shows that the final target position depends on the sensor position and attitude, imaging geometry, target elevation, coordinate transformations and the applied geo-location model [15].

4.1. Direct comparison with reference coordinates

Direct comparison with reference coordinates is the basic method for accuracy assessment. The tested acquisition system determines the coordinates of a selected target, and the obtained coordinates are compared with independently determined reference coordinates.

This method directly estimates the coordinate error of the tested system and enables the detection of both random and systematic effects. It is conceptually similar to positional accuracy assessment of geospatial data, where independent checkpoints and coordinate residuals are used for accuracy evaluation [3]. The main requirement is that the uncertainty of the reference coordinates must be significantly smaller than the expected errors of the tested acquisition system. Comparison of measured and reference coordinates is shown in Figure 4.

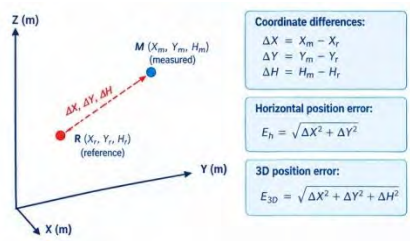

Figure 4. Comparation of measured and reference coordinates

4.2. Repeated observations

Repeated observations of the same target are used to evaluate the repeatability of the acquisition system. The same target is observed several times under identical or similar conditions, and the dispersion of the obtained coordinates is analysed. This method is useful for determining short-term stability, operator influence, aiming repeatability and measurement noise.

However, repeated observations cannot by themselves prove coordinate accuracy. A system may provide highly repeatable results that are still affected by a systematic error. Therefore, repeatability testing should always be combined with comparison against reference coordinates. This distinction is consistent with the ISO approach, where precision describes the closeness of repeated measurements, while accuracy includes both trueness and precision [1].

Repeated observations should be performed for different target distances and target types. Short-range observations may be used to evaluate aiming and angular measurement effects, while longer-range observations are more sensitive to orientation, distance measurement, target elevation and atmospheric influences. Long-range oblique reconnaissance studies also show that target geo-location accuracy is strongly affected by observation geometry and by the availability or uncertainty of target elevation information [16].

4.3. Relative geometric checks

Relative geometric checks are based on the comparison of geometric relationships between targets. Instead of analysing only absolute coordinates, distances, directions, angles or height differences between pairs of targets are computed from the measured coordinates and compared with the corresponding reference values.

This method is useful for detecting scale effects, angular effects, local geometric distortions and range-dependent errors. It can also help identify whether the dominant error component is related to distance measurement, orientation or coordinate transformation. Relative checks are especially useful when several targets are observed from the same station or when the same target group is observed by different acquisition systems.

The limitation of this method is that it may not detect a common translation of all target coordinates. Therefore, relative geometric checks should be used as a complementary method, not as a replacement for direct

comparison with reference coordinates.

4.4. Operational scenario testing

Operational scenario testing evaluates the performance of acquisition systems under conditions similar to real use. The test should include different observation distances, azimuths, vertical angles, target types, visibility conditions, operators and observation platforms. Depending on the system, testing may be performed from tripod-mounted stations, vehicles, UAVs or other platforms.

The purpose of this method is to determine how the accuracy changes when observation conditions are no longer ideal. For EO/IR systems with laser rangefinders, tests should include different visibility and range. For thermal systems, target acquisition performance is commonly related to detection, recognition and identification criteria, while thermal imager performance depends on target characteristics, atmosphere, background and sensor parameters [12], [13], [14]. For GNSS/INS-based systems, tests should include open terrain, semi-urban areas and areas with reduced GNSS quality. UAV-based image acquisition systems should be tested with different flight geometries, image overlaps, camera orientations and target distances. Multi-view and long-range UAV target geo-location experiments show that observation geometry, sensor accuracy and reference target coordinates have a significant influence on the final target position [8], [16].

Operational testing should also include repeated observations by different operators. This makes it possible to estimate the influence of target selection, aiming procedure and interpretation of the target reference point. The results should be reported separately for different scenarios, because one overall accuracy value may hide important differences between short-range, medium-range, long-range, optical, thermal and image-based observations.

4.5. Combined testing approach

No single method is sufficient for a complete assessment of target coordinate accuracy. Direct comparison with reference coordinates should be the primary method, because it provides the most direct estimate of coordinate error. Repeated observations provide information about precision and stability. Relative geometric checks help identify geometric and systematic effects, while operational scenario testing shows how the system performs under realistic field conditions.

For a reconnaissance-oriented reference test field, the recommended testing procedure is therefore based on a combination of these methods. Each tested system should observe the same set of reference targets under predefined scenarios. Coordinate differences, horizontal and three-dimensional errors, RMSE values, systematic offsets and empirical percentiles should then be calculated and reported. The interpretation of results should also consider the uncertainty of reference coordinates and the general principles of measurement uncertainty evaluation [4].

5. STATISTICAL INDICATORS AND REPORTING

The results of target coordinate accuracy testing should be reported using a limited set of clear and comparable statistical indicators. The basic quantities are coordinate residuals, calculated as differences between the coordinates determined by the tested acquisition system and the corresponding reference coordinates. These residuals are used for the analysis of systematic offsets, random dispersion and overall position error.

Mean coordinate residuals should also be calculated, because they indicate possible systematic effects in the coordinate solution. Standard deviations of repeated observations provide information about precision and short-term stability. However, standard deviation alone is not sufficient for accuracy assessment, because it does not describe the offset from reference coordinates.

For operational evaluation, empirical percentiles of horizontal or three-dimensional position errors are also useful. The values $(P_{\{50\}})$, $(P_{\{90\}})$and $(P_{\{95\}})$ indicate the error level below which 50%, 90% and 95% of the observed errors are located. These indicators are practical for comparing different systems and scenarios, especially when the error distribution is not perfectly normal.

The results should not be reported only as one overall value. They should be grouped by acquisition system, target distance, target type, observation platform, operator and test scenario. This makes it possible to identify whether the coordinate error is mainly related to distance, orientation, target identification, sensor type or operational conditions. The uncertainty of reference coordinates should also be stated, because it directly affects the interpretation of the obtained differences [4].

6. PROPOSED TESTING PROCEDURE

he proposed testing procedure is based on the use of a reconnaissance-oriented reference test field and a predefined set of observation scenarios. The procedure should be applicable to different acquisition systems, including tripod-mounted, vehicle-mounted, UAV-based, electro-optical, thermal, laser rangefinder, GNSS/INS and photogrammetric systems [18].

In the first step, reference target points and observation stations should be established. Each target must have a clearly defined reference point, such as the centre of a panel, the centre of a thermal target, a marked point on a vehicle silhouette or a selected structural corner [19]. The coordinates of all targets and observation stations should be determined by higher-accuracy geodetic methods. The coordinate reference system, height system, survey method and estimated uncertainty should be documented [20].

In the second step, test scenarios should be defined. Targets should be grouped according to distance, target type and observation conditions. A basic configuration may include short-range targets from 100 m to 500 m, medium-range targets from 1 km to 3 km and long-range targets beyond 5 km. The test should include optical

targets, geodetic targets, photogrammetric markers, thermally contrasted targets and operationally representative objects such as mock vehicles, shelters, observation posts and building corners.

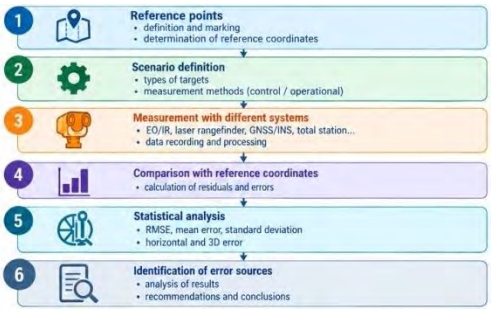

Figure 5. Flowchart of the proposed testing procedure

Flowchart of the proposed testing procedure is shown on Figure 5. In the third step, each acquisition system should determine the coordinates of the selected targets according to the same predefined procedure. For each system, the observation position, sensor configuration, operator, time of observation, atmospheric conditions, visibility, target type and measurement mode should be recorded. Repeated observations should be performed in order to evaluate precision and short-term stability [21].

In the fourth step, the obtained coordinates should be compared with the reference coordinates. Coordinate residuals, horizontal and three-dimensional errors, RMSE values, mean residuals, standard deviations and empirical percentiles should be calculated [22]. The results should be reported separately for different systems, target distances, target types, operators and test scenarios [18].

In the final step, the results should be analysed in order to identify dominant error sources. Direct comparison with reference coordinates provides the main estimate of accuracy, repeated observations describe precision and stability, relative geometric checks indicate possible scale or orientation effects, and operational scenario testing shows the behaviour of the system under realistic field conditions. The interpretation of the results should also include the uncertainty of reference coordinates and the limitations of the applied test configuration [4].

7. CONCLUSION

The accuracy of ground target coordinates determined by different acquisition systems cannot be reliably assessed only from manufacturer specifications or repeated observations. A complete evaluation requires comparison with independently determined reference coordinates, supported by repeatability analysis, relative geometric checks and testing under operationally realistic conditions.

The proposed methodology is based on a reconnaissance-oriented geodetic test field with clearly defined targets, known reference coordinates and different observation geometries. Such a field enables the testing of tripod-mounted, vehicle-mounted, UAV-based, electro-optical, thermal, laser rangefinder, GNSS/INS and photogrammetric acquisition systems under comparable conditions.

Direct comparison with reference coordinates should be the primary method for estimating coordinate accuracy, while repeated observations provide information about precision and stability. Relative geometric checks can help detect scale, orientation and transformation effects, and operational scenario testing allows the assessment of system performance under real field conditions.

The results should be reported using coordinate residuals, horizontal and three-dimensional errors, RMSE values, systematic offsets, standard deviations and empirical percentiles. This provides a consistent basis for objective evaluation, verification and comparison of different target acquisition systems. The proposed approach links geodetic traceability with operational requirements and may support the development of dedicated military geodetic test fields for reconnaissance and target coordinate accuracy assessment.

Abstract: *This paper presents contemporary trends in a weapon system acquisition programs through analyses of the newest strategic document related to the subject in few selected but relevant cases – the U.S. and the EU. Observed changes in conducting modern warfare are perceived as radical changes which generate a need for change of strategic documents and approaches in many fields, including ackuisition of weapons and military equipment. Main characteristics of those changes are related to rapid development and fast fielding of new technological solutions and systems, innovative approaches, application of artificial intelligence and advanced information and communication technologies.*

Keywords: *acquisition, strategy, defense industry, weapon systems, program management.*

1. INTRODUCTION

Contemporary armed conflicts during past several years are characterized by huge changes at all levels – tactical, operational and strategic. Changes are not linear nor straight forward, but iterative and multidirectional with mutual influence and impact. Dynamics of involvement of new weapon systems and combat use of dual-use technologies, became very high. The result of that, is enlarged pressure on weapon system suppliers to obtain a better, and better weapons, in a shorter time, and in required quantities.

At the opposite ends of supply chain for weapon systems and technologies, are producers (weapons factories) and end users (military units). In between the two, are organizational entities which are the main bridge between users of weapons systems and the producers. That intermediary is called acquisition system. Certainly, in various countries and in various historical time acquisition system has various names and organizational location inside the structure of armed forces and/or ministry of defense.

Principally, the main task of acquisition system is to obtain exactly that what is needed and required by the end users. However, that task is very complex, demanding and uncertain. In a case of civilian supply chains, the role of main mediator between producers and users is delegated to the free market. This fact is one of key differences between military and civilian supply chains. In that sense, defense acquisition system has very important role as main bridge between production side with defense industry as the cornerstone, and the armed forces as end-users.

Studying topics similar to this one is useful from the perspective of drawing lessons from foreign experiences and possible application for one's own needs. Also, knowledge on acquisition system and defense industrial base of the U.S. could be very useful for foreign parties which are interested in technological cooperation and arms-trade with industrial and technological companies as well as with defense institutions in the U.S.

Next sections of this paper present in short main points from the newest acquisition strategy of the U.S. Department of War (former Department of Defense), issued in 2025. Then follows presentation of novel trends in the EU and its specific characteristics. Fourth section offers two illustrative examples: first, review of growing investment in acquisition in NATO countries; and second, basic information for one of the newest, the largest and the most expensive complex acquisition program in defense, known aa "Golden Dome".

2. NEW ACQUISITION STRATEGY OF THE U.S.

New Acquisition strategy of the U.S. was issued by the end of last year from the U.S. Department of War [1]. It was a result of implementation of one executive order of the President of the U.S., [1], issued in the April, the same year, which was related to modernization of defense acquisition and to defense industry.

Initial assumption in new acquisition strategy points out two moments. First, existing acquisition system is perceived as outdated ("antiquated"). Second, defense industrial base is considered as insufficient and limited in capacity and performance ("atrophied"). Those two

Corresponding author: N. Nikolić;
E-mail: nebojsa.nikolic@pmc.edu.rs
DOI: 10.5937/OTEH26158N

positions combined with the huge changes in modern armed conflicts and consequently requirements for enhanced capabilities of military forces, were more than sufficient causes for creation of new acquisition strategy.

2.1. Main goals of new acquisition strategy

Main strategic goals of the new acquisition strategy, were defined along three directions as follows. First, implementation of new technologies in order to modernize systems at the level which is higher than it could be the case with potential adversaries. Second, enlargement production capacity of defense industry with the focus on those who produce weapons, ammunitions and key systems. Third, transform acquisition system and industrial base in such a way that it corresponds to a wartime regime and is capable to respond to the urgent needs.

First two strategic directions are more general and logical having in mind that modernization is present and relevant for each field of industry and business, while enlargement of industrial production of military equipment could be seen as a response to a global weapons market trends and increased demands. However, the third strategic goal has the largest transformational change potential because it declares the need, will and intention to transit complete defense industrial base and the acquisition system from peacetime regime towards wartime regime.

Strategic importance of defense industrial base is additionally confirmed by the newest National Defense Strategy [3], where it is defined as one of four main strategic goals for national defense (other three goals are: defend the country; deter main adversaries; and increase burden-sharing with allies and partners). This strategy says that it will be undertake “urgent actions” in order to “mobilize, renew and secure” defense industrial base.

2.2. Specific tasks of new acquisition strategy

New American acquisition strategy is intended to achieve above mention main strategic goals through defining and realization of five sets of specific tasks as follows.

First, rebuilding, or supercharging and overhaul of defense industrial base. This rebuilding efforts encompasses following actions:

- Expand number of companies which will produce military equipment and relax their joining; welcome better ideas; promote fast contracting and speed delivering of results.
- Stabilization of demands dynamics through longer and bigger deals with companies which produce weapons and military equipment. It is expected that such companies will be more willing to invest in their capacity for weapons and equipment production.
- Attract private capital investment in defense industry. This measure will impact both above actions (expanding capacity, and enlarging number of companies).
- Use off-the-shelf purchase of products, parts and services whenever it is more costly-efficient and faster.
- Renovate bid protest procedures in such a way that they are faster in a whole and more costly for those protesters who lose.
- Make contracting more flexible so that process is faster, that is achieved in a shorter time.
- Increase and systemize communication between Department of War and companies in defense industrial base, through establishing appropriate consortium.

Second, improve capacity and capability of acquisition workforce and its authorization level, through following actions:

- Attract top talents from industry and government, hire them in acquisition bodies and let them to make work better.
- Educate its own workforce through systemic advancement of the Warfighting Acquisition University.
- Sustain and keep best leaders and teams.
- Authorize acquisition program leaders to conduct full control of program outcomes quality, budget and deadlines.
- Improve capability portfolio management through optimization of purchasing of similar products in a sense efficiency, effectiveness and timely realization.
- Include acquisition managers in early phases of warfighting requirements defining.
- Increase speed of reform of the Planning, Programming, Budgeting and Execution processes, by focusing on enabling leaders’ agility to schedule financial resources, preferencing new technologies and simplify approval procedures.
- Finally, improve stimulating system of workforce by connecting their results in acquisition processes with their payment.

Third, enlarge flexibility in all phases of acquisition processes. This should result in reduced regulations and reduced time parameters for acquisitions. To achieve that, following should be undertaken:

- Digitalization of acquisition processes, smart use of Artificial Intelligence (AI) for reduction of administrative issues and planning with a main goal to reduce overall acquisition time and make it faster.
- Permanent control of acquisition programs through access to relevant data in a real-time, measure progress and make appropriate corrections if needed.
- Modernization of testing processes and infrastructure, with intention to make testing decisioning faster.
- Reducing number of bureaucratic testing procedures in favor of real testing.
- Increase quality of acquisition of information technology, particularly software and hardware.
- Reduce and replace procedure known as “Analysis of alternatives” which is demanding and time-consuming.
- Make better Cost estimation, use realistic data, make accurate prediction about real and overall cost of acquiring weapon system or equipment.
- Make transition towards commercially used accounting system.

- Rebuild Foreign military sales, strengthen industrial base capacity for export, and make effective and precise procedures to support arming allies and partners with American weapons.

Fourth, rise quality standards and technical excellence in order to produce systems of high performances, through following directions:

- Modernization of system engineering, upgrading quality standards for weapon systems, and at the same time make it more efficient and faster.
- Use open system architecture in the sense of wider use of common components and standards in weapon systems, which will enable fair compete among more companies.
- Enable adaptive acquisition framework in order to obtain fact implementation of the newest technological advancements in weapon systems.
- Re-engineering of the "kill-chains" studies, that is, reconsidering tactical procedures and decision making related to use of weapons (in short: sense-identify-track-decide-act-report chain).

Fifth, advance of lifecycle risk management. It should be realized by actions as follows:

- Size and sustain complete maintenance and repair of weapons system, by own capacities (military and government, not commercial). This intention is interesting, by the way, because there were efforts in the opposite direction [4].
- Impose comprehensive and overall control on supply chain for defense industry, and fix broken and weak points.
- Make lifecycle management as long-range sustainable, cost-efficient and with mapped risks and their possible impact.

In summary, the Department of War of the U.S. is main initiator, strategic planner and supervisor of transformation of the whole system of defense acquisition. The change dynamic is very high starting in 2025 with the presidential strategic directives, which was followed by transformation strategy in the same year, with precise and relatively short deadlines for some singular steps measured by months, and with good prospects to be realized in foreseeable future. It will be useful to follow defense acquisition transformation activities in the U.S., in the coming years and register how it advance and what problems appears in this transformation.

3. DEFENSE PROCUREMENT IN THE EU

Question of defense acquisition in the European Union and in its' member states, is also very actual and is subject of research analyses, political considerations, government decisions and industrial preparations in a longer period [5]. However, the situation here is much more complicated than it is in the case of the U.S. In the European context we have individual countries in Europe and some of them are member countries of the EU, some of them are not; some of them are members of the NATO, some are not; also, there are institutional bodies and agencies of the EU, and finally there are commercial companies in the defense industrial sector. Also, there are defense industry companies which are still owned by government.

Recent research study about European defense issues, in a separate section dedicated to defense procurement (European synonym for acquisition) point out the state-of-the-art in few concise notes, [6]:

- There are evident changes in defense procurement in European countries, where increased spending on new weapons and equipment is the main change. Also, there are some changes in approaches to defense procurement.
- There is evident trend of orientation of European states towards European based procurement, that is, buying defense gods from European producers. Not so far in the past such practice would be convicted as discrimination or at least as non-fair market behavior, but today it is accepted as politically correct and even very positive.
- In order to keep and sustain increased level of investment in defense, it will be needed reliable and permanent support from high political level. This is important for European countries due to their reluctant position towards military spending in a long period from the end of the Cold War up to 2014 and even up to 2022 (years of conflict escalation between Ukraine and Russia).
- Due to complex issues in relations among national governments and political bodies of the European Union, there are two almost simultaneous processes of a collaboration at international level inside the EU, and a fragmentation as a dealing with defense issues at internal national level.
- At the moment, in Europe, dominant approach in defense procurement is nationally focused which means prioritization of national priorities, national industrial politic, and national legislation. Consequently, preference of national approach has negative impact on unionist or collaborative approach.

It is clear that a "renaissance" of the European defense issues including but not limited only on industry, is motivated by dominant security perceptions of Russia as an adversary, particularly after beginning of open armed conflict with Ukraine in 2022. Not to forget, besides the so called "Russian threat", there was occasional critique of European countries by administration of the U.S. for low level of defense spending among European countries. Europeans were steadily resistant to that American pressure for greater defense spending, but after 2022 situation changed dramatically.

As a result, there are many changes in strategic documents, development and application of all kind of sanction, search for alternative sources of energy, transportation routes, preparation of domestic population for potential conflict, enlargement of defense budgets, re-introduction of mandatory military service, and many other measures.

European countries were main beneficiaries of the "peace

dividend" after the end of the Cold war and theirs armed forces and defense industry had not priority in national development plans. However, in a relatively short time situation has changed and instead of "reduction" and "cut-off" of armed forces and defense industrial capacities, geopolitical environment forced changes in the opposite direction -towards enlargement and growth.

3.1. European defense industry transformation strategy

There are systematic efforts at the EU level and among member states to find the way for much more collaboration, cooperation and joint efforts for common approach in defense procurement. One result of that common efforts is a novel strategic document related to the roadmap for defense industry transformation in the European Union [7].

European defense industry strategy points out at the very beginning imperative significance of innovation, speed, agility and risk-taking aspects, which is similar with the U.S. point of view. Also, the newest lessons learned from ongoing armed conflicts, like war in Ukraine, has prominent place in perceiving the requirements needed for future weapon systems.

In order to speed up involvement of new technological achievements and innovations in a new weapons development, European administration and member states have started with stronger support to technological startups in defense industry business. In that sense, in a just few years after 2022, more than 230 small companies gained support for their programs in defense related technologies, [7], such as combat application of artificial intelligence, cyber tools, use of space-based systems, drone and counter-drone systems, radar and other sensing systems, dual-use technologies and systems, etc.

3.2. European Defense Agency and procurement issue

Main strategic document of the European Defense Agency (EDA), defines five core tasks. One of those core tasks clearly confirms importance of procurement and main approach which will be used for that. It is declared as: "Aggregating demand towards joint procurement", [8].

However, in other core tasks of EDA, there are elements and aspects related to procurement, such as follows [8]: "Enabling collaborative defense research, technology and innovation"; "harmonize requirements and ensuring interoperability".

European Defense Agency is positioned as the main intergovernmental body at the EU level which is authorized and dedicated to all aspects of defense industrial and research issues. As such, EDA mission is to support national ministers of defense "along all the steps of the capability development cycle and beyond that" [8].

While EDA operational budget is at the level of several tenths of million EUR (about 68 million EUR), total defense spending in the EU is much more (more than 400 billion EUR). So, the potential for influence, at least indirect, by EDA on the European Union defense spending is huge. This fact could be motivational factor for small states to establish and sustain good relations and connections with EDA and make some cooperation in the field of defense research and defense industry and so enter in big European defense market.

4. SOME INTERESTING EXAMPLES RELATED TO ACQUISITION

4.1. Budgeting acquisition – NATO case

Budget financing of acquisition of weapon systems and equipment have had steadily growth during last ten years in many countries. It was the consequence of crucial changes in geopolitical environment, strategic shifts in global interest of great powers, and of course because of several inter-state armed conflicts and innovative application of new technologies in those conflicts.

Scale of change in share of weapons and equipment expenditure inside the defense budget was tremendous. Very illustrative are data for NATO countries [9]:

- In year 2014., only several countries have had expenditure for weapons and equipment more than 20% of the defense budget. Those were: the U.S., the U.K., Sweden, Norway, France, Turkey, Estonia and Luxemburg [9].
- However, in year 2025, all NATO countries, except Belgium, reached the level of 20% of equipment expenditure.

Additionally, that grows of spending money on new weapon and equipment were extremely high and much more than 20% – meaning many times more. Here are some examples of that grow:

- Poland spent more than 54% in 2025, compared with below 20% in 2014.
- Finland spent more than 53% in 2025, compared with below 15% in 2014.
- Hungary, Latvia, Greece, Montenegro, North Macedonia and Czeckia spent more than 30% in 2025, compared with below 10% in 2014 [9].

4.2. Agile acquisition for the Golden Dome

The newest acquisition initiative for ballistic missile defense in the U.S., is known under a name: Golden Dome. The name is chosen as association on the Israeli's Iron Dome – an already fielded system for ballistic missile and aerial defense which has proved itself as efficient during last several years.

As official start of the Golden Dome program could be taken January 2025, when President of the U.S. issued executive order for development of this acquisition program [10]. Vision of the finishing of this program, is projected up to the end of the mandate of current presidential administration, which is in 2029.

Cost estimation for the program are relatively unprecise and vary from $175B up to $1,300B. Lower number is more related to estimation of the development of all subprograms and prototyping, while upper cost estimation

relates more on adding operational and logistical costs for additional 20 years of service.

Acquisition of the Golden Dome program some authors called as "non-traditional" due to its unique characteristics such as follows:

- The highest strategic importance – it is intended to protect the whole territory of the U.S. from all kinds of aerial and space threats (ballistic missiles, hypersonic vehicles of all kind, etc).
- Global deployment - in order to fulfil its mission, it has to be deployed globally including the space.
- Complexity – it will consist of many kind of systems and platforms in a large number (hundreds of space based satellites, latter thousands for surveillance, tracking, guiding; layered missile systems on earth, surface, air and even in space; combat information network, command and control centers and infrastructure; logistical sustainment, etc).
- Enormous cost of the program even with the lower estimate.
- Technical aspects of development of all subprograms and projects – many technical solutions and system are yet to be developed.
- Relatively short time for an such a large, innovative and complex program.

5. CONCLUSION

From the point of view of strategic management, huge changes in a "military business" which are evident from ongoing armed conflicts around the globe, present fundamental changes in a wider environment of comprehensive defense sector perceived as a strategic organization. In such cases, the organization have to react to that changes in its environment, and creation of new strategy and strategic plans are starting steps. New "Acquisition Transformation Strategy" of the U.S. is exactly such case, as well as corresponding strategic documents in the European Union.

Quality and successfulness of each strategy will be seen after some period and by the results of its implementation in practice. Future research should be oriented in that direction - tracking successfulness of application of strategies and strategic plans, and analysis of problems in its realization.

In a wider sense of acquisition goals, future research could be focused as well, towards search for still unresolved problems in conducting modern combat and defense, such as:

- Ballistic missile defense;
- Counter-drone technologies, systems and tactics;
- Radar and sensing technologies;
- Autonomuos swarming drones;
- Comand & Control systems for faster and more reliable decision making at all levels.

It is interesting that some of above challenges has longer history, that is, still with no solutions during several decades. Such case is with the long-standing problem of ballistic missile defense. Namely, this problem in real combat conditions was identified long ago, during the First Gulf War, in 1991. In that time a wide global coalition lead by the U.S., and authorized by the U.N. mandate, attacked Iraq forces in Kuwait, forcing them to leave Kuwait which they were occupied in a year before. In a after-action-reviews and in comprehensive analyses after the war, military experts and war-participants of the highest level, concluded that ballistic missile defense is a huge and unresolved problem, [11]. This problem is still actual and search for effective and efficient solution continues.

STANDARDIZATION AS A REGULATOR FOR THE USE OF ARTIFICIAL INTELLIGENCE IN FRAUD DETECTION

IGOR ĐORIĆ
Military Tehnical Institute, Belgrade, igor.djoric@mod.gov.rs

SNEŽANA ZUROVAC
Military Tehnical Institute, Belgrade, zurovac@medianis.net

Abstract: *Artificial intelligence (AI) is becoming one of the most significant drivers of the digital transformation of the financial sector, enabling the development of advanced systems for the detection and prevention of financial fraud. By applying machine algorithms learning, deep learning and analysis of large data sets, it is possible to identify suspicious behavior patterns in real time and significantly improve the effectiveness of risk management systems. However, the growing application of artificial intelligence simultaneously raises issues of transparency of algorithms, data protection, responsibility for decisions made, ethical aspects and cyber security. Therefore, standardization represents one of the key regulatory mechanisms that enables the responsible, safe and reliable application of systems based on artificial intelligence. The aim of this review is to analyze the role of standardization in regulating the application of artificial intelligence in the detection of financial fraud. Special attention is paid to ISO/IEC international standards, the European Act on artificial intelligence (EU AI Act), the NIST framework for artificial intelligence risk management, as well as the challenges brought by the abuse of artificial intelligence, cybercrime and new forms of digital fraud. The paper synthesizes contemporary scientific knowledge and points to the importance of integrating technical standards and regulatory frameworks in order to improve the security of the financial system and increase user confidence in AI technologies...*

Keywords: *artificial intelligence, standardization, financial fraud, financial sector, risk management.*

1. INTRODUCTION

Digitization of financial services represents one of the most significant processes of modern economic development. Electronic banking, mobile payments, cryptocurrencies, open banking and digital identity have enabled faster, more efficient and more accessible financial transactions, on the one hand. In contrast, but at the same time, new information technologies have enabled criminal groups to apply sophisticated attack methods that exceed the capabilities of traditional protection systems.

Today, financial institutions on a global level process billions of transactions every day, which makes manual control an almost impossible task. In response to this challenge, artificial intelligence-based systems have been developed that enable automatic recognition of anomalies, analysis of user behavior patterns, and assessment of the probability that a particular transaction represents a fraud attempt. Compared to traditional systems based on predefined rules, machine learning algorithms can continuously learn from new data, adapt to changes in user behavior and identify previously unknown patterns of behavior, which can indicate possible fraudulent activities.

lthough such systems significantly increase the efficiency of financial institutions, their implementation raises numerous questions. One of the biggest challenges is the so-called "black box" problem, i.e. the inability to clearly explain how complex algorithms arrive at a certain decision. Lack of transparency can lead to wrong risk assessments, discrimination of certain categories of users or unjustified blocking of financial transactions. In addition, artificial intelligence systems can be the target of cyber attacks or the subject of abuse by criminal organizations.

Contemporary research shows that the business value of artificial intelligence does not depend solely on the quality of algorithms, but also on how organizations manage data, risks and regulatory requirements. The sustainable implementation of AI requires the integration of technological, organizational and management aspects, with an appropriate regulatory framework being one of the key prerequisites for creating business value (Enholm, I.M., et al., 2022).

t is precisely for this reason that standardization gains strategic importance. Standards enable the establishment of unique rules for the design, development, implementation and maintenance of artificial intelligence systems. Their application contributes to increasing interoperability, transparency, data management quality and user trust. Standardization has a significant positive impact on economic development because it encourages innovation, increases productivity, and reduces the cost of implementing new technologies (Blind, K., et al., 2011). This conclusion is especially important in the field of

Corresponding author: I. Đorić ;
E-mail: igor.djoric@mod.gov.rs
DOI: 10.5937/OTEH26159D

artificial intelligence, where standards are the basis for aligning technological development with regulatory requirements.

n addition to economic aspects, standardization plays an important role in preserving the security of the digital environment. Modern AI systems can be misused to create fake digital content, automate cyber attacks or carry out sophisticated financial fraud. The development of deepfake technologies, generative artificial intelligence and automated systems for social engineering shows that the same technology can have both positive and negative effects. Okolie points to the serious challenges that deepfake technologies pose for the privacy and security of individuals, while Montasari emphasizes that the abuse of artificial intelligence is becoming one of the key issues of national and cyber security. (Okolie, C., 2023) (Montasari, R., 2022)

An additional challenge is the fact that criminal and extremist organizations are increasingly using artificial intelligence to automate propaganda, create fake content and plan attacks. The development of generative artificial intelligence significantly increases the possibilities of misuse of modern information technologies for extremist and terrorist purposes (Đorić, M., & Milošević, T., 2021).

he development of international standards is one of the most effective mechanisms for limiting the criminal use of AI systems (Ayyaswamy, K., et al., 2025). In this context, standardization is not only a technical issue but also a regulatory instrument that defines the requirements for security, transparency, responsibility and ethical application of artificial intelligence systems. In recent years, numerous international standards have been developed, among which ISO/IEC 42001, ISO/IEC 23894 and ISO/IEC 38507 stand out, while the European Union, by adopting the AI Act, laid the foundations for the first comprehensive regulatory framework for the application of artificial intelligence.

Starting from the mentioned facts, the aim of this paper is to analyze the role of standardization as a regulatory mechanism for the responsible application of artificial intelligence in the detection of financial fraud. Through a review of modern literature, the technological aspects of AI application, the importance of international standards, the regulatory framework of the European Union, as well as the security challenges arising from the increasingly intensive use of intelligent systems will be analyzed.

2. ARTIFICIAL INTELLIGENCE IN THE FINANCIAL SECTOR

Today, artificial intelligence represents one of the key technologies of the digital transformation of the financial sector. Its application includes almost all business segments of financial institutions - from the automation of customer support and credit risk assessment to investment portfolio management, fraud detection and money laundering prevention. The development of advanced algorithms enabled the transition from traditional rule-based systems to adaptive models that learn from data and continuously improve their performance.

The banking sector was among the first to recognize the potential of artificial intelligence. Modern banks use AI to process loan applications, assess customer solvency, personalize financial services, optimize business processes and improve customer experience. In addition, machine learning algorithms are used to identify suspicious transactions in real time, thereby significantly reducing financial losses caused by fraud.

The business value of AI results from a combination of technological capabilities, organizational capacity and quality management. AI contributes to increasing operational efficiency, improving decision-making processes and developing innovative business models, but only if its implementation is accompanied by appropriate management mechanisms and a regulatory framework (Enholm, I.M., et al., 2022).

he financial sector represents a particularly sensitive environment for the application of AI due to the large volume of data at its disposal and the high level of regulatory requirements. Banks and other financial institutions process huge amounts of personal, financial and biometric data, which is why artificial intelligence systems must ensure a high level of accuracy, reliability and privacy protection. Any wrong assessment can lead to financial damage, damage to the reputation of the institution or violation of the user's rights.

herefore, in the last few years, the need for responsible application of artificial intelligence (Responsible AI) has been increasingly emphasized, which implies transparency of algorithms, the possibility of explaining the decisions made, data protection, model fairness and continuous risk management. The following chapter will analyze the application of these technologies in the detection of financial fraud, as one of the most important areas of their use.

3. ARTIFICIAL INTELLIGENCE IN DETECTING FINANCIAL FRAUD

inancial fraud is one of the biggest challenges of the modern financial system. The global digitization of banking and payment services has led to a significant increase in the number of electronic transactions, but at the same time it has enabled the development of new forms of criminal activities. Traditional fraud detection systems, based on predefined rules and manually created risk indicators, have shown limited effectiveness in the face of increasingly complex and dynamic patterns of criminal behavior. In response to these challenges, financial institutions are increasingly applying artificial intelligence and machine learning methods to improve the processes of identifying, analyzing and preventing financial fraud.

he application of artificial intelligence enables the processing of large amounts of structured and unstructured data in real time. Unlike traditional systems, AI models do not depend exclusively on pre-defined rules, but independently identify patterns of behavior that indicate potential abuses. This approach is particularly important in situations where criminals continuously

change their methods of committing fraud in order to avoid existing protection mechanisms.

In the literature, financial fraud is most often classified as payment card fraud, electronic banking fraud, identity theft, money laundering, insurance fraud, investment fraud, tax fraud, and digital currency fraud. Each of the mentioned categories is characterized by specific patterns of behavior and different levels of risk, which is why artificial intelligence systems must be adapted to the specific business environment.

One of the most important areas of application of AI is fraud detection in payment transactions. During the processing of card transactions, algorithms analyze a large number of parameters, including the amount of the transaction, the geographical location of the user, the execution time, the frequency of purchases, the device from which the transaction was executed, the IP address and the previous behavior of the user. By combining this data, it is possible to estimate in a very short time the probability that a particular transaction represents a fraud attempt.

The application of artificial intelligence enables the processing of large volumes of structured and unstructured data in real time. Unlike traditional systems, AI models do not rely only on predefined rules, but can independently identify behavioral patterns that may indicate potential, fraudulent activities.

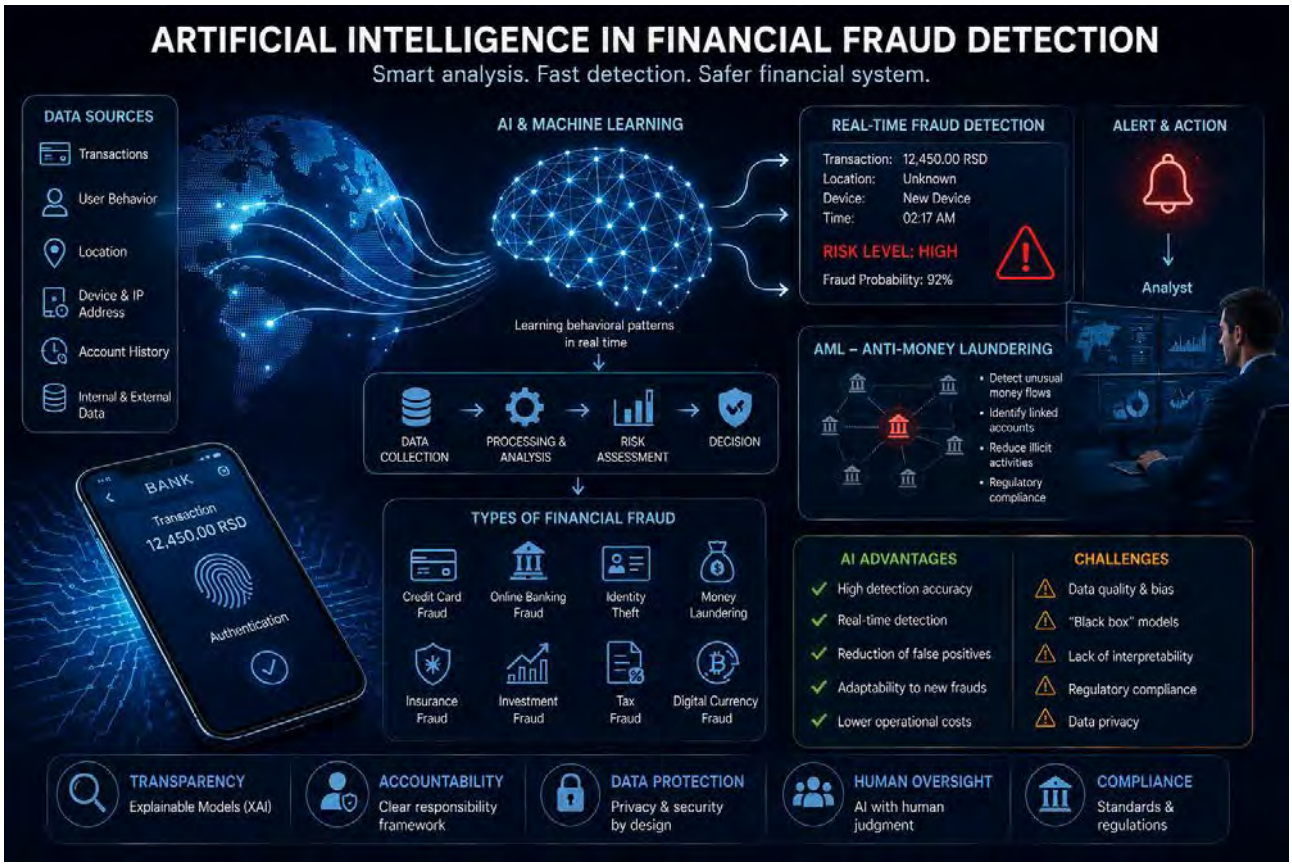

Figure 1. Conceptual illustration of the application of artificial intelligence in financial fraud detection

In addition to card fraud, an important area of application is the prevention of money laundering (Anti-Money Laundering - AML). Financial institutions analyze millions of transactions every day to identify unusual cash flows, linked accounts and potentially illegal financial activity. By applying machine learning algorithms, it is possible to identify patterns that would go unnoticed by traditional methods, thereby increasing the efficiency of regulatory controls and reducing business costs.

Methods based on machine learning achieve significantly better results than classical statistical models, especially in cases where large and unbalanced data sets are involved (Phua, C., et al., 2010). Similarly, adaptive systems represent the most effective approach for detecting new patterns of financial fraud, as they allow continuous adaptation to changes in perpetrator behavior (Bolton, R. J., & Hand, D. J., 2002).

In addition to increasing detection accuracy, artificial intelligence contributes to reducing the number of false positive results. In traditional systems, a large number of legitimate transactions are wrongly marked as suspicious, leading to user dissatisfaction and increased operational costs. By applying modern AI models, it is possible to achieve a better balance between the sensitivity of the system and the number of false warnings.

However, despite the significant benefits, the

implementation of artificial intelligence in the financial sector faces numerous challenges. The quality of the models depends largely on the quality of the data used to train them. Incomplete, outdated or biased data can lead to wrong risk assessments and discriminatory decisions. An additional problem is the fact that many deep learning models behave like a "black box", which is why users and regulators are often unable to understand the decision-making process.

This is precisely why modern regulatory frameworks increasingly insist on the development of explainable artificial intelligence (Explainable Artificial Intelligence - XAI), which enables the interpretation of the results of algorithms and increases user confidence in automated decision-making systems. The transparency of the model is one of the basic prerequisites for their application in the financial sector, where every decision can have significant legal and economic consequences.

4. METHODS AND ALGORITHMS OF ARTIFICIAL INTELLIGENCE IN THE DETECTION OF FINANCIAL FRAUD

The development of machine learning methods has enabled the application of a large number of algorithms in financial fraud detection systems. The choice of the appropriate algorithm depends on the available data, the type of fraud, the accuracy requirements of the model and the possibility of interpreting the results.

The most commonly used approach is supervised learning, where the algorithm is trained using historical data that contains information about whether a particular transaction was legitimate or fraudulent. Among the most commonly applied algorithms are logistic regression, Decision Trees, Random Forest, Support Vector Machine, Gradient Boosting and XGBoost. These models achieve high accuracy in the classification of transactions and enable relatively simple integration into existing banking systems.

When historical data is not available or is incomplete, unsupervised learning methods are applied. Their goal is not to classify pre-known patterns but to identify anomalies that deviate from the usual behavior of users. This group includes Clustering Algorithms, Principal Component Analysis (PCA), Isolation Forest and various anomaly detection models. Such approaches are particularly important for the detection of new forms of fraud that have not been registered before.

In recent years, deep learning models have been increasingly used. Neural networks enable the analysis of very complex relationships between a large number of variables and achieve extremely good results in the processing of unstructured data. Recurrent neural networks (RNN) and Long Short-Term Memory (LSTM) models are particularly suitable for the analysis of time series of transactions, while convolutional neural networks (CNN) find application in the analysis of digital documents, biometric data and identification documents.

An increasingly important role is also played by Graph Neural Networks (GNN), which enable the analysis of relationships between users, bank accounts and financial transactions. Unlike classical algorithms, GNN models analyze the network of connections between different actors and enable the identification of organized criminal groups and complex money laundering schemes.

In addition to machine learning algorithms, financial institutions also apply Natural Language Processing (NLP). NLP models are used to analyze email, user communications, suspicious activity reports and text documents. Application of large language models enables automated identification of attempted phishing attacks, fraudulent payment requests and other forms of social engineering.

Although the mentioned algorithms achieve exceptional results, their application requires appropriate infrastructure, high data quality and continuous monitoring of model performance. The business value of AI does not derive solely from the choice of algorithm, but from the organization's ability to integrate technology solutions with business processes, data management and regulatory requirements (Enholm, I.M., et al., 2022).

In addition to technical challenges, special attention should be paid to the ethical aspects of the application of algorithms. Models trained on biased data sets can lead to discriminatory decisions or unwarranted labeling of certain groups of users as high risk. Therefore, modern financial fraud detection systems must be developed in accordance with the principles of responsible artificial intelligence, which include transparency, fairness, responsibility and privacy protectioni.

All of the above indicates that the effectiveness of financial fraud detection systems no longer depends only on the development of advanced algorithms, but also on the existence of appropriate standards that regulate the way they are developed, implemented and managed. This is precisely why standardization represents a necessary regulatory framework for the sustainable application of artificial intelligence in the financial sector.

4.1 Benford's law as statistical support for AI detection of financial fraud

In addition to machine learning algorithms, financial forensics also uses statistical methods that can serve as an initial filter for extracting unusual data. One of the most famous methods is Benford's law, that is, the law of the first digit, which describes the expected frequency of initial digits in naturally occurring numerical sets. Its application includes financial reports, accounting records, public spending and other large databases in which deviations from the expected distribution can represent a signal for additional verification (Đorić, I., et. al., 2021).

The importance of Benford's law for artificial intelligence systems is reflected in the possibility to use the results of digital analysis as additional features when training and applying models for anomaly detection. Deviation from the Benford distribution does not in itself prove the existence of fraud, but directs the auditor's or algorithm's attention to data that requires more detailed analysis.

Therefore, Benford's law can be seen as a complementary instrument to supervised and unsupervised machine learning models, rather than a replacement for them.

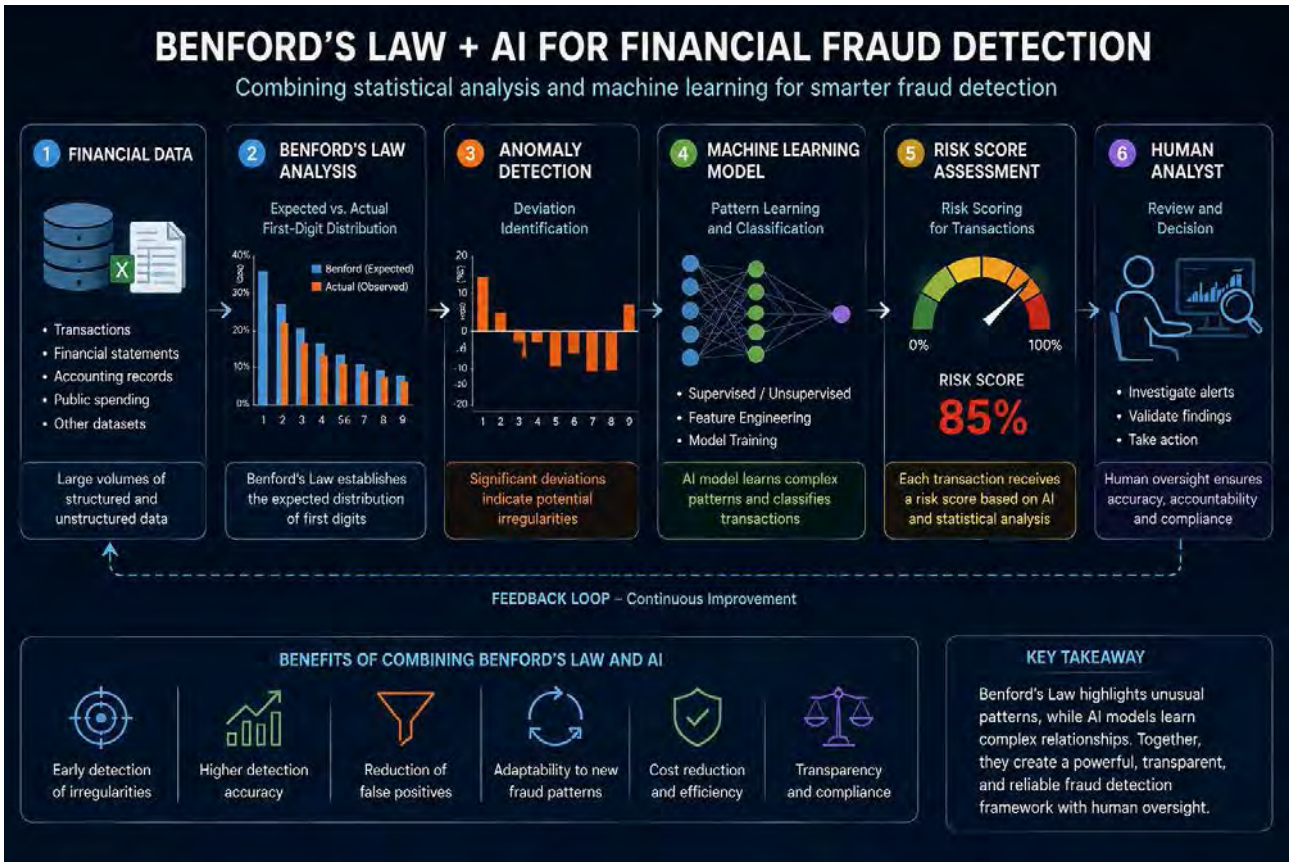

Figure 2. Benford's Law and AI-based financial fraud detection framework

Standardization of this combined methodology requires defining the conditions under which the application of Benford's law is justified, minimum data quality and volume, deviation thresholds, validation procedures and mandatory human supervision. This reduces the risk that a statistical deviation is automatically interpreted as fraud and ensures the traceability of the entire decision-making process.

5. STANDARDIZATION AS A REGULATOR OF AI APPLICATION IN FRAUD DETECTION

The development of artificial intelligence in recent years has significantly outpaced the development of regulatory frameworks that should ensure its safe and responsible application. Despite the undoubted advantages that artificial intelligence systems bring to the financial sector, their application raises numerous questions related to the transparency of algorithms, responsibility for decisions made, data protection, cyber security and ethical aspects of automated decision-making. For this reason, standardization becomes one of the most important instruments for establishing a balance between technological innovation and regulatory requirements.

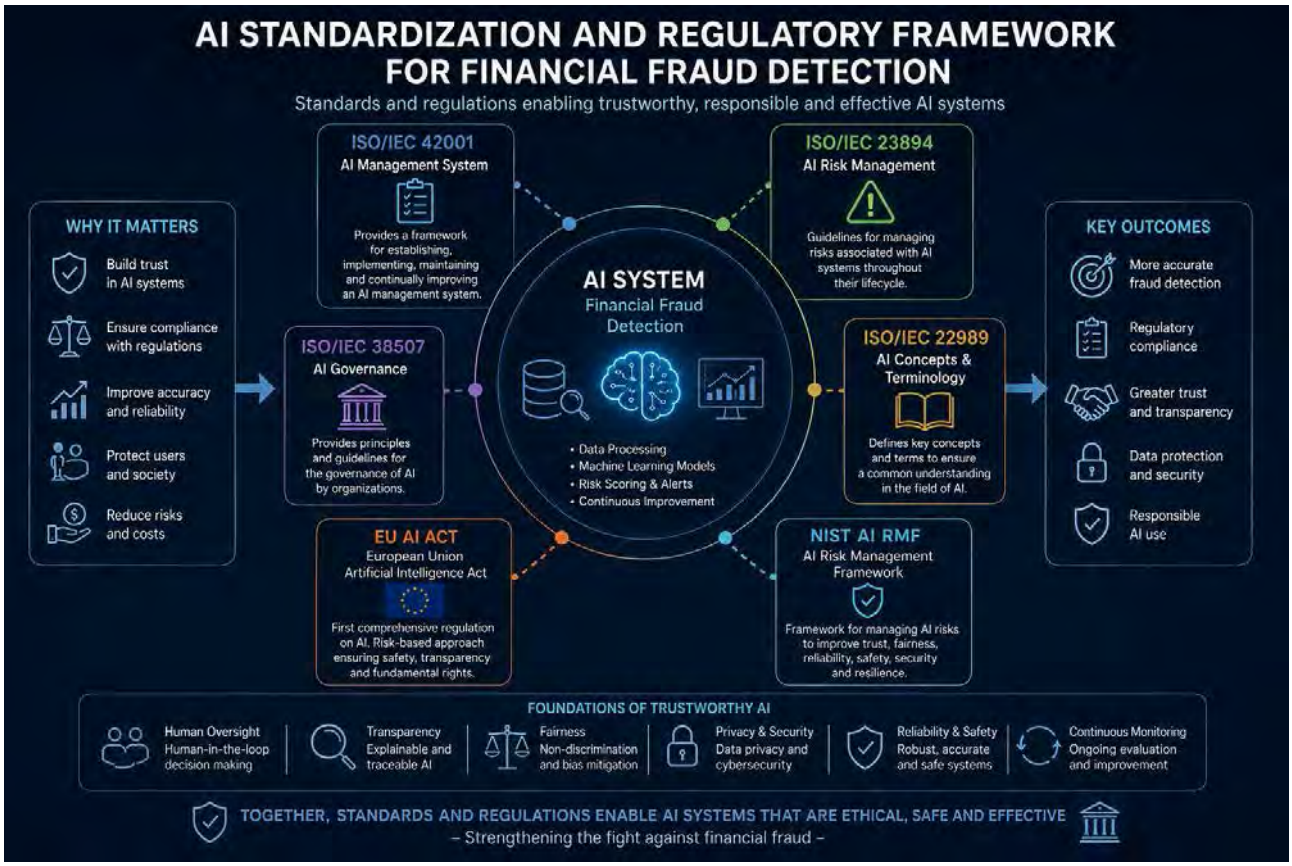

Figure 3. AI Standardization and Regulatory Framework for Financial Fraud Detection

Standardization represents the process of development and application of unique technical, organizational and management rules that enable interoperability, security and reliability of information systems. Standards have a significant positive impact on the national economy as they increase productivity, encourage innovation, reduce development costs and facilitate international trade. Standardization is not an administrative burden, but an important factor in economic development and technological progress. From there, standards represent the basis for building trust between technology producers, regulators and end users, so this conclusion gains importance in the field of artificial intelligence application (Blind, K., et al., 2011).

The field of artificial intelligence is in a phase of intensive development, which is why standardization must follow technological innovations in order not to represent a limitation for the development of new solutions. Standards should be flexible enough to support innovation, yet precise enough to enable safe and responsible deployment of AI systems. (Zielke, T., 2020). This approach is particularly important in the financial sector, where algorithms make decisions every day that have a direct impact on the financial resources of citizens and business entities.

The special importance of standardization is reflected in increasing the transparency of algorithms. Financial institutions must be able to explain to regulatory authorities why a particular transaction has been flagged as suspicious or why a particular customer has been classified as high-risk. In this sense, the standards represent the basis for the development of explainable artificial intelligence (Explainable AI - XAI), which enables the interpretation of the work of algorithms and increases user confidence in automated decision-making systems.

5.1 SO/IEC 42001 - Artificial intelligence management system

y publishing the ISO/IEC 42001:2023 standard, international standardization made a significant step forward in regulating the application of artificial intelligence. It is the first international standard that defines the requirements for establishing an Artificial Intelligence Management System (AIMS).

he structure of the standard is based on the principles already known from the ISO 9001 and ISO/IEC 27001 standards, but it is adapted to the specifics of the AI system. The standard includes planning, development, implementation, performance monitoring, risk assessment and continuous improvement of artificial intelligence systems.

or financial institutions, ISO/IEC 42001 is of particular importance because it enables the establishment of clear organizational responsibility for the development and use of AI models. The standard defines the obligation to identify interested parties, assess the impact of AI systems, manage risks, document the development process and conduct regular internal checks.

he application of this standard contributes to increasing the transparency of financial fraud detection systems and

facilitates the demonstration of compliance with regulatory requirements, including the AI Act and data protection regulations.

5.2 SO/IEC 23894 – Risk management of AI systems

One of the most important challenges in the application of artificial intelligence is risk management. Unlike traditional information systems, AI models can change their behavior over time due to new data or additional model training.

ISO/IEC 23894:2023 defines guidelines for the identification, assessment, treatment and continuous monitoring of risks during the entire lifecycle of an AI system.

The standard recognizes several risk categories: technical risks, organizational risks, legal risks, ethical risks, privacy risks and security risks.

In the case of financial fraud detection systems, there are particularly significant risks associated with misclassification of transactions, discrimination of users, inadequate data quality and the possibility of manipulating models through adversarial attacks.

Application of this standard enables financial institutions to continuously assess the reliability of AI systems and identify new security challenges in a timely manner.

5.3 SO/IEC 38507 and the management of organizations using AI

Unlike the ISO/IEC 42001 standard, which defines an AI management system, the ISO/IEC 38507 standard focuses on the management of organizations using artificial intelligence.

The standard emphasizes management's responsibility for: strategic decision-making, ethical application of AI, risk management, protection of user interests and compliance with laws.

In the financial sector, management is responsible for the decisions made by AI systems. ISO/IEC 38507 therefore emphasizes that no automated decision should be completely exempt from human supervision.

5.4 SO/IEC 22989 – Terminology and basic concepts

One of the frequent problems in the field of artificial intelligence is the different interpretation of basic terms. ISO/IEC 22989 establishes a uniform terminology that allows regulators, researchers and manufacturers to use the same definitions.

he unified terminology is the basis for the development of other standards and regulatory documents.

5.5 Controlling and internal auditing as elements of AI systems management

he standardization of the AI system must be connected with the existing mechanisms of internal control, controlling and internal auditing. These mechanisms ensure that the technology performance of the model is not viewed in isolation from the organization's goals, regulatory compliance, asset protection and risk management quality.

Internal control can be preventive, ongoing (detective) and subsequent (corrective). This division is directly applicable to the life cycle of artificial intelligence systems for financial fraud detection. Preventive controls include checking the origin and quality of data, approving models before commissioning and segregation of responsibilities. Detective controls include continuous monitoring of performance, changes in data distribution, false positives and false negatives, and attempts at model manipulation. Corrective controls include incident investigation, model retraining, rule changes, and documenting lessons learned (Đorić, I., et al., 2022).

Controlling is focused on the future and on improving the efficiency and effectiveness of the implementation of plans, while internal auditing provides an independent and objective assessment of the control system and the performed activities (Đorić, I., et al., 2022). In the application of AI, this means that controlling monitors whether the system contributes to reducing losses, speeding up the processing of warnings and achieving the organization's goals, while internal auditing checks the legality, reliability of data, integrity of records, documentation of decisions, adequacy of human supervision and compliance with ISO/IEC standards and regulatory requirements.

The special value of this approach is the linking of financial and non-financial indicators. In addition to the amount of prevented losses, it is necessary to monitor the accuracy and responsiveness of the model, the rate of false warnings, the time to solve cases, the number of user complaints, the stability of the model and the quality of the explanation of decisions. Thus, internal auditing and controlling become operational mechanisms for implementing the requirements of ISO/IEC 42001 and ISO/IEC 23894, and standardization gets practical application through clearly defined responsibilities, documented controls and measurable success criteria.

6. EU REGULATORY FRAMEWORK AND INTERNATIONAL GUIDELINES

In addition to international standards, the development of a regulatory framework is a key element of the responsible application of artificial intelligence. The European Union has adopted the AI Act, the first comprehensive regulation governing the development, marketing and use of artificial intelligence systems.

A key feature of the AI Act is a risk-based approach. AI systems are classified into four categories:

- systems with **unacceptable risk**,
- **high-risk** systems,
- **limited risk** systems,
- **minimal risk** systems.

Systems used to assess credit risk, detect financial fraud and prevent money laundering are classified as high-risk systems. They are subject to strict requirements that include risk management, high data quality, technical documentation, record keeping, algorithm transparency, human oversight and cyber security.

An important international framework is the NIST AI Risk Management Framework (AI RMF 1.0), which defines four basic functions of managing AI systems:

Govern - management and responsibility;
Map - risk identification;
Measure - risk assessment and measurement;
Manage - continuous management and improvement.

For financial institutions, it is particularly important that the principles of the NIST framework are compatible with the requirements of ISO/IEC 42001 and the AI Act. This enables the development of a unique management system that simultaneously meets international standards and regulatory requirements.

It can be concluded that standardization and regulation do not represent competing mechanisms, but mutually complementary instruments. While regulatory regulations define the legal obligations of organizations, international standards provide practical guidelines for their implementation. It is the synergy of these two approaches that is the basis for the responsible and sustainable application of artificial intelligence in the detection of financial fraud.

7. RISKS AND ABUSES OF ARTIFICIAL INTELLIGENCE

Although the application of artificial intelligence brings significant benefits to the financial sector, the same technology can be used to carry out various forms of criminal activities. The development of generative artificial intelligence, Large Language Models (LLM), technologies for voice and image synthesis, as well as automated systems for analyzing large amounts of data, has enabled criminal groups to develop new methods of committing financial fraud. This is precisely why the question of the security of AI systems becomes as important as the question of their functionality.

One of the most serious challenges is the emergence of deepfake technologies. Advanced models of generative artificial intelligence make it possible to create extremely convincing videos, audio recordings and photos that can be used for identity theft, user manipulation or financial fraud. The development of these technologies represents a serious threat to the privacy of individuals, the protection of personal data and digital trust (Okolie, C., 2023). In the financial sector, deepfake content can be used to impersonate company executives, authorize financial transactions, or bypass biometric authentication systems.

In addition to digital identity abuse, artificial intelligence enables the automation of various forms of cybercrime. Modern AI tools can analyze the vulnerabilities of information systems, automatically generate phishing messages tailored to specific users, create malicious program code and optimize attacks on financial institutions. The misuse of artificial intelligence represents one of the key issues of national security, as it enables the execution of complex cyber operations with minimal human involvement (Montasari, R., 2022). Such attacks can have serious consequences for the stability of the financial system, especially if they target critical infrastructure or electronic payment systems.

An additional dimension of the problem is represented by the activities of extremist and terrorist organizations that use artificial intelligence to automate propaganda, manipulate information and plan attacks. The development of generative artificial intelligence significantly increases the possibilities of misuse of digital technologies for extremist and terrorist purposes. Although these activities are not directly related to financial fraud, they indicate a broader security context in which AI systems are developed and used (Đorić, M., et al., 2021). Financial institutions that have large amounts of sensitive data are potential targets of such activities, which is why security risk management must be an integral part of AI system development.

The fight against the criminal use of artificial intelligence cannot be based solely on the development of new fraud detection technologies. It is necessary to establish a comprehensive framework that includes international standards, regulatory regulations, exchange of information between institutions and continuous education of employees. It is especially important that standardization represents one of the most effective mechanisms for preventing the misuse of AI systems, as it enables the definition of unique requirements for their safe implementation (Ayyaswamy, K., et al., 2025).

The development of artificial intelligence has significant implications in the field of defense and national security. Artificial intelligence represents one of the key technologies of future military systems, whereby the same technological solutions can be adapted for civilian purposes, including the financial sector (Nazil, A. R., 2025). This fact further confirms the need for international standardization and a harmonized regulatory approach to prevent uncontrolled or unethical use of intelligent systems.

Good practices for the development of secure digital products are of special importance for the security of the digital environment. The application of international standards, security guidelines and appropriate development procedures significantly contributes to reducing the risk of cyber attacks and limiting the possibility of conducting offensive cyber operations. These conclusions can be directly applied to artificial intelligence systems used in the financial sector, since the security of AI models depends not only on the quality of the algorithms but also on the security of the entire digital environment in which they are implemented (Radunović, V., 2026).

The aforementioned challenges confirm that standardization has a much broader role than defining technical requirements. It represents the basis for the development of reliable, safe and ethically acceptable AI

systems that can respond to modern threats in the digital financial environment.

8. DISCUSSION

A review of the analyzed literature shows that the application of artificial intelligence in the financial sector is developing much faster than the regulatory mechanisms that should ensure its safe use. Although machine learning and deep learning algorithms achieve exceptional results in the detection of financial fraud, their effectiveness is not the only criterion for evaluating the success of an AI system. Equally important are transparency, the ability to explain decisions, privacy protection, risk management and compliance with regulatory requirements.

Analysis of international standards shows that ISO/IEC 42001 represents a significant step forward in the establishment of an artificial intelligence management system. Combined with the ISO/IEC 23894 and ISO/IEC 38507 standards, organizations are enabled to develop a comprehensive framework that includes risk management, management accountability, data security and continuous improvement of AI systems.

On the other hand, the AI Act of the European Union introduces legally binding requirements for high-risk AI systems, including financial fraud detection systems. Thus, for the first time, a direct connection between international standardization and regulatory law is realized. It can be expected that the future development of international standards will be largely harmonized with the requirements of European regulations.

A special challenge is the fact that the same technology can be used both to improve security and to carry out criminal activities. This is precisely why the future development of AI systems must be based on the principles of "Security by Design", "Privacy by Design" and "Ethics by Design", which imply that security, ethical and regulatory requirements are integrated already at the system design stage.

Based on the conducted analysis, it can be concluded that the successful application of artificial intelligence in the financial sector will depend on the ability of organizations to simultaneously develop advanced algorithms, apply international standards and harmonize business with regulatory requirements.

The inclusion of controlling, internal auditing and Benford's law complements the two-level regulatory model. At the organizational level, controlling and internal auditing ensure continuous monitoring of AI system objectives, risks and compliance. On an analytical level, Benford's Law is a transparent statistical indicator that can help initially isolate unusual financial data. Their integration with machine learning methods contributes to a hybrid approach where automated detection remains verifiable, documented and under human supervision.

9. CONCLUSION

Artificial intelligence represents one of the most important technologies of the modern financial sector and plays a key role in improving the system for detecting and preventing financial fraud. The application of machine learning algorithms, deep learning and analysis of large data sets enables financial institutions to more effectively identify suspicious transactions, reduce operational costs and improve risk management.

However, the growing application of AI systems also brings new challenges related to transparency, accountability, data protection, ethical aspects and cyber security. Therefore, standardization is a key regulatory mechanism that establishes common rules for the development, implementation and management of artificial intelligence systems.

Analysis of international standards ISO/IEC 42001, ISO/IEC 23894, ISO/IEC 38507 and ISO/IEC 22989, together with the regulatory framework of the European Union and the NIST AI RMF guidelines, shows that the modern approach to regulating AI systems implies the integration of technical, organizational, legal and ethical requirements. Such an approach enables the development of reliable and transparent systems that simultaneously achieve a high level of efficiency and compliance with regulatory requirements.

Based on the conducted literature review, it can be concluded that standardization will not represent a limitation of the development of artificial intelligence, but one of the basic prerequisites for its sustainable and responsible application. In the coming period, further convergence of international standards and regulatory regulations can be expected, which will contribute to greater user confidence, increased security of financial systems and more effective suppression of financial fraud.

Additionally, linking standardization with controlling, internal auditing and statistical methods, such as Benford's law, enables the practical implementation of the requirements of responsible artificial intelligence. Controlling provides future direction and monitoring of results, internal audit an independent assessment of compliance and controls, while Benford analysis provides an understandable indicator of possible anomalies. Their joint application can improve the reliability, explainability and auditability of AI systems for financial fraud detection.
